NOTE: Distinguish among methanogens, which generate methane; methanotrophs, which oxidize methane; and methylotrophs, which oxidize single-carbon compounds other than methane, such as methanol or methylamine.

TO SUMMARIZE:

- **Lithotrophy (chemolithotrophy)** is the acquisition of energy by oxidation of inorganic electron donors.
- **Sulfur oxidation** includes oxidation of H_2S to sulfur or to sulfuric acid by sulfur-oxidizing bacteria. Sulfuric acid production leads to extreme acidification, damaging stone structures and poisoning mine drainage.
- **Iron oxidation** often accompanies sulfur oxidation.

- **Nitrogen oxidation** includes successive oxidation of ammonia to hydroxylamine, nitrous acid, and nitric acid. Anammox, the anaerobic oxidation of ammonium by nitrate, generates nitrogen gas from anoxic environments.
- **Hydrogenotrophy** uses hydrogen gas as an electron donor. Hydrogen (H_2) has sufficient reducing potential to donate electrons to nearly all biological electron acceptors, including chlorinated organic molecules (through dehalorespiration).
- **Methanogenesis** occurs by oxidation of H_2 by carbon dioxide to form methane. Methanogenesis is performed only by the methanogen group of archaea.
- **Methane oxidizers** use O_2, nitrate, or sulfate to oxidize the methane produced by methanotrophs.

14.6 Phototrophy

On Earth today, the ultimate source of electrons driving metabolism is phototrophy, the harnessing of photoexcited electrons to power cell growth. Every year, photosynthesis converts more than 10% of atmospheric carbon dioxide to biomass, most of which then feeds microbial and animal heterotrophs. Most of Earth's photosynthetic production, especially in the oceans, comes from microbes (discussed in Chapter 21).

In phototrophy, the energy of a photoexcited electron is used to pump protons. Different kinds of phototrophy include the bacteriorhodopsin proton pump; the single-cycle chlorophyll-based photosystems I and II; and the double-cycle Z pathway of oxygenic photosynthesis in cyanobacteria and chloroplasts.

Bacteriorhodopsin: A Simple Light Pump

In most ecosystems, the dominant source of carbon and energy is photosynthesis based on chlorophyll. At the same time, many halophilic archaea and marine bacteria supplement their metabolism with a simpler, more ancient form of phototrophy based on a single-protein light-driven proton pump, **bacteriorhodopsin**. We present bacteriorhodopsin first as a simple case to grasp, followed by the more complex ETS-based photolysis in bacteria and chloroplasts.

Bacteriorhodopsin. Bacteriorhodopsin is a small membrane protein commonly found in halophilic archaea (or haloarchaea) such as *Halobacterium salinarum*, a single-celled archaeon that grows in evaporating salt flats containing concentrated NaCl. For many years, bacteriorhodopsin-like proton pumps were thought to be limited to extreme halophilic archaea. As bacterial genomes were sequenced, however, homologs of the protein appeared in several species of gram-negative bacteria or proteobacteria; the homologs were termed **proteorhodopsin**. In 2005, Oded Béjà and colleagues from Israel, Austria, Korea, and the United States surveyed the genomes of unculturable bacteria from the upper waters of the Mediterranean and Red Seas. They found that 13% of the marine bacteria contain proteorhodopsins, accounting for a substantial—and previously unrecognized—fraction of marine phototrophy.

Bacteriorhodopsin absorbs light with a broad peak in the green range; thus, the organisms containing large amounts of bacteriorhodopsin reflect blue and red, appearing purple. The protein consists of seven hydrophobic alpha helices surrounding a molecule of **retinal**, the same cofactor bound to light-absorbing opsins in the vertebrate retina (**Fig. 14.27A**). In bacteriorhodopsin, the retinal is attached to the nitrogen end of a lysine residue (**Fig. 14.27B**).

Retinal has a series of conjugated double bonds that absorb visible light. Upon absorbing a photon, an electron in one of the double bonds is excited to a higher energy level. As the electron falls back to the ground state, the bond shifts position from *trans* (substituents pointing opposite) to *cis* (substituents pointing in the same direction). This change in shape of the retinal alters the conformation of the entire protein, causing it to pick up a proton from the cytoplasm. Eventually, the retinal switches back to its original *trans* configuration. The reversion to *trans* is coupled to the release of the proton from the opposite end of the protein facing outside of the cell. Thus, photoexcitation of bacteriorhodopsin is coupled to the pumping of one H^+ across the membrane.

The proton gradient generated by bacteriorhodopsin drives ATP synthesis by a typical F_1F_o ATP synthase. Light capture by bacteriorhodopsin supplements, but does not replace, catabolism for energy and heterotrophy for carbon source. The combination of light absorption and heterotrophy is called **photoheterotrophy**.

Purple membrane captures light rays. One problem every phototroph needs to solve is how to "capture" light rays. For chemotrophs, food molecules diffuse in solution and can be picked up by receptors for transport into a cell. In phototrophy, however, a photon impinges on one point of the cell, where it either is absorbed or passes through. Thus, the only way to absorb a high percentage of photons is to spread light-absorbing pigments over a wide surface area. To maximize light absorption, *Halobacterium salinarum* archaea pack their entire cell membranes with bacteriorhodopsin. The protein forms trimers that pack in hexagonal arrays, forming the so-called "purple membrane" (**Fig. 14.28**).

While the bacteriorhodopsin cycle is much simpler than the chlorophyll-based photosynthesis (discussed below), it nevertheless illustrates several principles that apply to more complex forms of phototrophy:

- A photoreceptor absorbs light, causing excitation of an electron to a higher energy level, followed by return to the ground state.
- To maximize light collection, large numbers of photoreceptors are packed throughout a membrane.
- The photocycle (absorption and relaxation of the light-absorbing molecule) is coupled to energy storage in the form of a proton gradient.

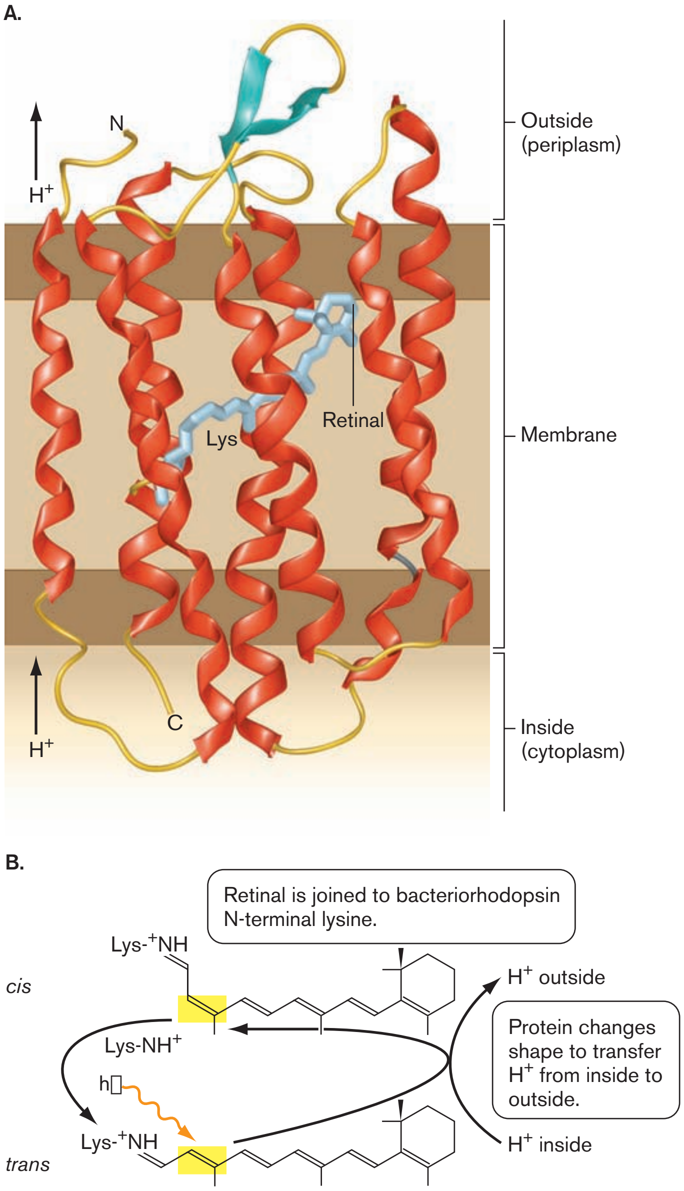

Figure 14.27 The light-driven cycle of bacteriorhodopsin. **A.** Bacteriorhodopsin contains seven alpha helices that span the membrane in alternating directions and surround a molecule of retinal, which is linked to a lysine residue. (PDB code: 1FBB) **B.** A photon ($h\nu$) is absorbed by retinal, which shifts configuration from *trans* to *cis*. The cycle of excitation and relaxation back to the *trans* form is coupled to pumping of $1H^+$ from the cytoplasm across the membrane.

NOTE: Distinguish these terms: **Phototrophy** covers all forms of energy-yielding metabolism that involve absorption of light energy. **Photolysis** means light absorption coupled to splitting an electron from a molecule. **Photosynthesis** means photolysis with CO_2 fixation and biosynthesis. Thus the bacteriorhodopsin light cycle is a form of phototrophy, but it is *not* photolysis or photosynthesis.

Photolysis: Light Absorption Separates an Electron from Chlorophyll

The energy-yielding phase of photosynthesis is **photolysis**, in which the photoexcitation of a chlorophyll leads to electron transfer through an ETS. The elucidation of photolysis in bacteria and chloroplasts—the fundamental source of energy for Earth's biosphere—was one of the most exciting projects of the twentieth century. Among hundreds of important contributors, we note two major figures: Roger Stanier (1916–1982) and Germaine Cohen-Bazire (1920–2001) (**Figs. 14.29A** and **B**). Stanier, a Canadian microbial physiologist at the University of California, Berkeley, clarified the nature of cyanobacteria as phototrophic prokaryotes distinct from eukaryotic algae, and he helped distinguish the photolytic cycles of cyanobacteria from those of sulfur-metabolizing purple

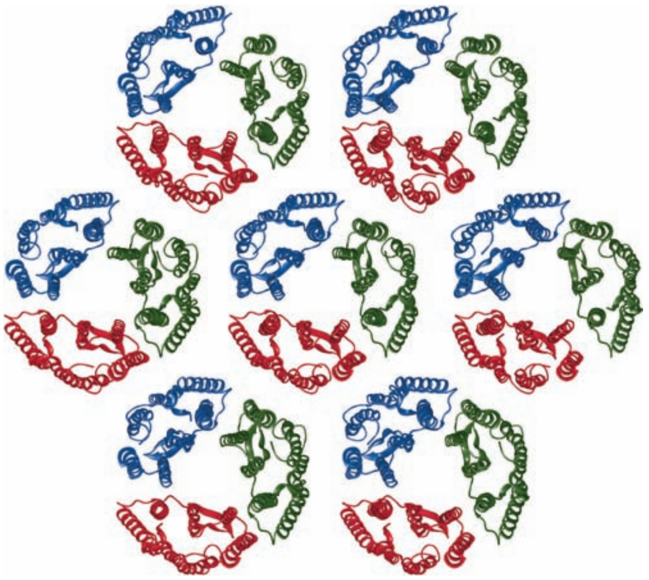

Figure 14.28 Bacteriorhodopsin purple membrane. Trimers of bacteriorhodopsin (monomers shown red, blue, and green) are packed in hexagonal arrays, forming the purple membrane. bacteria. He married Cohen-Bazire, a French bacterial geneticist who had studied *lac* operon regulation with Nobel laureate Jacques Monod at the Institut Pasteur in Paris. Cohen-Bazire applied her genetics skills to phototrophs, and she conducted the first genetic analysis of photosynthesis in purple bacteria and cyanobacteria.

Cyanobacteria, the only oxygen-producing bacteria, appear green, like algae or plants (**Fig. 14.29C**). Cyanobacteria include a wide range of species, such as the ocean's major producers, the submicroscopic *Prochlorococcus marinus*, barely visible under a light microscope. Other cyanobacteria have cells as large as algae and form complex developmental structures with important symbiotic associations (see Chapters 19 and 21). Cyanobacteria are among the most successful and diverse groups of life on Earth. Cyanobacteria, and the chloroplasts of algae and plants produce all the oxygen available for aerobic life.

Overview of photolysis. The energy for photosynthesis derives from the photoexcitation of a light-absorbing pigment. Photoexcitation leads to photolysis, the light-driven separation of an electron from a molecule coupled to an ETS. The components of the ETS are often homologous to those of respiratory electron transport, and they share common electron carriers such as iron sulfur clusters.

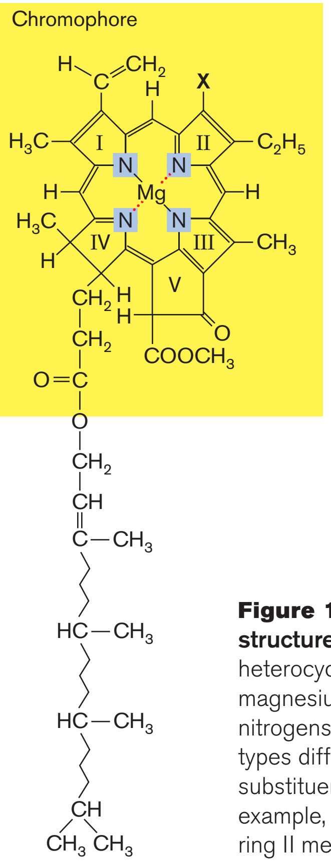
In plant chloroplasts, photolysis is also known as the "light reaction," coupled to the "dark reaction" of carbon dioxide fixation. In green plants and cyanobacteria, photolysis is tightly coupled to the "dark reaction" in which CO_2 is fixed into biomass. We discuss CO_2 fixation with other biosynthetic pathways in Chapter 15. Note, however, that many of the sulfur- or organic-based bacterial phototrophs, such as *Rhodospirillum rubrum*, combine photolysis with heterotrophy instead of CO_2 fixation.

In ETS-based photosynthesis, photoexcitation leads to actual charge separation—that is, separation of an electron from a donor molecule such as H_2O or H_2S. Each electron is then transferred to an ETS, whose components show common ancestry with respiratory ETS proteins. The photolytic ETS generates a proton potential and the reduced cofactor NADPH. The proton potential drives ATP synthesis through an F_1F_o ATPase, similar or identical to the one for respiration.

Chlorophylls absorb light. The main light-absorbing pigments are **chlorophylls**. Each type of chlorophyll contains a characteristic **chromophore**, a light-absorbing electron carrier. The chlorophyll chromophore consists of a heteroaromatic ring complexed to a magnesium ion (Mg^{2+}) (**Fig. 14.30**). As we saw for ETS electron carriers, metal ions and aromatic bonds offer electrons with relatively narrow energy transitions. The chromophore absorbs a photon through a reversible energy transition, such that the chlorophyll can alternate between excited and relaxed states.

Chlorophyll molecules differ slightly in their substituent groups around the ring; for example, chlorophyll *a* of chloroplasts has a methyl group in ring II, whereas chlorophyll *b* has an aldehyde. These slight differences alter their absorption spectra (**Fig. 14.31A**). Chlorophyll *a* absorption peaks in the red, whereas chlorophyll *b* absorbs mainly blue. Both chlorophylls *a* and *b* are made by chloroplasts and by cyanobacteria, their nearest bacterial relatives. Because they absorb red and blue, they reflect the middle range of the spectrum and so appear green.

By contrast, the chlorophylls of anaerobic phototrophs, or "purple bacteria," such as *Rhodobacter* and *Rhodospirillum*, absorb most strongly in the far-red (infrared) and in some cases ultraviolet range (**Fig. 14.31B**). These chlorophylls are specifically named **bacteriochlorophylls**. In purple bacteria, bacteriochlorophylls are supplemented by accessory pigments called **carotenoids**, which absorb



Chlorophyll

Figure 14.30 Chlorophyll structure. Chlorophyll has a heterocyclic chromophore with a magnesium ion coordinated to four nitrogens. Different chlorophyll types differ mainly in small substituents of the chromophore; for example, an aldehyde replaces the ring II methyl group in chlorophyll *a* to make chlorophyll *b*.

light of green wavelengths and transfer the energy to bacteriochlorophyll. The combination of green-absorbing carotenoids and infrared-absorbing bacteriochlorophylls makes cultures appear deep purple or brown.

The infrared radiation absorbed by bacteriochlorophylls is too weak to permit splitting H_2O to produce oxygen. Thus, purple bacteria are limited to photolysis of H_2S and small organic molecules; most are photoheterotrophs. On the other hand, infrared rays are available in water below the oxygenic phototrophs absorbing red and blue. Thus, anaerobic phototrophs grow at depths where their more high-powered oxygenic relatives do not.

NOTE: Distinguish among these classes of photopigments: **bacteriorhodopsin**, a retinal-containing proton pump; **chlorophyll**, a charge-separating photopigment (usually referring to chloroplasts and cyanobacteria); **bacteriochlorophyll**, a charge-separating chlorophyll of anaerobic purple and green bacteria (also known generically as chlorophyll); and **carotenoid**, an accessory pigment that absorbs the midrange of light wavelengths but does not directly conduct photolysis.

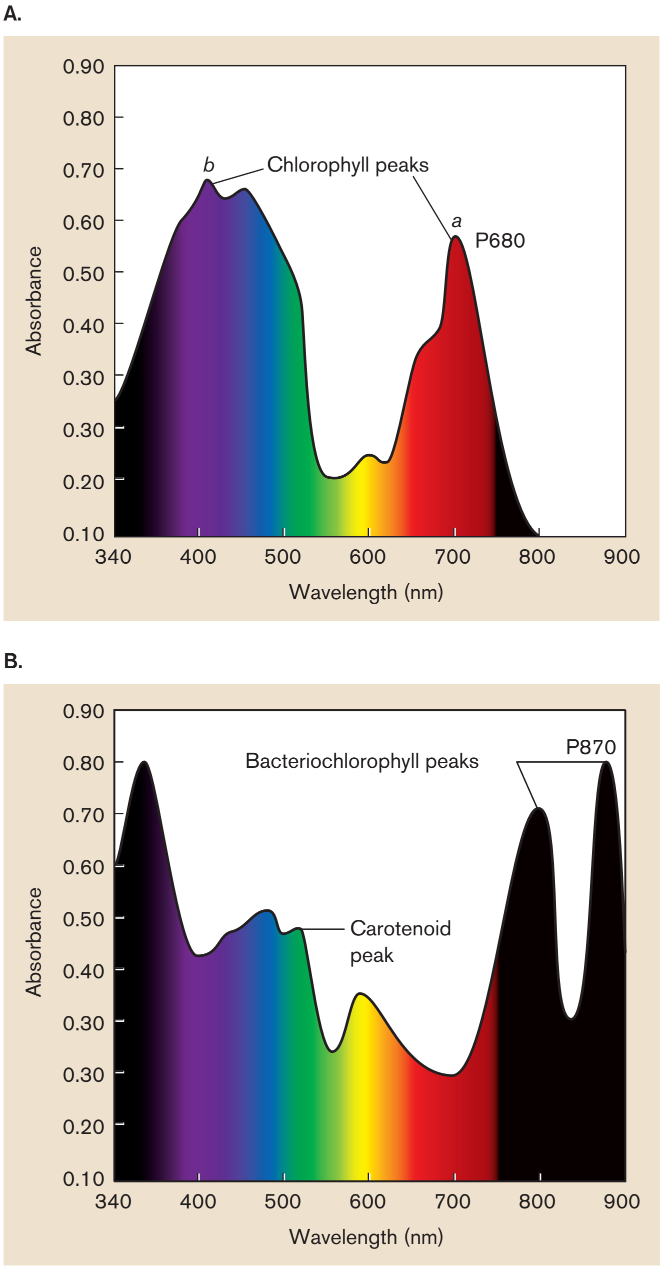


Figure 14.31 Absorption spectra of photosynthetic pigments. **A.** Absorption by chloroplasts including chlorophyll *a* (P680), chlorophyll *b*, and carotenoid accessory pigments. The middle range (green) is reflected. **B.** Absorption by purple photosynthetic bacteria, including bacteriochlorophyll (P870) and carotenoids. The main absorption is infrared (range 750–900 nm); therefore, the bacteria appear purple or brown.

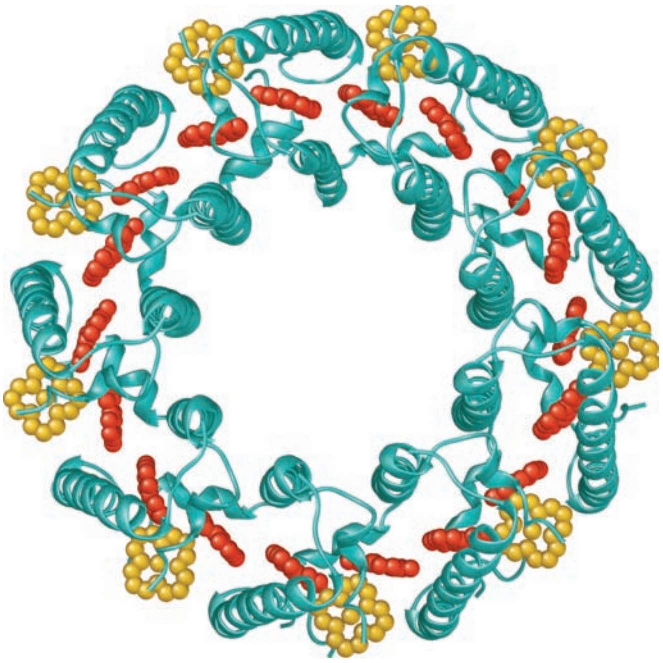
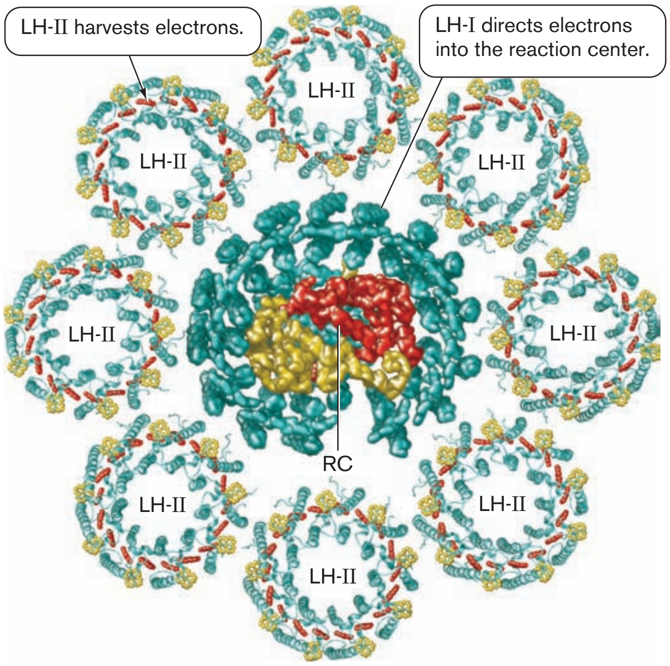
Antenna complex and reaction center. To maximize light collection, many molecules of chlorophyll are grouped in an **antenna complex**. These antenna complexes are arranged like a satellite dish within the plane of the membrane in an elaborate cluster around accessory proteins (**Figure 14.32A**). The clusters then associate in

A. Light-harvesting antenna complex (LH-II)



B. Antenna complexes surround the reaction center (RC)



LH-II harvests electrons.

LH-I directs electrons into the reaction center.

Figure 14.32 Antenna complexes surround the reaction center. A. The antenna complex of *Rhodopseudomonas viridis* contains 9 chlorophylls with chromophores facing parallel to the membrane (gold) and 18 with chromophores facing out from the ring (red). **B.** Multiple rings of chlorophyll-protein antenna complexes surround the reaction center, like a funnel collecting photons. LH-II is the accessory light-harvesting antenna complex; LH-I is the central complex directing electrons into the reaction center (RC). (PDB codes: 1PYH, 2FKW) *Source*: Quantum Biology of the PSU, NIH Resource for Macromolecular Modeling and Bioinformatics—BChl antenna.

a ring around the **reaction center (RC)**, the protein complex in which chlorophyll photoexcitation connects to the ETS (**Fig. 14.32B**). Throughout the complex of bacteriochlorophylls and accessory pigments, whichever pigment molecule happens to be in "the right place at the right time" captures the photon. The electron energy from the photon then transfers at random from one chromophore to the next, until it arrives at the reaction center for electron transfer to the ETS. Details of the antenna structure differ in cyanobacteria and chloroplasts, but overall it has the same effect of funneling electrons to the reaction center.

In purple bacteria, the efficiency of photon uptake is increased even more by the extensive back folding of the photosynthetic membranes in oval pockets, stacked like pita breads (**Fig. 14.33A**). These oval pockets, also typical of chloroplasts, are called **thylakoids**. The extensive packing of thylakoids gives an incident photon hundreds of chances to meet a chlorophyll at just the right angle for absorption.

The thylakoids are connected by tubular extensions, so that overall there exists one interior space, the **lumen**, separated topologically from the regular cytoplasm, or **stroma**. Protons are pumped from the stroma across the thylakoid membrane into the lumen. The F_1F_o complex is embedded in the thylakoid, where it makes ATP using the proton current running through it into the cell. The F_1 knob of ATP synthase appears to face "outward" in photosynthetic organelles (as opposed to "inward" in respiratory chains). In each case, however, the proton current and ATP motor face in the same direction with respect to the cytoplasm (or stroma). The proton potential is more negative in the cytoplasm (or stroma), thus drawing protons through the ATPase to generate ATP.

The photolytic electron transport system. In photolysis, the absorption of light by chlorophyll or bacteriochlorophyll drives the separation of an electron from a molecule. The photolyzed molecule may be the chlorophyll itself, as in *Rhodospirillum* or *Rhodobacter,* or it may be a hydrogen donor such as H_2S or H_2O, depending on the photosystem of a given bacterial species. The excited electron enters a membrane-embedded chain of oxidoreductases and quinones/quinols, as we saw for the ETS of respiration and lithotrophy.

Diverse kinds of photosynthesis in different environmental niches include oxygenic, sulfur-based, iron-dependent, and even heterotrophic photolysis. Nevertheless, all forms of photolysis share a common design (**Fig. 14.34**):

1. **Antenna system.** A complex of chlorophylls and accessory pigments in the photosynthetic membrane collects photons. Energy from each photoexcited electron is transferred to the reaction center.

2. **Reaction center complex.** A quantum of light energy absorbed by chlorophyll raises an electron to a higher-energy orbital. In the reaction center, the energy from chlorophyll photoexcitation is used to separate an electron from a small molecule such as H_2S (photosystem I) or from bacteriochlorophyll (photosystem II).
3. **Electron transport system.** Each photoexcited electron enters an ETS. In PS I, electrons separated from H_2O or H_2S are transferred to NAD^+ to form NADPH. In PS II, the electron separated from bacteriochlorophyll is replaced by an electron returned from the ETS. In the oxygenic Z pathway (H_2O photolysis), electrons flow from PS II into PS I, ultimately releasing O_2 from H_2O.
4. **Energy carriers.** In PS I, electrons are used to make NADPH. In PS II, electron transfer provides energy to pump protons and drive synthesis of ATP. The Z pathway makes both NADPH and ATP, which are used to fix CO_2.

Figure 14.34 Energy transformation in photosynthesis. Light energy is absorbed by the antenna system of chlorophylls and proteins, which channel the energy to a single reaction center. The excitation of the reaction center drives splitting of a hydrogen atom from a donor such as H_2S or succinate (anaerobic photosynthesis) or H_2O (oxygenic photosynthesis). Each electron from the hydrogen atom is transferred to an electron transport system, where it may drive pumping of protons or formation of a reduced cofactor (NADH or NADPH). The proton gradient drives synthesis of ATP.

Electrons Are Transferred through Photosystems I and II

The steps of photolysis and electron transport occur in three different kinds of systems, in different classes of bacteria:

- **Anaerobic photosystem I** separates electrons associated with hydrogens from H_2S or an organic electron donor such as succinate or from reduced iron (Fe^{2+}). Found, for example, in chlorobia, "green sulfur" bacteria.
- **Anaerobic photosystem II** separates an electron from bacteriochlorophyll. Found, for example, in alpha-proteobacteria, "purple nonsulfur" bacteria.
- **Oxygenic Z pathway** includes homologs of photosystems I and II. Two pairs of electrons are separated from two water molecules to generate O_2. Found in cyanobacteria and in the chloroplasts of green plants.

The components of photosystems I and II (PS I and PS II) show homology with each other, implying common ancestry. Each system runs anaerobically, producing sulfur or oxidized organic by-products, but not O_2. Each photosystem shows more recent homology with the respective PS I and PS II components of the oxygenic Z pathway (so called because the electron path through a diagram of the two photosystems traces a Z). The Z pathway ultimately generates O_2—the only biochemical reaction known to produce molecular oxygen.

NOTE: In photolysis, each quantum of light excites a single electron. Some ETS components, such as the quinones/quinols ($Q \rightleftharpoons QH_2$) actually process two of these electrons in completing their redox cycle. The single-electron intermediate states of quinones are not shown.

Photosystem I in chlorobia. In bacteria such as *Chlorobium* species, light is absorbed primarily by bacteriochlorophyll P840, named for its peak absorption at 840 nm. The wavelength range for PS I typically extends into the near infrared (750–850 nm). Some chlorobia actually conduct photosynthesis using thermal radiation from deep-sea thermal vents.

In the PS I reaction center, the light energy from the antenna complex is used to separate an electron from H_2S or an organic electron donor (**Fig. 14.35A**). The high-potential electron is transferred by a quinone, phylloquinone (PQ) to **ferredoxin**, an FeS protein. Ferredoxin transfers the electron to the enzyme ferredoxin NAD-reductase; a pair of these electrons then reduce NAD^+ or the energetically equivalent $NADP^+$. The reduced carrier (NADH or NADPH) provides reductive energy for CO_2 fixation and biosynthesis (to be discussed in Chapter 15). Bacteria using PS I also generate a net proton gradient by consuming H^+ inside and generating H^+ outside the cell, thus providing proton motive force to drive ATP synthesis.

Photosystem II in alpha-proteobacteria. Phototrophic alpha-proteobacteria such as *Rhodospirillum rubrum* are typically found in wetlands and streams, where they capture light not used by other phototrophs. The wavelength absorbed by bacteriochlorophyll P870 lies so far into the infrared that the photon energy is insufficient to split hydrogenated substrates. Instead, the light energy at the reaction center separates an electron from the bacteriochlorophyll itself (**Fig. 14.36**). The high-energy electrons are then transferred by quinones to a terminal cytochrome oxidoreductase, as in the respiratory ETS.

The reduction potential, however, is too small to reduce $NADP^+$ to NADPH. Instead, as in respiration, the quinols pass their electrons to cytochromes, while transferring $2H^+$ across the membrane. No extra protons are pumped, but the proton potential drives synthesis of ATP. When the electrons reach cytochrome *c*, they flow back to bacteriochlorophyll, where they can be reexcited by photon energy from the antenna complex. Because the electron path traces back to its source, the ETS of photosystem II leading to ATP synthesis is called **cyclic photophosphorylation**.

Photosystem II, unlike photosystem I, provides no direct way to make NADH or NADPH for reductive biosynthesis such as CO_2 fixation. To make NADPH, purple bacteria obtain hydrogen from molecules such as H_2, H_2S, or organic acids in a pathway outside photolysis. The mechanism is poorly understood, but it involves reverse electron flow through the ETS, driven by the proton potential.

THOUGHT QUESTION 14.13 Suppose you discover bacteria that require a high concentration of Fe^{2+} for photosynthesis. Can you hypothesize what the role of Fe^{2+} may be? How would you test your hypothesis?

Oxygenic photolysis. The "Z" pathway of photolysis found in cyanobacteria and chloroplasts combines key features of both PS I and II (**Fig. 14.37**). Both reaction centers, however, contain chlorophylls that absorb at shorter wavelengths (higher energy) than those of the respective purple or green homologs: P680 instead of P870 (PS II), and P700 instead of P840 (PS I). Thus, the cyanobacterial reaction centers can split water and yield

Figure 14.35 Photosystem I separates electrons from sulfides and organic molecules. **A.** In green sulfur bacteria, red light photoexcites bacteriochlorophyll P840 (Bchl P840; photosystem I). Photoexitation of P840 enables splitting (photolysis) of two hydrogens from H_2S or an organic electron donor. The $2e^-$ are transferred by a quinone (phylloquinone, PQ) to ferredoxin (Fd). Ferredoxin is oxidized by ferredoxin NADH oxidoreductase (FNR), transferring the $2e^-$ to NAD^+ (or the energetically equivalent $NADP^+$) to form NADH (or NADPH). **B.** The PS I reaction center within a photosynthetic membrane.

greater energy overall. Oxygenic phototrophs dominate the shallow water depths, whereas anaerobes grow at lower depths using light at wavelengths unused by cyanobacteria and algae near the surface.

The P680 reaction center of photosystem II possesses sufficient potential to split H_2O (see **Fig. 14.37**). The entire cycle of water splitting involves $4H^+$ removed from $2H_2O$, $4e^-$ transferred to carriers, and formation of O_2. The net reaction forming oxygen is

$$2H_2O \rightarrow 4H^+ + 4e^- + O_2$$

Through the ETS, the electrons are transferred to quinones. As in respiration, each $2e^-$ reduction of quinone to quinol requires pickup of $2H^+$ from the stroma (equivalent to cytoplasm). Thus the four electrons transferred generate a net change in the proton gradient of $4H^+$. Furthermore, the energy of electron transfer to cytochrome *bf* enables pumping of an additional $2H^+$ across the membrane. Thus, in all, for each conversion of $2H_2O$ to O_2, the net protons transferred across the thylakoid membrane include $4H^+$ (water photolysis) plus $4 \times 2H^+$ (quinones to quinols) through cytochrome *bf*, to yield a total of $12H^+$ for the proton gradient. The proton gradient drives the synthesis of approximately 3ATP per O_2 formed.

The electrons from PS II do not cycle back to the PS II reaction center, as they do in purple bacteria. Instead they are transferred to PS I by a protein called plastocyanin. The energy of the electron transferred by plastocyanin is augmented through absorption of a second photon by the chlorophyll of PS I. Subsequent electron flow through ferredoxin can now generate NADH or NADPH. If the reduction potential is too large, however, particularly under intense light, some of the electron flow instead cycles back to cytochrome *bf*.

Figure 14.36 Photosystem II separates an electron from bacteriochlorophyll. A. In the PS II reaction center, bacteriochlorophyll P870 (Bchl P870; photosystem II) absorbs primarily infrared light. Bacteriochlorophyll P870 donates an energized electron to a quinone (Q). Two of these donated electrons complete the conversion of quinone to quinol (QH_2). Electrons flow through cytochrome *bc*, coupled to pumping of protons. The proton potential drives synthesis of ATP. The cytochrome *bc* complex transfers the electrons back to P870. **B.** The PS II reaction center within a photosynthetic membrane. *Source*: A. Based on Whitmarsh and Govindjee.

The overall equation for energy yield of oxygenic photolysis can be represented as

$$2H_2O + 2NADP^+ + 3[ADP + P_i] \rightarrow$$
$$O_2 + 2[NADPH + H^+] + 3ATP + 3H_2O$$

To generate one molecule of glucose by CO_2 fixation, we need six rounds of the photolysis equation—one per CO_2 molecule "fixed" into sugar ($C_6H_{12}O_6$) (discussed in Chapter 15). The CO_2 fixation equation works out to

$$12H_2O + 12NADP^+ + 18[ADP + P_i] \rightarrow$$
$$6O_2 + 12[NADPH + H^+] + 18ATP + 18H_2O$$
$$6CO_2 + 12[NADPH + H^+] + 18ATP + 18H_2O \rightarrow$$
$$\underline{C_6H_{12}O_6 + 6H_2O + 12\ NADP^+ + 18\ [ADP + P_i]}$$
$$12H_2O + 6CO_2 \rightarrow C_6H_{12}O_6 + 6H_2O + 6O_2$$

Combined Metabolism: Facultative Phototrophy

Biology courses often give the impression that heterotrophy, lithotrophy, and photosynthesis are discrete metabolic pathways utilized by completely different organisms. In fact, however, a microbial species rarely depends on a single option. Many bacteria found in soil or water use alternative metabolic options such as respiration and photosynthesis, often with shared components. The combined pathways of a facultative phototroph possess useful properties for biotechnology and environmental remediation.

An example of a facultative phototroph is *Rhodopseudomonas palustris*, a purple alpha-proteobacterium that grows in soil and water samples throughout our biosphere. The metabolic diversity of *R. palustris* was revealed by Caroline Harwood and colleagues by analysis of its genome sequence, using methods described in Chapter 8. The bacterium that "eats everything," *R. palustris* catabolizes sugars, fatty acids, and lignin components, including benzene rings, through aerobic or anaerobic respiration. It degrades toxic compounds such as 3-chlorobenzoate, which makes it valuable as an agent of bioremediation. Alternatively, *R. palustris* fixes CO_2 by photosynthesis or by lithotrophy, while fixing nitrogen gas into ammonia and giving off hydrogen gas, a property of interest for biofuel production. Besides all this metabolic versatility, *R. palustris* possesses at least seven different multidrug resistance pumps that may unfortunately be acquired by human pathogens (a less happy accomplishment, from the human point of view).

TO SUMMARIZE:

- **Bacteriorhodopsin** is a light-driven proton pump that supplements heterotrophy in haloarchaea. The homolog, proteorhodopsin, is found in marine proteobacteria.
- **The antenna complex** of chlorophylls and other photopigments captures light for transfer to the reaction center in chlorophyll-based photosynthesis.
- **Thylakoids** are folded membranes within phototrophic bacteria or chloroplasts. The membranes extend the area for chlorophyll light absorption, and they separate two compartments to form a proton gradient.
- **Photosystem I** separates electrons from H_2S or an organic electron donor. The electrons are ultimately transferred to NADH or NADPH.
- **Photosystem II** separates an electron from bacteriochlorophyll. An electron ultimately returns to bacteriochlorophyll through cyclic photophosphorylation**.**
- **The oxygenic Z pathway in cyanobacteria and chloroplasts** includes homologs of photosystems I and II. Eight photons are absorbed and two electron pairs are removed from $2H_2O$, ultimately producing O_2.
- **Oxygenic photosynthesis generates 3ATP + 2NADPH** per $2H_2O$ photolyzed and O_2 produced. The ATP and NADPH are used to fix CO_2 into biomass.

Concluding Thoughts

Seemingly disparate biochemical means of nutrition, such as respiration and photosynthesis, share common mechanisms of electron flow and proton transfer. A recurring theme is that all forms of metabolism involve charge separation and electron transfer. As molecules are rearranged by transfer of electrons from one substrate to another, energy is obtained and harnessed to the formation of ion gradients and energy carriers. The energy carriers always need to be balanced between redox-neutral carriers, such as ATP, and reducing carriers, such as NADH or NADPH, for biosynthesis (as discussed in Chapter 15).

Whatever the means of obtaining energy, ultimately the energy must be applied to biosynthesis. Chapter 15 presents how microbes spend their energy to construct the most fundamental "nuts and bolts" of their cells.

CHAPTER REVIEW

Review Questions

1. Explain the source of electrons and the sink for electrons (terminal electron acceptor) in respiration, lithotrophy, and photolysis.
2. How do bacteria combine redox couples for a metabolic reaction that yields energy? Cite examples, calculating the reduction potential.
3. How do environmental conditions affect the reduction potential of a metabolic reaction?
4. Explain the role of cytochromes and redox cofactors in electron transport systems. What features of a molecule make it useful for redox biochemistry?
5. Explain how a proton potential is composed of a chemical concentration difference plus a charge difference. Explain how each component of Δp can drive a cellular reaction.

6. Explain the role of the substrate dehydrogenase (oxidoreductase), the quinones, and the cytochrome oxidase (oxidoreductase) in the respiratory ETS.
7. Compare the ETS function in lithotrophy with that in respiration.
8. Summarize the inorganic redox couples that can be used in anaerobic respiration and those that can be used in lithotrophy. What constraints determine whether a given molecule can serve as electron acceptor or as electron donor?
9. How do diverse forms of anaerobic respiration and lithotrophy contribute to ecosystems?
10. Explain the differences and common features of bacteriorhodopsin phototrophy and chlorophyll phototrophy.
11. Explain the differences and common features of photosystems I and II. Explain how the two photosystems combine in the Z pathway. Why can the Z pathway generate oxygen, whereas PS I and PS II cannot?

Chapter 15

Biosynthesis

15.1 Overview of Biosynthesis
15.2 CO_2 Fixation: The Calvin Cycle
15.3 CO_2 Fixation in Anaerobes and Archaea
15.4 Biosynthesis of Fatty Acids and Polyesters
15.5 Nitrogen Fixation
15.6 Biosynthesis of Amino Acids and Nitrogenous Bases
15.7 Biosynthesis of Tetrapyrroles

How do microbes build their cells? Autotrophic bacteria and archaea build themselves entirely from carbon dioxide and nitrogen gas plus a few salts. From these simple molecules, microbial enzymes construct amino acids, the cell wall and envelope, and all the machinery of the cell. Some microbes produce complex secondary products with valuable properties, such as antibiotics. In the laboratory, microbial biosynthesis can be engineered to make cloned proteins, pesticides, and industrial reagents.

Once the key elements of carbon and nitrogen are incorporated into small molecules, more complex structures are built using many enzymes in intricate pathways. How do cells organize their biosynthesis to build precisely the forms they need? How do they avoid wasting energy on excess production? These questions are answered by the use of radioisotope tracers, genetic analysis of mutants, and the decoding of genomes. When a new species is discovered, its genome can reveal its capacities for biosynthesis, including hints of new pharmaceuticals.

Streptomyces bacteria synthesize hundreds of kinds of antibiotics starting from simple organic compounds. A newly discovered antibiotic produced by *Streptomyces platensis* inhibits fatty acid biosynthesis. The antibiotic, platensimycin, kills methicillin-resistant strains of *Staphylococcus aureus* (MRSA), a cause of deadly skin infections. Platensimycin was discovered by Jun Wang, et al. 2006. *Nature* 441:358. *Source:* © Brad Mogen/Visuals Unlimited.

Microbes synthesize complex products such as vitamin B_{12} (**Fig. 15.1**), an essential cofactor for human enzymes. Vitamin B_{12} deficiency causes anemia, the failure to make sufficient red blood cells. In developed countries, virtually all our dietary B_{12} is produced by bacteria in the digestive tract of animals whose meat and dairy products we consume. Our own intestinal bacteria produce only small amounts of B_{12}, which are insufficient for our needs. Thus, strict vegetarians require vitamin B_{12} as a supplement, produced industrially by bacteria such as the Swiss cheese fermenter *Propionibacterium freudenreichii*. In vegan diets of traditional cultures, fermenting bacteria in unrefrigerated foods provide this essential vitamin.

The biosynthesis of vitamin B_{12} requires about 25 genes, each specifying a different enzyme to catalyze an essential step—a large amount of DNA to maintain error-free in the genome. Smaller carbon skeletons, such as succinyl coenzyme A (succinyl-CoA) and glycine, must be synthesized and joined to form a tetrapyrrole ring. Expression of all those enzymes, as well as the steps they catalyze, entails a substantial cost in energy. The energy is obtained by microbes as described in Chapters 13 and 14.

Chapter 15 shows how microbes assimilate the key elements carbon and nitrogen to build complex biomolecules, and how they regulate biosynthesis to make only the products they need. Microbial products find key applications as antibiotics, vitamins, and industrial chemicals.

15.1 Overview of Biosynthesis

Biosynthesis is the building of complex biomolecules, also known as **anabolism**, the reverse of catabolism. Products of biosynthesis include the common building blocks of cells, such as amino acids and sugars, as well as secondary products to be exported from the cell, such as antibiotics and signaling molecules. Biosynthesis requires a source of essential elements, such as carbon, oxygen, hydrogen, and nitrogen. The central element carbon is obtained either through CO_2 fixation (autotrophy) or through catabolism (heterotrophy). In either case, the carbon and associated atoms (oxygen and hydrogen, for example) must be formed into various small molecules that serve as substrates or building blocks for structural and functional parts of the cell.

Substrates for Biosynthesis Are Metabolic Intermediates

Many substrates for biosynthesis arise from the catabolic pathways discussed in Chapter 13 (**Fig. 15.2**). For example, the succinyl-CoA molecules used to build the tetrapyrrole ring of vitamin B_{12} come directly from the tricarboxylic acid (TCA) cycle, while the glycines derive from 3-phosphoglycerate, an intermediate of glycolysis. Glycerol 3-phosphate provides the glyceride backbone of lipids. Pyruvate forms the backbone of several amino acids with aliphatic side chains, whereas erythrose 4-phosphate contributes to the ring structures of aromatic amino acids. Other amino acids derive their carbon skeleton from TCA cycle intermediates oxaloacetate and 2-oxoglutarate, which incorporate nitrogen in the form of ammonium ion.

Biosynthesis Spends Energy

Biosynthesis entails substantial costs to the organism. The organism's genome must maintain the DNA that encodes all the enzymes that catalyze all the steps of the pathway; a mutation in any one enzyme may negate the entire process.

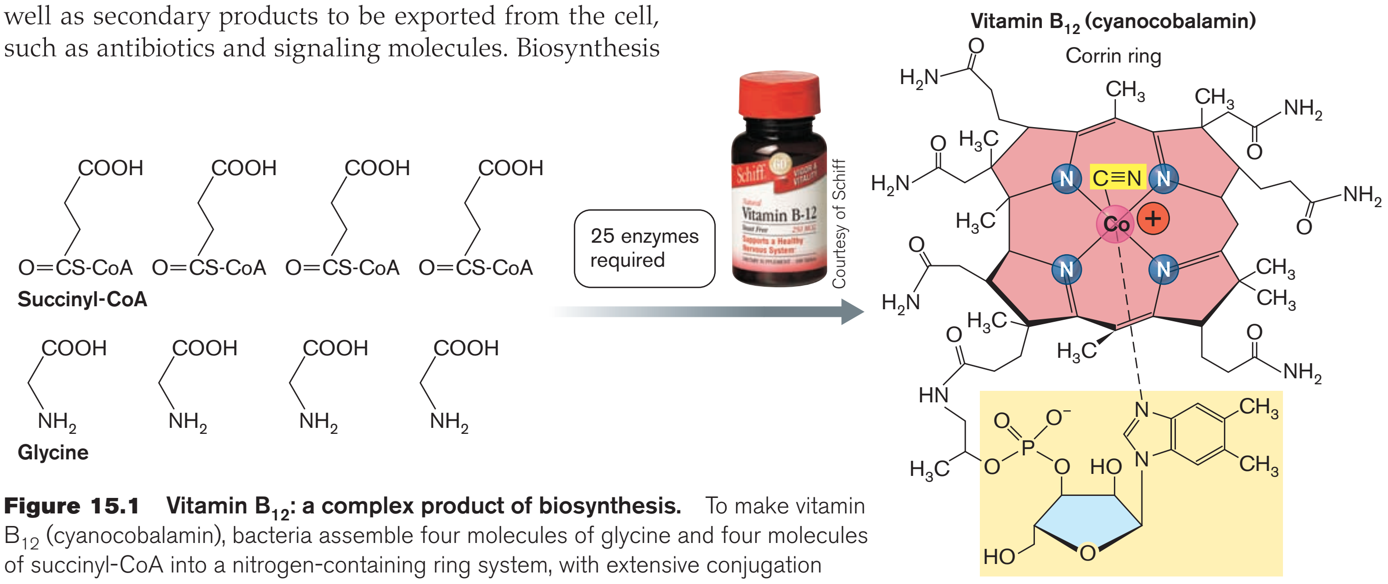

Figure 15.1 Vitamin B_{12}: a complex product of biosynthesis. To make vitamin B_{12} (cyanocobalamin), bacteria assemble four molecules of glycine and four molecules of succinyl-CoA into a nitrogen-containing ring system, with extensive conjugation and numerous side groups. Biosynthesis of vitamin B_{12} requires a substantial genomic investment in enzymes as well as expenditure of energy.

Figure 15.2 **Substrates for biosynthesis.** Substrates for biosynthesis of lipids and amino acids derive from the amphibolic pathways of glycolysis and the TCA cycle. Acetyl-CoA links these two pathways and serves as a substrate for many products of biosynthesis.

Enzyme activity requires substantial expenditure of energy in the form of ATP, NADPH, and other energy stores. The genomic and energetic costs lead different microbes to evolve different strategies to control these costs:

- **Regulation.** Biosynthesis is regulated at several levels by the enzyme products. In this way, microbes avoid making more than they need under given environmental conditions. Regulation occurs at the levels of transcription and translation of enzymes, as well as through feedback inhibition of enzyme activity.
- **Genome degeneration.** Each species makes an evolutionary "choice" whether to maintain the expense of a particular assimilatory or biosynthetic pathway, such as N_2 fixation, or to lose the pathway and become dependent on other species in the environment. Parasitic microbes that grow only inside a host cell show extensive loss of biosynthetic genes.
- **Secondary products.** Free-living bacteria often produce secondary products that are not essential nutrients but enhance nutrient uptake or inhibit competitors. Many secondary products are antibiotics, such as streptomycin, produced by the actinomycete *Streptomyces coelicolor*.

First, we present the pathways by which autotrophs assimilate carbon and nitrogen into simple building blocks, such as acetyl-CoA. Then we will present pathways of construction of the key parts of the cell, such as fatty acids and amino acids. Finally, we will consider exciting recent discoveries in the biosynthesis of secondary products such as antibiotics.

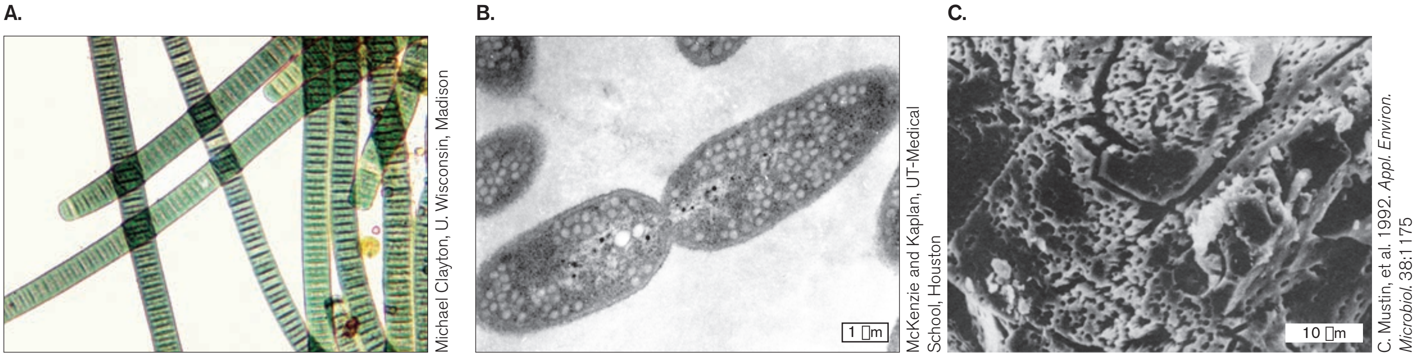
15.2 CO_2 Fixation: The Calvin Cycle

The fundamental significance of **carbon dioxide fixation** by green plants and algae was recognized in the early twentieth century. "Fixation" refers to the covalent incorporation of a small molecule into larger biochemical material. The bulk of biomass on Earth consists of carbon fixed by chloroplasts and bacteria through the **reductive pentose phosphate cycle**, which recycles a pentose phosphate intermediate. The cycle is also known as the **Calvin cycle**, for which Melvin Calvin (1911–1997) was awarded the 1961 Nobel Prize in Chemistry. The mechanism of the pentose phosphate cycle was solved by Calvin with colleagues Andrew Benson and James Bassham, at the University of California, Berkeley. The importance of the Calvin cycle to the global ecosystem can scarcely be overestimated; it plays a major role in removing atmospheric CO_2. The Calvin cycle's responsiveness to CO_2, temperature, and other factors must be considered in all models of global warming.

NOTE: The Calvin cycle is also known as the **Calvin-Benson cycle**, the **Calvin-Benson-Bassham cycle**, or the **CBB cycle**. This book uses the terms *Calvin cycle* and *CBB cycle*.

The Calvin cycle is performed by several categories of organisms (**Fig. 15.3**):

- **Oxygenic phototrophic bacteria**, mainly cyanobacteria, fix CO_2 by the Calvin cycle coupled to oxygenic photosynthesis. Cyanobacteria are believed to generate the majority of oxygen gas in Earth's atmosphere.
- **Chloroplasts** of algae and multicellular plants use the Calvin cycle as the "dark reaction" or "light-independent reaction" of oxygenic photosynthesis.
- **Facultatively anaerobic purple bacteria**, including sulfur oxidizers and photoheterotrophs such as *Rhodospirillum* and *Rhodobacter*, use the Calvin cycle to fix CO_2. These bacteria also obtain carbon through catabolism.
- **Lithotrophic bacteria** fix CO_2 through the Calvin cycle, using NADPH and ATP provided by the O_2 oxidation of minerals.



Michael Clayton, U. Wisconsin, Madison

McKenzie and Kaplan, UT-Medical School, Houston

C. Mustin, et al. 1992. *Appl. Environ. Microbiol.* 38:1175

Figure 15.3 Aerobic and facultatively anaerobic phototrophs use the Calvin cycle. **A.** *Oscillatoria*, a filamentous cyanobacterium, fixes CO_2 through oxygenic photosynthesis. Filaments are about 8 µm wide (light micrograph). **B.** *Rhodobacter sphaeroides*, purple photoheterotrophs with spherical photosynthetic membranes (TEM). **C.** The iron and sulfur bacterium *Thiobacillus ferrooxidans* oxidizes the sulfur in pyrite (FeS_2), using the Calvin cycle to fix CO_2 (TEM).

To date, the Calvin cycle has not been found among archaea and is largely absent in obligate anaerobic bacteria (**Table 15.1**). Archaea and anaerobes fix carbon by several different pathways, as described in Section 15.2.

^{14}C Labeling and Chromatography Revealed Calvin Cycle Intermediates

Early in the twentieth century, biochemists tried to figure out the mechanism of CO_2 fixation, believing that agricultural photosynthesis could be made more efficient. With the tools then available, however, researchers had no hope of sorting out the intermediate products through which CO_2 was fixed. Elucidating the pathways of CO_2 fixation required development of two fundamental tools: tracer radioisotopes, which are specific compounds labeled with radioactivity; and paper chromatography, a means of separating labeled compounds based on differential migration in a solvent. Both isotope labeling and chromatographic separation remain key tools of biochemical analysis today, enhanced by modern developments.

Carbon isotope labeling. As a means of tracking the conversion of intermediates within a biochemical pathway, specific atoms within molecules can be "labeled" for detection. Atoms are labeled by substituting an uncommon isotope, a version of an element containing a number of neutrons different from that of the most common isotope found in nature. Chemically, the isotopes of an element behave nearly the same in biochemical reactions, although enzymes may show a slight preference for one isotope.

The number of neutrons added to the number of protons (atomic number) yields the mass number of the isotope. For example, the predominant isotope of carbon, ^{12}C (carbon = 12), contains six protons and six neutrons, adding up to a mass number of twelve. The next most abundant isotope, ^{13}C, contains seven neutrons. An isotopic label needs to be detected based on its physical properties, such as its mass (by mass spectroscopy) or its nuclear magnetic resonance (by NMR). The most sensitive property for detection and the most widely available to researchers is based on radioactive decay. Radioactive decay requires an unstable isotope (radioisotope), such as ^{14}C.

In the 1930s, when Calvin started his research, few useful radioisotopes were known for biological molecules. The discovery of ^{14}C by Martin Kamen (1913–2002) in 1940 revolutionized biochemistry, enabling discovery of all kinds of cellular metabolism (**Special Topic 15.1**).

Paper chromatography separates intermediates of CO_2 fixation. When ^{14}C-labeled substrates became available in the 1940s, a method was needed to isolate and characterize the unknown intermediates. The technique of **paper chromatography** was developed by Calvin for his studies of carbon fixation. In paper chromatography**,** a mixture of chemicals is spotted on a special paper, one end of which is immersed in a carrier solvent (**Fig. 15.4A**). The solvent is then drawn up through the paper by capillary action. Because the various chemical components of the solution differ in their solubility, they travel in the solvent at different rates. After, the paper is dried and turned at a right angle. A second solvent is then added and drawn through in the crosswise direction. In the second solvent, the chemicals travel at different rates than in the first solvent, thus separating the chemicals in two dimensions. The chance of two different kinds of molecule migrating the same distance in both solvents is very low.

Figure 15.4B shows one of Calvin's original chromatographic separations. The alga *Chlorella* was exposed to light so it could conduct photosynthesis. $^{14}CO_2$ was added. Then samples of the alga were killed at specific times by plunging them into boiling alcohol. Five sec-

Figure 15.4 Discovery of the Calvin cycle. **A.** Melvin Calvin won the Nobel Prize for elucidating CO_2 fixation through the Calvin cycle. **B.** Paper chromatography reveals early intermediate products. Five seconds after addition of $^{14}CO_2$ to photosynthesizing *Chlorella*, the main spots showing radioactivity contain 3-phosphoglycerate (PGA) and glyceraldehyde 3-phosphate (G3P). Thirty seconds after $^{14}CO_2$ addition, radiolabel has entered subsequent products such as amino acids. **C.** Model of CO_2 fixation suggested by the chromatogram of ^{14}C-labeled intermediates.

onds after the addition of $^{14}CO_2$, the main spots showing radioactivity correspond to 3-phosphoglycerate (PGA) and glyceraldehyde 3-phosphate (G3P), early intermediates of CO_2 fixation. Thirty seconds after $^{14}CO_2$ was added, radiolabel is detected in subsequent products such as amino acids.

The chromatography data illustrate the extraordinary speed of CO_2 fixation, while revealing a glimpse of its earliest intermediates. At even earlier times (2 seconds) only PGA shows radiolabel. **Figure 15.4C** shows the portion of the cycle deduced from the data: CO_2 is incorporated to form PGA, then is hydrogenated to G3P by an unknown reducing agent (later shown to be NADPH). In this particular experiment, the key intermediate that first assimilates CO_2 remains undetected. The key intermediate was later identified as ribulose 1,5-bisphosphate, also known for its role in the pentose phosphate pathway of glucose catabolism (discussed in Section 13.5).

THOUGHT QUESTION 15.1 Propose a simple experiment to reveal the key intermediate to receive CO_2.

Since Calvin's time, chromatographic separation has been developed into ever more sophisticated forms. High-performance liquid chromatography (HPLC) provides extremely high-resolution separation of chemical products through columns packed with beads of various physical properties.

Overview of the Calvin Cycle

Decades of biochemical and genetic experiments established the details of CO_2 fixation in the Calvin cycle. An overview is shown in **Figure 15.5**; greater detail appears in **Figure 15.7**.

In each "turn" of the cycle, one molecule of CO_2 is condensed (combined, forming a new C–C bond) with the five-carbon sugar ribulose 1,5-bisphosphate. The resulting six-carbon intermediate splits into two molecules of 3-phosphoglycerate (PGA). The fixed CO_2 ultimately ends up as a carbon of glyceraldehyde 3-phosphate (G3P), reduced by $2H + 2e^-$ from $NADPH + H^+$. Recall from Chapter 13 that NADPH is a phosphorylated derivative of NADH commonly associated with biosynthesis.

How does the fixed CO_2 become one "corner" of a glucose molecule? For every three turns of the cycle, fixing three molecules of CO_2, the cycle feeds one molecule of G3P ($C_3H_5O_3–PO_3^{2-}$) into biosynthesis:

$$3CO_2 + 6NADPH + 6H^+ + 9ATP + 9H_2O \longrightarrow$$
$$C_3H_5O_3–P + 6NADP^+ + 9ADP + 8P_i$$

Figure 15.5 The Calvin cycle: overview. The Calvin cycle condenses CO_2 and H_2O with the intermediate ribulose 1,5-bisphosphate. Overall, three molecules each of CO_2 and of H_2O are fixed and split into six molecules of 3-phosphoglycerate (PGA), which are reduced by 6NADPH (with 6ATP) to six glyceraldehyde 3-phosphate (G3P). An additional 3ATP are consumed during sugar exchange reactions to regenerate three molecules of the recycled 5C intermediate ribulose 1,6-bisphosphate.

The H_2O and the phosphoryl group of G3P are ultimately recycled during biosynthetic assimilation of G3P. Two molecules of G3P may condense (that is, form a new C–C bond) in a pathway to form glucose. The overall condensation of $6CO_2 \longrightarrow 2\text{ G3P} \longrightarrow$ glucose yields:

$$6CO_2 + 12NADPH + 12H^+ + 18ATP + 18H_2O \longrightarrow C_6H_{12}O_6 + 12NADP^+ + 18ADP + 18P_i$$

Alternatively, instead of forming glucose, G3P can enter biosynthesis of amino acids, vitamins, and other essential components of cells. Glyceraldehyde 3-phosphate is the fundamental unit of carbon assimilation into biomass.

The Calvin Cycle Requires Reduction and Regeneration of Ribulose 1,5-Bisphosphate

Each "turn" of the Calvin cycle has three main phases: carboxylation and splitting into two three-carbon (3C) intermediates; reduction of two molecules of PGA to two molecules of G3P; and regeneration of ribulose 1,5-bisphosphate (see **Fig. 15.5**):

1. **Carboxylation and splitting: 6C $\longrightarrow$ 2[3C].** Ribulose 1,5-bisphosphate condenses with CO_2 and H_2O, mediated by ribulose 1,5-bisphosphate carbon dioxide reductase/oxidase, generally referred to by the acronym **rubisco**. Rubisco generates a six-carbon intermediate, which immediately hydrolyzes (splits into two parts by incorporating H_2O). The split produces two molecules of PGA, one of which contains the CO_2 fixed by this cycle.
2. **Reduction of PGA to G3P.** The carboxyl group of each PGA molecule is phosphorylated by ATP. The phosphorylated carboxyl group is then hydrolyzed and reduced by NADPH, forming G3P.
3. **Regeneration of ribulose 1,5-bisphosphate.** Of every six G3P, resulting from three cycles of fixing CO_2, five G3P enter a complex series of reactions (including hydrolysis of 3ATP) to regenerate three molecules of ribulose 1,5-bisphosphate. The net conversion of five G3P molecules to three molecules of ribulose 1,5-biphosphate yields two H_2O, restoring two of the $3H_2O$ fixed with $3CO_2$. The remaining sixth G3P exits the cycle, available to be used in the biosynthesis of sugars and amino acids. Thus, three fixed carbons lead to one three-carbon product.

Overall, each CO_2 fixed sends one carbon into biosynthesis and regenerates one ribulose 1,5-bisphosphate.

The full Calvin cycle occurs only in bacteria and in plastid organelles (chloroplasts) that evolved from bacteria. It has not been found in archaea or in the cytoplasm of eukaryotes. Thus, the Calvin cycle appears

Special Topic 15.1 The Discovery of ^{14}C

In 1937, a young physicist from the University of Chicago, Martin Kamen (1913–2002), arrived at the University of California at Berkeley to study nuclear reactions. Berkeley possessed one of the world's largest cyclotrons, an instrument in which charged particles are accelerated to high speeds by passage through a voltage potential (**Fig. 1**). One use of a cyclotron was to generate special isotopes of many elements by particle collision. A charged particle collides with a target atom, whose nucleus then undergoes a reaction to form a new isotope. For example, a deuteron (proton plus neutron, mass 2) can collide with ^{10}B (boron 10: five protons, five neutrons) to produce ^{11}C (six protons, five neutrons) plus a neutron. The radioactive isotope ^{11}C decays to ^{10}B with a half-life of 21 minutes.

Kamen and a colleague, chemist Samuel Ruben, were assigned the task of providing radioisotopes requested by physicians for use in cancer therapy, an arrangement that generated funding for the cyclotron. As a result, Kamen and Ruben heard from biochemists about the need for a tracer isotope for carbon. At that time, the only radioactive isotope of carbon that Kamen and Ruben knew how to produce was the short-lived ^{11}C. But it occurred to them that with a ready supply of ^{11}C at their cyclotron, they themselves could attempt tracer experiments in physiology. They focused on a key question: the identity of the first compound to assimilate CO_2 during photosynthesis.

Kamen and Ruben designed experiments in which ^{11}C-radiolabeled CO_2 was assimilated by photosynthesis in *Chlorella*, a species of alga that is a food source for aquarium fish (**Fig. 2**). But the short half-life of ^{11}C made it difficult to complete an experiment while enough radioactivity remained to be detected. As the day's supply of ^{11}C was prepared by the cyclotron, the researchers in the biochemistry laboratory felt "like sprinters at the starting gate," according to Kamen: "Anyone looking in . . . when an experiment was in progress would have had the impression of three madmen hopping about in an insane asylum, what with the frenzied activity punctuated by loud classical music from the radio monitor, and Sam's yells to get on with it and hand him samples while he sat at the counter table, feverishly taking background and sample counts."

With their limited technology, Kamen and colleagues failed to identify intermediates, but they made another key discovery: Fixation of CO_2 occurs in organisms that lack photosynthesis. Colleagues had shown that an anaerobic bacterium fermented glycerol to succinate, a process that appeared to involve the addition of a fourth carbon from CO_2. So Kamen and Ruben used ^{11}C to test for assimilation by various bac-

to have evolved after the divergence of the three domains of life. The relative uniformity of the pathway across species, compared with the diversity of anaerobic pathways of CO_2 fixation, supports the view of late emergence. Nevertheless, some archaeal genomes do show a homolog of rubisco. The function of archaeal rubisco is not yet understood.

Ribulose 1,5-Bisphosphate Fixes CO_2 and Is Regenerated

Rubisco is found in large quantities in CO_2-fixing cells; it is one of the most prevalent proteins on Earth. Its characteristics determine the rate and efficiency of CO_2 fixation. The structure of rubisco is highly conserved across teria, by yeast, and even by rat liver and muscle. All of these organisms assimilated radioactive CO_2. It was ultimately established that all organisms—including humans—fix some CO_2 as part of their central metabolism, usually by reversal of steps in the TCA cycle.

Kamen and his colleagues sought a longer-lived radioisotope of carbon. Theoretical predictions suggested that a much longer half-life would be exhibited by the isotope ^{14}C. But ^{14}C had yet to be generated and isolated from the cyclotron. Kamen recalled observing unusual collision trails in a sample of nitrogen gas (^{14}N) exposed to neutrons from the cyclotron. Each collision of ^{14}N with a neutron formed a long trail characteristic of a positron (an emitted proton), attached to a short trail expected for a more massive product. The more massive product, Kamen guessed, was ^{14}C.

The isotope ^{14}C proved to have a half-life of 5,700 years. This stability made ^{14}C exactly the kind of tracer needed for experiments in biology. In 1945, Kamen reported the first biological experiment utilizing ^{14}C to investigate the assimilation of CO_2 by the bacterium *Clostridium thermoaceticum*. The bacteria were shown to assimilate two molecules of CO_2 to form acetic acid.

Kamen's own use of ^{14}C for tracer studies was cut short in 1944 by his dismissal from Berkeley stemming from charges that he was a security risk. During the war years, the cyclotron was devoted to weapons development, and all researchers were under tight scrutiny. Kamen faced a decade of accusations, including an appearance before the House Un-American Activities Committee, before he cleared himself of all charges. By that time, however, the fundamental questions of CO_2 fixation in oxygenic photosynthesis had been answered by Melvin Calvin and colleagues, using ^{14}C back at Berkeley. Kamen eventually discovered other kinds of CO_2 fixation in anaerobic bacteria, and he received the Enrico Fermi Award in 1996 for his original discovery of ^{14}C.

Today, short-lived radioisotopes such as ^{11}C find new applications in medical research. For human subjects, short-lived isotopes are desirable because their rapid decay limits exposure to harmful radiation. ^{11}C is particularly useful in positron-emission tomography (PET), a technique in which a molecule labeled with ^{11}C is followed in the body based on detection of emitted positrons. PET can be used to follow the fate of neurotransmitters and psychotropic substances in the brain.

bacterial and chloroplast domains. It consists of two types of subunits, designated small and large (**Fig. 15.6A**). The large (L) subunit contains the active (catalytic) site. Different species contain different multiples of the small and large subunits: eight (in lithotrophs, green phototrophs, and some algae), six (in plant chloroplasts and some algae), or two (in purple phototrophs). Nevertheless, the fundamental mechanism of CO_2 fixation in all these organisms appears to be similar.

Mechanism of rubisco. Initially, rubisco adds CO_2 to ribulose 1,5-bisphosphate to give an unstable six-carbon intermediate that remains bound to the enzyme (**Fig. 15.6B** and **C**). The intermediate hydrolyzes into two molecules

Figure 15.6 The mechanism of rubisco. **A.** Rubisco from *Alcaligenes eutrophus* consists of eight large subunits (L) crowned by eight small subunits (S). Only the upper four L and S subunits are shown. On each L subunit, a catalytic site contains two phosphates (orange) that compete with the substrates for binding. (PDB code: 1BXN) **B.** Rubisco adds CO_2 to ribulose-1,5-bisphosphate to give an unstable six-carbon intermediate bound to the enzyme. The bound intermediate hydrolyzes to form two molecules of 3-phosphoglycerate (PGA). Both PGA molecules enter the cellular pool of PGA and behave equivalently in the rest of the cycle. **C.** The mechanism of CO_2 fixation at the catalytic site. CO_2 adds to the ketone, generating the 6C intermediate, which splits into two molecules of PGA. The two phosphates appear to act as anchors for the molecule(s) throughout the CO_2 assimilation and cleavage. (PDB code: 1RUS)

of PGA, each held at the active site by its phosphate. Only one molecule of PGA contains a carbon from the newly fixed CO_2; nevertheless, as both molecules dissociate from the enzyme, they enter the cellular pool of PGA and behave equivalently in the rest of the cycle.

Rubisco has a high affinity for CO_2, and the typical concentration of rubisco active sites (one per large subunit, six per complex) in plant chloroplasts is 4 mM, about 500 times greater than the concentration of CO_2. Thus, considerable energy is invested in CO_2 absorption. Yet the efficiency of carbon fixation by rubisco is lowered by the existence of a competing reaction with O_2 that leads to 2-phosphoglycolate instead of 3-phosphoglycerate. Researchers are trying to engineer a more efficient oxygen-resistant rubisco enzyme to improve efficiency of crop yields.

THOUGHT QUESTION 15.2 Speculate why rubisco catalyzes a competing reaction with oxygen. Why might researchers be unsuccessful in attempting to engineer rubisco without this reaction?

Regeneration of ribulose 1,5-bisphosphate. Overall, each glyceraldehyde 3-phosphate (G3P) arises from three rounds of CO_2 fixation by ribulose 1,5-bisphosphate. Thus, to maintain the cycle, for each G3P provided to biosynthesis, five other molecules of G3P must be recycled into three ribulose 1,5-bisphosphate. Details of regenerating the intermediate are shown in the lower half of **Figure 15.7**.

Figure 15.7 The Calvin cycle in detail. This diagram shows the fixation of CO_2, reduction of 3-phosphoglycerate to glyceraldehyde 3-phosphate (G3P), and conversion of five G3P into three ribulose 1,5-phosphate.

The regeneration pathway is summarized here:

- Two molecules of G3P condense to form the six-carbon sugar fructose 6-phosphate.
- Fructose 6-phosphate condenses with a third G3P. The nine-carbon molecule splits to form a five-carbon sugar (xylulose 5-phosphate) and a four-carbon sugar (erythrose 4-phosphate). Xylulose 5-phosphate rearranges to ribulose 5-phosphate.
- Erythrose 4-phosphate condenses with a fourth G3P (rearranged to dihydroxyacetone 3-phosphate) to make a seven-carbon sugar.
- The seven-carbon sugar condenses with the fifth G3P and splits into two five-carbon sugars (ribulose 5-phosphate via xylulose 5-phosphate and ribose 5-phosphate).
- Each of the three five-carbon sugars receives a second phosphoryl group from ATP, generating ribulose 1,5-bisphosphate. Each ribulose 1,5-bisphosphate is now ready for rubisco to fix another CO_2.

Why would a cycle have evolved requiring so many enzymatic steps to so many different intermediates? First, a cycle with many steps breaks down the energy flow into numerous reversible conversions with near-zero values of ΔG. The nearer to equilibrium, the more energy is conserved in the conversion. Second, the multiple different intermediates provide substrates for biosynthesis. For example, some molecules of erythrose 4-phosphate and ribose 5-phosphate are withdrawn from the cycle to build aromatic amino acids and nucleotides.

THOUGHT QUESTION 15.3 Why does ribulose 1,5-bisphosphate have to contain two phosphoryl groups, whereas the other intermediates of the Calvin cycle contain only one?

THOUGHT QUESTION 15.4 Which catabolic pathway (see Chapter 13) includes some of the same sugar-phosphate intermediates as those of the Calvin cycle? What might this suggest about the evolution of the two pathways?

Regulation of the Calvin Cycle

The Calvin cycle is tightly organized and regulated within cells. Expression of the CO_2-fixing enzymes varies with CO_2 concentration, light levels (for phototrophs), and temperature. The concentration of CO_2 is a special problem because CO_2 diffuses readily through phospholipid membranes. Thus, cells cannot concentrate this substrate across the cell membrane to reach the level needed to drive rubisco. The gas concentration problem is solved by some species through special carbonate-concentrating structures. Other bacteria use alternative CO_2-fixing systems adapted to different CO_2 concentrations.

Carboxysomes. Many organisms that fix CO_2 contain the rubisco complex within subcellular structures called **carboxysomes** (**Fig. 15.8**). A carboxysome consists of a polyhedral shell of protein subunits surrounding packed molecules of rubisco. The protein shell sequesters carbon dioxide, permitting less leakage than a membrane-bounded organelle. Mutant strains of bacteria lacking carboxysomes can fix CO_2 only at high concentration (5%), much higher than the atmospheric CO_2 concentration (0.037%). Carboxysomes are found within CO_2-fixing lithotrophs, as well as within cyanobacteria and chloroplasts.

Regulation of gene expression. When CO_2 levels decline, genes are induced to express transmembrane transporters of CO_2 and bicarbonate (HCO_3^-) (**Fig. 15.9**). The inducible genes encode transport systems known collectively as the **CO_2-concentrating mechanism (CCM)**. The CCM enables rapid concentration of HCO_3^- into the carboxysome, where it is dehydrated to CO_2 by the enzyme carbonic anhydrase. The CO_2 is then fixed by rubisco to PGA, which exits the carboxysome for further conversion in the cytoplasm.

The CO_2-concentrating mechanism is regulated genetically. The CCM genes encode a low-affinity CO_2 transporter (NdhF4), a high-affinity CO_2 transporter (NdhF3), and two high-affinity HCO_3^- transporters

The HCO_3^- is concentrated in the carboxysome and converted to CO_2 by carbonic anhydrase. *Source:* Model from Dean Price and colleagues, Australian National University at Canberra; McGinn, et al. 2003. *Plant Physiology* 132:218.

(CmpABCD and SbtA). The low-affinity CO_2 transporter is effective only when CO_2 concentration is high. By contrast, the high-affinity transporters are induced by CO_2 starvation.

Induction of transporters by low CO_2 levels is shown by reverse transcriptase PCR (RT-PCR), a technique for detection of minute quantities of mRNA using the enzyme reverse transcriptase followed by polymerase chain reaction, a technique discussed in Chapter 12, **Fig. 12.15.** In RT-PCR, the RNA transcripts are reverse-transcribed to DNA; the DNA is then amplified by PCR to generate a detectable product. RNA transcripts are obtained for genes expressed before and after CO_2 limitation. The *sbtA* and *cmpA* transcripts, encoding HCO_3^- transporters, show particularly strong induction by CO_2 (see **Fig. 15.10**). By contrast, the constitutive low-affinity CO_2 transporter NdhF4 shows no induction.

Alternative CO_2 fixation systems. Instead of carboxysomes, some phototrophs possess entire alternative systems of CO_2 fixation adapted to different levels of CO_2. For example, the genome of the purple phototroph *Rhodobacter sphaeroides* includes two unlinked operons, each encoding a different set of CO_2 fixation genes, called form I and form II. Form I and form II each encode all the key enzymes such as rubisco. When CO_2 is limiting, form I enzymes work best; when CO_2 levels are saturating, form II enzymes work best.

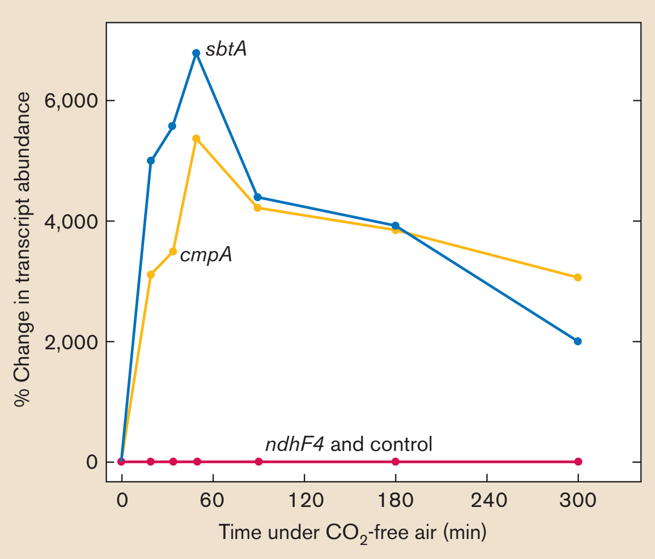

Figure 15.10 Time course of CCM gene transcription. When CO_2 is limiting, *Synechocystis* genes encoding the carbon uptake complexes show induced transcription. Induction is measured by reverse transcriptase PCR (RT-PCR). The *sbtA* and *cmpA* genes show especially high induction, whereas the constitutive system (*ndhF4*) shows no induction.

TO SUMMARIZE:

- **The Calvin cycle** fixes CO_2 by reductive condensation with ribulose 1,5-bisphosphate. The Calvin cycle is used by cyanobacteria and chloroplasts and by some lithotrophs and photoheterotrophs.
- **^{14}C radiolabel and paper chromatography** were first used to identify intermediates of the Calvin cycle.
- **Rubisco** catalyzes the condensation of CO_2 with ribulose 1,5-bisphosphate. The six-carbon intermediate immediately splits into two molecules of 3-phosphoglycerate (PGA), which are activated by ATP and reduced by NADPH to glyceraldehyde 3-phosphate (G3P).
- **One of every six G3P is converted to glucose** or amino acids. The other five molecules of G3P undergo reactions to regenerate ribulose 1-5-bisphosphate.
- **Carboxysomes sequester and concentrate CO_2** for fixation by the Calvin cycle. CO_2 levels regulate gene expression for carboxysome transporters and the Calvin cycle.

15.3 CO_2 Fixation in Anaerobes and Archaea

We have seen how aerobic organisms and facultative anaerobes fix CO_2 by the Calvin cycle. Some anaerobes, however, fix CO_2 by alternative means (see **Table 15.1**). The most ancient pathways, from the standpoint of evolution and phylogenetic distribution, are the reductive, or reverse, TCA cycle of anaerobic phototrophs and the reductive acetyl-CoA pathway of methanogens. Anaerobic CO_2 fixation plays an essential role in soil, aquatic, and wetland ecosystems, as well as in the digestive systems of animals such as cattle.

The Reductive, or Reverse, TCA Cycle

Portions of the TCA cycle (discussed in Section 13.6) are found in all major groups of organisms. Most of the individual reaction steps of the TCA cycle are reversible, enabling the assimilation of small amounts of CO_2. Furthermore, all organisms, including humans, fix small amounts of CO_2 that regenerate TCA cycle intermediates. These regeneration steps are called **anaplerotic reactions**. Common anaplerotic reactions are the formation of oxaloacetate from phosphoenolpyruvate (PEP), catalyzed by PEP carboxylase, and the formation of malate from pyruvate, catalyzed by malate dehydrogenase.

In some anaerobic bacteria and archaea, the entire TCA cycle functions in "reverse," reducing CO_2 to generate acetyl-CoA and build sugars (**Fig. 15.11A**). The **reductive** or **reverse TCA cycle** is used by bacteria such as *Chlorobium tepidum*, a thermophilic green sulfur bacterium originally isolated from a New Zealand hot spring (**Fig. 15.11B**). *Chlorobium* conducts anoxygenic photosynthesis by photolyzing H_2S to produce elemental sulfur, which collects in extracellular granules. Sulfur granule formation is of interest for the development of a process to remove H_2S from sulfide-generating industries such as refining of coal and oil. The reductive TCA cycle is also used by epsilon-proteobacteria of hydrothermal vent communities and by sulfur-reducing archaea, such as *Thermoproteus* and *Pyrobaculum*.

Reversal of the TCA cycle uses four or five ATP molecules to fix four molecules of CO_2 and generates one molecule of oxaloacetate. The enzymes used are the same as for the "forward" cycle, except for three key enzymes that spend ATP to drive the reaction in reverse: ATP citrate lyase, 2-oxoglutarate:ferredoxin oxidoreductase, and fumarate reductase. For example, the enzyme ATP citrate lyase catalyzes the cleavage of citrate into acetyl-CoA and oxaloacetate. CO_2 assimilation requires reduction by NADPH. The reductive TCA cycle is believed to be the most ancient means of CO_2 fixation and amino acid biosynthesis, the original cycle of biomass generation in the ancestors of all three living domains.

From CO_2 to acetyl-CoA, the reverse TCA cycle essentially reverses the complementary reaction of catabolism:

$$2CO_2 + 2ATP + 8[H] + H\text{-}SCoA \longrightarrow CH_3CO\text{-}SCoA + 3H_2O + 2ADP + 2P_i$$

The coenzyme A is recycled as the acetyl group enters biosynthesis. For example, acetyl-CoA can assimilate another CO_2 with reduction to pyruvate. Pyruvate then builds up to glucose and related sugars by **gluconeogenesis** or reverse glycolysis, with expenditure of ATP and NADPH. Alternatively, acetyl-CoA can enter biosynthetic pathways to produce fatty acids or amino acids.

Unlike the Calvin cycle, the reverse TCA cycle provides several different molecular intermediates that can assimilate CO_2. Here are the key steps:

- Succinyl-CoA assimilates CO_2 to form 2-oxoglutarate (alpha-ketoglutarate).
- 2-oxoglutarate assimilates CO_2 to form isocitrate.
- Acetyl-CoA (produced by the reverse TCA cycle) assimilates CO_2 to form pyruvate.

Each CO_2 assimilation requires one or more reduction steps. 2-oxoglutarate is reduced by the protein ferredoxin (FDH_2). Ferredoxin also mediates acetyl-CoA reduction to pyruvate. Other reduction steps may be accomplished by NADPH or NADH.

Figure 15.11 The reductive, or reverse, TCA cycle for CO_2 fixation. A. Anaerobic phototrophs and archaea use the reverse TCA cycle to fix carbon into biomass. CO_2 is fixed by several intermediates including succinyl-CoA, 2-oxoglutarate, and acetyl-CoA. Reduction (addition of $2H^+ + 2e^-$) is performed by NADPH or NADH and by reduced ferredoxin (FDH_2). **B.** *Chlorobium tepidum*, a green sulfur bacterium that fixes CO_2 by the reductive TCA cycle (TEM). Chlorosome membranes contain the reaction centers of photolysis.

Acetyl-CoA Pathway

Yet another route for CO_2 assimilation into acetyl-CoA and pyruvate is the **reductive acetyl-CoA pathway (Fig. 15.12A)**. In the acetyl-CoA pathway, two CO_2 molecules are condensed through converging pathways to form the acetyl group of acetyl-CoA. The acetyl-CoA pathway is used by anaerobic soil bacteria, such as *Clostridium thermoaceticum*, and by most autotrophic sulfate reducers, such as *Desulfobacterium autotrophicum*. It also provides the main source of biomass for methanogens. Most of the CO_2 absorbed by methanogens is used to yield energy by reducing CO_2 to methane (discussed in Chapter 14). However, 5% of the CO_2 absorbed by a methanogen enters the acetyl-CoA pathway for biosynthesis, generating the entire biomass of the organism.

The substrates and ultimate products of the acetyl-CoA pathway are the same as those of the reverse TCA cycle, except that the reducing agent is H_2 instead of NADPH. The acetyl-CoA pathway is slightly more efficient than the TCA cycle, requiring one less ATP:

$$\begin{aligned}&2CO_2 + ATP + 4H_2 + H\text{-}SCoA \longrightarrow\\&\quad CH_3CO\text{-}SCoA + 3H_2O + ADP + P_i\end{aligned}$$

Nevertheless, the form of the pathway and its intermediate compounds are completely different from those of the TCA cycle. The

Figure 15.12 The reductive acetyl-CoA pathway of CO_2 fixation. A. The first CO_2 enters the linear pathway by reduction to formate and is transferred onto the cofactor tetrahydrofolate (THF). Following reduction, the methyl group is transferred to a vitamin B_{12}-like cofactor (TB). The second CO_2 is reduced to carbon monoxide (CO) by the enzyme carbon monoxide dehydrogenase, then incorporated as the ketone of acetyl-CoA. The two carbons are condensed as acetyl-CoA. **B.** *Methanocaldococcus jannaschii*, a thermophilic marine methanogen that fixes CO_2 by the reductive acetyl-CoA pathway (SEM).

reductive acetyl-CoA pathway is linear, with no recycled intermediates.

Reduction of the first CO_2. The first CO_2 enters the linear pathway by reduction to formate. The formate is transferred onto tetrahydrofolate (THF), a reduced form of **folate**. Folate (folic acid) is a heteroaromatic cofactor, comparable to NADH. Folate is required by many living organisms and is an essential vitamin for humans. It is particularly important for fetal brain development.

The carbon carried by reduced folate (THF) is reduced in successive steps to a methyl group. In methanogens, a THF methyl group is converted to methane for net energy acquisition. An occasional methyl group, however, is fixed into biomass. For incorporation into biomass, the methyl must be transferred from THF onto a different cofactor, a specialized tetrapyrrole (TB) related to vitamin B_{12}.

Reductive CO_2 incorporation into acetyl-CoA. The second CO_2 is reduced to carbon monoxide (CO) by the enzyme carbon monoxide dehydrogenase. This same enzyme is used in reverse reaction by some lithotrophs to gain energy from carbon monoxide as an electron donor. For fixation, the CO is condensed with the methyl group carried by TB to form acetyl-CoA. The acetyl-CoA then enters pathways of biosynthesis, as it does when formed by the reverse TCA cycle.

The fixation of CO_2 and the release of methane by methanogens is a major concern for cattle farming. Within the rumen, bacteria convert feedstock into CO_2 and H_2; and methanogens divert a significant portion of these gases into methane. The methane then escapes through burping and flatulence. If methanogen growth could be prevented, the CO_2 and H_2 could be fixed by other microbes into fermentation acids assimilated by the rumen. Beef production would be more efficient, with less release of the greenhouse gas methane.

The 3-Hydroxypropionate Cycle

New pathways of carbon fixation continue to be discovered. In the **3-hydroxypropionate cycle**, CO_2 is fixed by acetyl-CoA into 3-hydroxypropionate (**Fig. 15.13A**). The cycle was discovered in the green photoheterotroph *Chloroflexus aurantiacus* (**Fig. 15.13B**). *Chloroflexus* bacteria are filamentous thermophiles that absorb light at longer wavelengths than cyanobacteria and often grow below cyanobacteria in thick mats of biofilm. The 3-hydroxypropionate cycle is also used by archaea, such as the thermoacidophile *Acidianus brierleyi* and the aerobic sulfur oxidizer *Sulfolobus metallicus*.

In the 3-hydroxypropionate cycle, acetyl-CoA condenses with hydrated CO_2 (bicarbonate ion, HCO_3^-) and is reduced by 2 NADPH to 3-hydroxypropionate. Through several intermediates, including succinyl-CoA, condensation with a second molecule of HCO_3^- yields malyl-CoA. These intermediates were detected by [^{14}C] acetate incorporation into the metabolism of *Chloroflexus* (**Fig. 15.13C**).

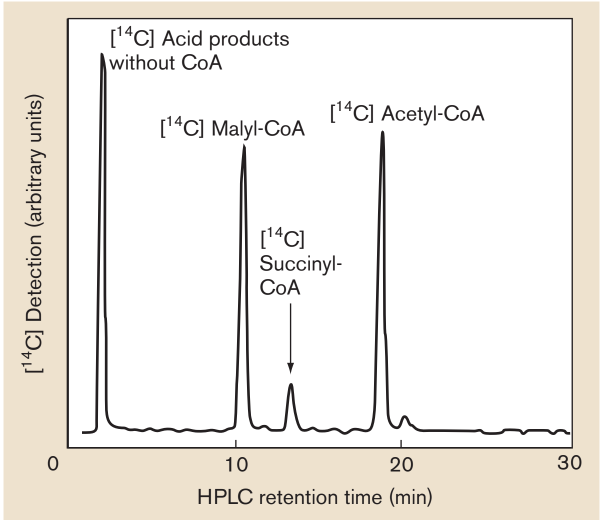

Figure 15.13 **The 3-hydroxypropionate cycle of CO_2 fixation.** **A.** In the 3-hydroxypropionate cycle, acetyl-CoA condenses with CO_2 in the form of bicarbonate ion (HCO_3^-), forming malonyl-SCoA (1). Reduction by 2NADPH yields the key intermediate 3-hydroxypropionate (2). Condensation with a second NADPH (3) and a second HCO_3^- yields methylmalonyl-CoA. Step 4 converts methylmalonyl-CoA to malyl-CoA. In step 5, malyl-CoA is cleaved to yield glyoxyalate plus acetyl-CoA, which reenters the 3-hydroxypropionate cycle. Glyoxalate condenses with a third HCO_3^- to yield pyruvate. **B.** *Chloroflexus*, a green phototroph that performs the 3-hydroxypropionate cycle. **C.** Products of [^{14}C] acetate incorporate into the 3-hydroxypropionate cycle. After 1 minute, samples were separated by HPLC (high-performance liquid chromatography). The nonpolar coenzyme A esters of each acid separate in the HPLC solvent. *Source:* A. Modified from Silke Friedmann, et al. 2006. *J. Bacteriol.* 188:2646. C. Herter, et al. 2002. *J. Biol. Chem.* 277:20277.

Malyl-CoA releases a molecule of acetyl-CoA to renew the cycle, plus glyoxalate. Glyoxalate condenses with a third HCO_3^- to yield pyruvate, which enters standard routes for biosynthesis of sugars and amino acids. Thus in all, three molecules of CO_2 are fixed into one molecule of pyruvate, which serves as a substrate for biosynthesis.

TO SUMMARIZE:

- **The reductive, or reverse, TCA cycle** fixes CO_2 in some anaerobes and archaea.
- **Anaplerotic reactions** in all organisms regenerate TCA cycle intermediates by fixing CO_2.
- **The acetyl-CoA pathway** in anaerobic bacteria and methanogens fixes CO_2 by condensation to form acetyl-CoA.
- **The 3-hydroxypropionate cycle** in chlorobia and in some hyperthermophilic archaea fixes CO_2 in a cycle generating the intermediate 3-hydroxypropionate.

15.4 Biosynthesis of Fatty Acids and Polyesters

The biosynthesis of cell parts begins with small, versatile substrates such as acetyl-CoA, a product of catabolic pathways such as the TCA cycle and benzoate catabolism. A key pathway of biosynthesis from acetyl-CoA generates fatty acids. Fatty acids condense with glycerol to form the phospholipids of cell membranes; they also form the lipid components of envelope proteins and are converted to enzyme cofactors. Fatty acid biosynthesis provides targets for antimicrobial drugs such as triclosan, an inhibitor of enoyl-ACP reductase. Related condensation pathways yield industrial materials, such as polyesters.

Fatty Acids Are Built from Repeating Units

Fatty acids exemplify the construction of cell components from repeating units (**Fig. 15.14**). The construction of molecules based on repeating units requires a cyclic pathway that feeds its products back repeatedly as substrates for further synthesis. The advantage of a cyclic process is that large polymers can be made using a limited number of enzymes; for example, the mycolic acids of *Mycobacterium tuberculosis* are extended to lengths of over 100 carbons.

While fatty acid structures used by cells include many different forms (discussed in Chapter 3), their synthesis always begins with the successive addition of two-carbon acetyl groups. Thus, most fatty acids contain an even number of carbon atoms.

The fatty acid synthase complex. The cyclic process of fatty acid synthesis is managed by the **fatty acid synthase complex**. The complex contains all the enzymes and component binding proteins bound together in proximity, so that all steps occur in one place without "losing" the unfinished molecule. The main bacterial version of this complex is designated FASII. All components are essential for viability and offer drug targets. Analogous multienzyme complexes are used by actinomycete bacteria to synthesize other long-chain products such as polyketide antibiotics.

Activation of acetyl-CoA. Most acetyl groups within the cell are "tagged" with coenzyme A (CoA), a cofactor that directs acetate into catabolic pathways such as the TCA cycle. To redirect acetyl groups into fatty acid biosynthesis (**Fig. 15.14**), acetyl CoA molecules are first tagged at the "back end" by condensation with CO_2 (step 1), catalyzed by acetyl-CoA carboxylase. The addition of CO_2 in this step does not "count" as carbon fixation, because the CO_2 added does not permanently add to the carbon skeleton. Instead, like phosphate or CoA, the CO_2 exists to be displaced when its function is no longer required. The CO_2-tagged acetyl-ACP is now called malonyl-CoA. The coenzyme A is replaced by **acyl carrier protein (ACP)**, making malonyl-ACP (**Fig. 15.14A**, step 2).

Malonyl-ACP condenses with the growing chain. In step 3, malonyl-ACP hooks onto the head of an acetyl-ACP or a longer-growing chain. The process of hooking onto the new unit involves displacement of CO_2 from the back end of malonyl-ACP, which replaces ACP from the front end of the growing chain. The growing chain now contains a ketone from the former acetyl group. The ketone must be reduced to CH_2 by 2 NADPH, gaining $4H^+ + 4e^-$ (steps 4–6). The chain is now fully hydrogenated (saturated).

Once hydrogenated, the chain is ready to take on the next malonyl-ACP, which, as before, loses CO_2 and replaces the ACP from the front of the growing chain (return to step 3). Successive addition can continue many times to build a saturated fatty acid of indefinite length. The regulation of fatty acid chain length is poorly understood.

Unsaturation. Certain fatty acids require unsaturated "kinks" in the chain to serve a structural purpose, such as to increase the fluidity of the membrane. Such a kink is created by an unsaturated double bond between adjacent carbons (an alkene). Unsaturation can be generated during a cycle of elongation (**Fig. 15.14B**). During the first four cycles of acetyl addition, an alkene bond forms between the *second* and *third* carbons of the fatty acid. After the fifth two-carbon addition, however, a special dehydratase enzyme forms the alkene double bond between the *third* and *fourth* carbons. This alkene fails to be hydrogenated further. Instead, several additional malonyl units are added, generating a long-chain fatty acid with a "kink" of a *cis* double bond.

Figure 15.14 **Fatty acid biosynthesis.** **A.** Stepwise elongation of a saturated fatty acid. Units of acetyl-CoA are carboxylated to malonyl-CoA, then successively condense to form the long chain of a fatty acid. Each two-carbon unit requires reduction by 2 NADPH. **B.** An alkene "kink" can be left unsaturated during chain extension. A special dehydratase enzyme forms the double bond between the third and fourth carbons, rather than the third and second. In this position, the double bond escapes reduction as the chain lengthens through subsequent cycles of malonyl addition.

Regulation of fatty acid synthesis. The synthesis of fatty acids consumes enormous quantities of reducing energy; thus, it must be regulated closely to avoid waste. From a structural standpoint, production of fatty acids incorporated into membranes must be balanced with growth of the cytoplasm. Furthermore, the many different variants of fatty acids are regulated in response to particular environmental needs. In *E. coli,* key points of regulation include the following:

- **Acetyl-CoA carboxylase represses its own transcription.** Transcription of an operon encoding two subunits of acetyl-CoA carboxylase (AccB, AccC) is repressed by one of its subunits, protein AccB. As AccB increases in concentration, it binds the promoter of the *accBC* operon, repressing further transcription. Thus, initiation of fatty acid biosynthesis (**Fig. 15.14**, step 1) is always limited by the amount of AccB-AccC enzyme present.
- **Starvation blocks fatty acid biosynthesis.** Starvation for carbon sources blocks fatty acid biosynthesis through the "stringent response." Blockage is mediated by the polyphosphorylated nucleotide ppGpp, the global regulator of the stringent response (discussed in Section 10.3).

- **Temperature regulates fatty acid composition.** Bacterial fatty acid composition is regulated by environmental factors such as temperature. In *E. coli*, low temperature favors unsaturated fatty acids because they are less rigid and maintain membrane flexibility. Low temperature induces expression of the gene *fabA* encoding the dehydratase enzyme that desaturates the fatty acid bond. As the dehydratase activity is increased, more unsaturated fatty acids are made.

THOUGHT QUESTION 15.5 For a given species, uniform thickness of a cell membrane requires uniform chain length of its fatty acids. How do you think chain length may be regulated?

The biosynthesis of fatty acids provides a model for study of the related biosynthesis of a major family of pharmaceuticals, the polyketides. A well-known polyketide is erythromycin, a broad-spectrum antibiotic frequently prescribed for pneumonia and other serious bacterial infections. Polyketides are commonly produced by actinomycetes, particularly species of *Streptomyces* (**Special Topic 15.2**). Antibiotics are produced as **secondary metabolites**, or **secondary products**—molecules not essential for survival, but which can enhance competition with other strains or species in a crowded natural environment. These secondary products accumulate to especially high levels during stationary phase, when growth of the cell is greatly slowed.

Bacterial Polyesters

Cyclic elongation routes comparable to fatty acid biosynthesis are used to build polymers for energy storage. For example, many bacteria synthesize polyesters (**Fig. 15.15**). The term *polyester* indicates the multiple ester groups that are formed by repeated esterification of the carboxylic acid group of the chain with the hydroxyl group of a new alkanoate unit. Because bacterial polyesters are biodegradable, they are of interest for commercial development as plastic materials. A current application of polyalkanoates is for surgical sutures that can be resorbed within the healed tissue.

The repeating forms of fatty acids, polyketides, and polyesters enables long-chain molecules to be synthesized with a relatively small number of different enzymes. By contrast, other cell components, such as amino acids, have more complex nonrepeating structures whose biosynthetic enzymes require long operons (presented in Section 15.6).

TO SUMMARIZE:

- **Fatty acid biosynthesis** involves successive condensation of malonyl-ACP groups formed from acetyl groups tagged with acyl carrier protein (ACP) and a carboxylate. Each successive malonyl group is transferred onto the growing acyl chain, with release of CO_2. The condensation reaction is catalyzed by acetyl-CoA carboxylase.
- **The growing acyl chain is dehydrogenated.** Each added unit is hydrogenated by two molecules of NADPH unless an unsaturated kink is required.
- **Some fatty acids are partly unsaturated.** An unsaturated kink may be generated by a special dehydratase, which forms the alkene double bond between the third and fourth carbons.
- **Fatty acid biosynthesis is regulated** by the levels of acetyl-CoA carboxylase and by the stringent response to carbon starvation. Bond saturation is regulated by temperature and other environmental factors.
- **Polyesters** for energy storage are synthesized by cyclic elongation of polyalkanoates.

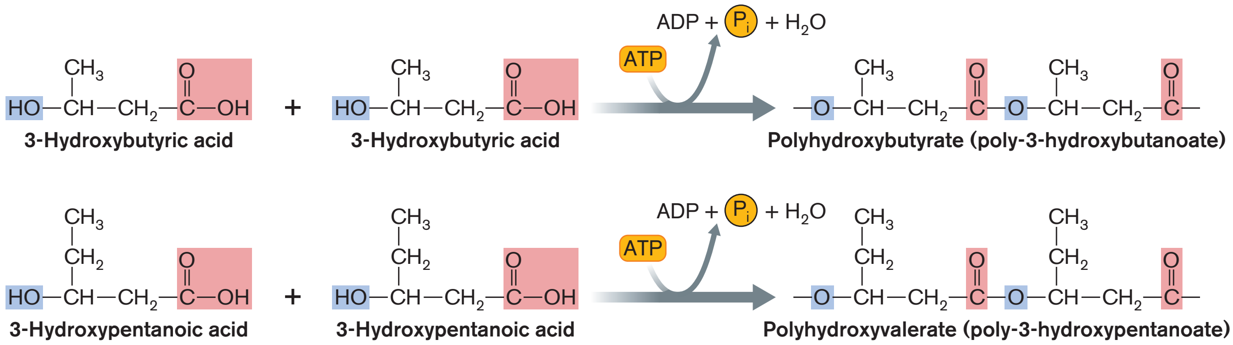

Figure 15.15 Microbial polyester: polyhydroxyalkanoates. Some bacterial species produce natural polyesters for energy storage. The term *polyester* refers to the multiple ester groups produced by successive esterification of the carboxylic acid group of the chain with the hydroxyl group of a new hydroxy acid unit.

Special Topic 15.2 Polyketide Drugs Are Synthesized by Multienzyme Factories

A majority of known antibiotics and antitumor drugs are derived from secondary products of *Streptomyces* bacteria. Many are polyketides, such as erythromycin, originally isolated from *S. erythreus;* ivermectin, a broad-spectrum antiparasitic drug used for heartworm and river blindness, isolated from *S. avermitilis;* and the experimental antitumor agent C-1027, isolated from *S. globisporus* (**Fig. 1**).

Like fatty acids, polyketides are built by the successive condensation of malonyl-ACP units; but each malonyl group carries a unique extension, or R group. In erythromycin, the R groups are all methyl groups. In other polyketides, the R groups range from hydroxyl groups and amides to aromatic rings, some of which undergo secondary reactions and interconnections.

How is the order of different R groups determined? The polyketide is actually constructed on a "modular enzyme" (**Fig. 2**). A modular enzyme contains a series of active sites, or modules, each of which catalyzes the addition of one of a series of units. Each module contains all the enzyme activities needed to add the unit and recognizes a unit with one specific R group. The modular polyketide synthase may consist of a single protein with a series of domains; or it may consist of a complex of several protein subunits. Either the multidomain enzyme or the complex acts as an assembly line to generate the specific polyketide.

Figures 2A and **B** show the chain-extension synthesis of a polyketide. The initial two domains of enzyme 1 are acyltransferase (AT) and an acyl carrier protein (ACP) domain, analogous to the ACP of fatty acid biosynthesis but specialized to accept one component of the polyketide. The acyltransferase transfers the acyl group (R_1-acetyl) from R_1-acetyl-CoA onto the ACP, with release of CoA (**Fig. 2A**). The R_1-acetyl is then transferred to a ketosynthase domain (KS).

Meanwhile, a malonyl group with its own R group (R_2-malonyl) has been transferred by a second AT onto the second ACP domain (**Fig. 2B**). The R_1-acetyl group then leaves KS and condenses with R_2-malonyl-ACP, releasing CO_2.

The R_1R_2 acyl chain subsequently undergoes a series of extensions by R-malonyl groups (**Fig. 2C**). For erythromycin, all R groups are methyl; other polyketides have R groups that are more complex. The initial AT and ACP domains constitute a "loading module" for the first acyl group, whereas subsequent sets of domains constitute "extender modules" that each add a different R-malonyl group. Extender modules can include secondary activities such as dehydratase (DH, removes OH) and ketoreductase (KR, hydrogenates a ketone to OH). In principle, the modular approach can construct a limitless range of products with diverse antibiotic properties.

Upon completion, elongation is terminated by the thioesterase (TE), which hydrolyzes the thioester bond to the final

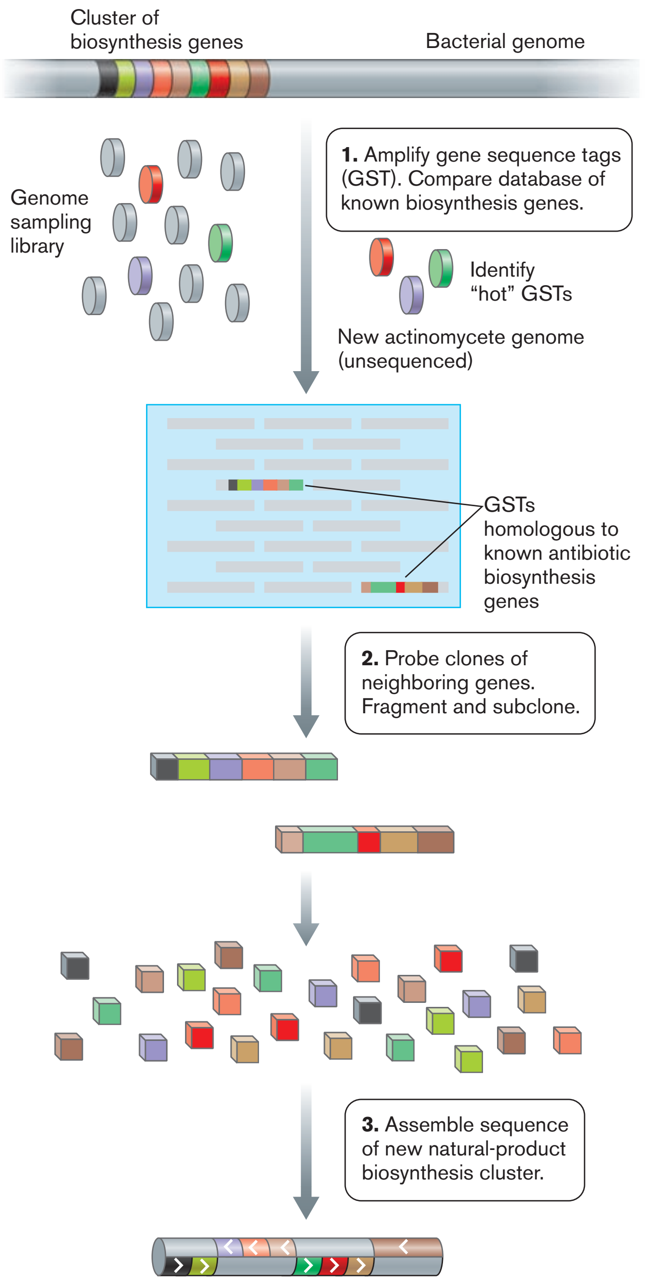
ACP. Additional enzymes (not shown) are required to link extra components, such as sugars, to the polyketide core, completing the product.

Bacteria in nature produce numerous kinds of antibiotics we have yet to discover. One way to discover and produce new polyketide antibiotics is by genome scanning of new bacteria isolates (**Fig. 3**). The scanning of a large number of unsequenced genomes enables cloning of biosynthesis operons for hundreds of new secondary products. The pharmaceutical activities of these products can then be tested.

Genome scanning was used by Ben Shen at the University of Wisconsin–Madison, to discover the potent antitumor agent C-1027. C-1027 is one of an unusual family of polyketides called enediynes, notable for the cyclized core containing two carbon-carbon triple bonds (see **Fig. 1**). The process of genome scanning is based on two assumptions. First, genes for biosynthesis of secondary metabolites tend to be variants of genes for known products. Second, the genes for synthesis of a particular product usually map together as a result of being transferred as a cluster from another organism.



Cluster of biosynthesis genes
Bacterial genome
Genome sampling library
1. Amplify gene sequence tags (GST). Compare database of known biosynthesis genes.
Identify "hot" GSTs
New actinomycete genome (unsequenced)
GSTs homologous to known antibiotic biosynthesis genes
2. Probe clones of neighboring genes. Fragment and subclone.
3. Assemble sequence of new natural-product biosynthesis cluster.

Figure 3 Genome scanning to identify a biosynthesis cluster for a new antibiotic. Biosynthesis genes occur in clusters in a bacterial genome. To identify an unknown cluster whose genes are related to known clusters: 1. Amplify gene sequence tags (GST) from an unsequenced actinomycete genome. Compare GST sequences from the new genome with a database of known antibiotic biosynthesis gene clusters. Identify promising GSTs. 2. Hybridize GST sequences to cloned plasmids containing sequences adjacent to the GST. Subclone and obtain the adjacent sequences, which may contain a new biosynthesis cluster. 3. Assemble the sequence of the new gene cluster for biosynthesis. *Source:* Based on Zazopoulos, et al. 2003. *Nature Biotechnology* 21:187.

Thus, genome scanning is designed to isolate an unknown cluster whose genes are related to known clusters in other organisms. The result is valuable because often a variant of a known antibiotic proves to be active against pathogens resistant to the original substance, or it may have fewer side effects in the host.

Step 1 of genome scanning is to amplify gene sequence tags (GSTs) from an isolated bacterium. A gene sequence tag is a short sequence of DNA bounded by primer ends homologous to known biosynthesis genes (see **Fig. 3**). The primer ends are then used to amplify and sequence the GST. The GSTs are amplified by PCR from plasmid clones in a genomic library of a suspected drug-producing organism. Next (step 2), the GSTs are compared with a database of known biosynthesis genes. The "hot" GSTs (those confirmed as biosynthetic homologs) are then used (step 3) to probe clones containing genes adjacent to the GST sequences. The adjacent genes may contain completely novel biosynthesis components. To identify these components, DNA is sequenced upstream and downstream of the GST. Finally, the sequences are assembled to reveal the biosynthesis gene cluster. The sequence is annotated and deposited in the database for future genome scanning.

To identify new polyketide antibiotics, including C-1027, Shen scanned genomic libraries of 50 different actinomycete strains for biosynthetic clusters encoding natural polyketides not known previously. Eight of the strains revealed novel antibiotic compounds. These new products show varying degrees of toxicity and antibacterial action; they are presently under testing for medical use.

15.5 Nitrogen Fixation

The synthesis of amino acids, cell walls, and other cofactors requires an additional element we have not yet considered, namely, nitrogen. In principle, nitrogen should be more accessible to cells than carbon, since nitrogen gas (N_2) comprises more than three-quarters of our atmosphere. In fact, however, N_2, with its triple bond, is one of the most stable molecules in nature. An enormous input of energy is required to reduce nitrogen to ammonia for assimilation into carbon skeletons. Early in evolution, all cells may have fixed their own N_2, but today only certain species of bacteria and archaea retain the ability. All other organisms depend on reduced or oxidized forms of nitrogen, which ultimately derive from N_2. Thus, all living organisms, directly or indirectly, depend on N_2-fixing prokaryotes.

NOTE: Prokaryotes play essential roles in global cycling of nitrogen, sulfur, and phosphorus. The geochemical cycling of these elements is discussed in Chapter 22.

Nitrogen Is Assimilated in Different Forms

To assimilate into biomass, any form of nitrogen must be fully reduced to ammonia (NH_3), which at pH 7 is mostly protonated to ammonium ion, NH_4^+. Unlike carbon, nitrogen rarely appears in oxidized form in complex biomolecules. Inorganic forms, such as nitric oxide (NO), are used as defense mechanisms against invading pathogens (see Chapter 24) or as signaling molecules. In macromolecules, however, virtually all the nitrogen is reduced; organic compounds containing oxidized nitrogen are generally toxic.

While N_2 is the ultimate source and sink of biospheric nitrogen, several oxidized or reduced forms occur in the environment (**Fig. 15.16**). Most free-living bacteria can acquire nitrate (NO_3^-) or nitrite (NO_2^-) for reduction to ammonium ion, although they repress these energy-expensive pathways when ammonium ion is present. Even nitrogen-fixing legume symbionts, such as *Rhizobium*, can utilize nitrate.

In natural environments, most potential sources of nitrogen are subject to competition from dissimilatory metabolism in which the molecule is oxidized or reduced for energy, as discussed in Chapter 14. For example, anaerobic respirers convert nitrate and nitrite to N_2 (denitrification), whereas lithotrophs oxidize NH_4^+ to nitrite and nitrate (nitrification). An important consequence of nitrification is that most of the commercial ammonia fertilizer spread on agricultural fields is soon oxidized by lithotrophs to nitrates and nitrites. High concentrations of nitrites in water are harmful because they combine with hemoglobin, generating a form that cannot take up oxygen.

Nitrogen Fixation: Early Discoveries

The first nitrogen fixers discovered by Martinus Beijerinck and colleagues in the late 1800s were soil and wetland bacteria such as *Beggiatoa* and *Azotobacter*. Species of *Rhizobium* were discovered to conduct nitrogen as endosymbionts of

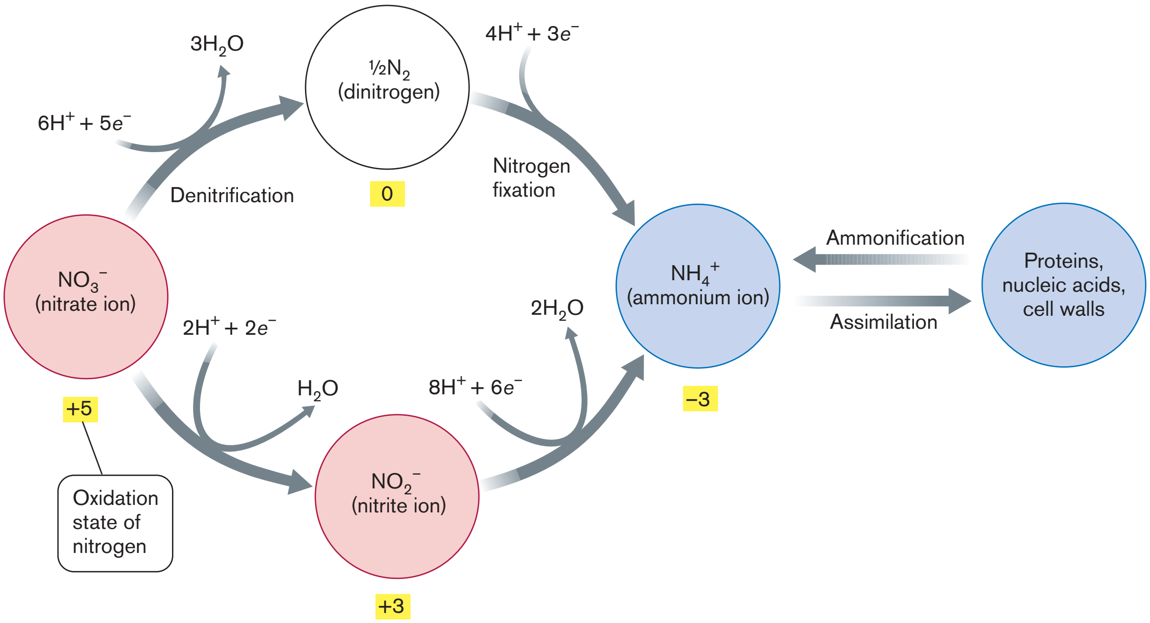


Figure 15.16 Nitrogen assimilation. Different oxidation states of nitrogen require different amounts of reducing energy for assimilation into biomass.

leguminous plants (see Chapter 23). For several decades, it was believed that N_2 was fixed only by a few special bacteria in the soil or in symbiotic plant bacteria. But in the 1940s, Martin Kamen and colleagues noticed that phototrophs such as *Rhodospirillum rubrum* produced hydrogen gas—a known by-product of nitrogen fixation. Nitrogen fixation was hard to demonstrate reliably in the laboratory because at that time researchers did not know that in *R. rubrum* nitrogen fixation was repressed by the presence of alternative nitrogen sources, such as ammonia. When traces of ammonia and other nitrogen sources were eliminated, Kamen's student Herta Bregoff found that photosynthetic bacteria actually fix nitrogen. The fixation of nitrogen was confirmed by experiments showing uptake of the radioisotope ^{15}N into biomass. In fact, N_2 is fixed by most phototrophic bacteria (green and purple bacteria, as well as cyanobacteria) and by many archaea. Marine cyanobacteria fix a large proportion of both the nitrogen and carbon dioxide assimilated by our biosphere.

By the end of the twentieth century, about half the nitrogen in the biosphere originated from human industry. Worldwide, factories fix enormous quantities of N_2 into ammonia for agricultural fertilizers. Industrial nitrogen fixation uses the **Haber process**, in which nitrogen gas is hydrogenated by methane (natural gas) under extreme heat and pressure. The anthropogenic (human-caused) influx of nitrogen into the biosphere is an astonishing example of the influence of human society on our planet.

The Mechanism of Nitrogen Fixation

In living cells, nitrogen fixation is an enormously energy-intensive process. The mechanism is largely conserved across species:

$$N_2 + 8H^+ + 8e^- + 16ATP \longrightarrow 2NH_3 + H_2 + 16ADP + 16P_i$$

The total energy investment includes approximately three ATP-equivalents per electron (assuming reduction by NADPH), plus sixteen ATP molecules as shown. That makes 24 + 16 = 40ATP in all, more than that provided by complete oxidation of glucose. The production of H_2 is surprising, as it consumes extra ATP. Hydrogen loss results from initiating the cycle of nitrogen reduction (discussed shortly). Some bacteria have secondary reactions to reclaim the lost hydrogen with part of its lost energy.

> **NOTE:** While nitrogen fixation is commonly represented as producing ammonia (NH_3), under most conditions of living cells the predominant form is protonated, ammonium ion (NH_4^+).

Nitrogenase reaction mechanism. The overall conversion of nitrogen gas to two molecules of ammonia is catalyzed in four cycles by **nitrogenase**, an enzyme highly conserved in nearly all nitrogen-fixing species. Like rubisco, nitrogenase probably evolved once in a common ancestor of all nitrogen-fixing organisms.

The mechanism of nitrogenase is of intense interest to agricultural scientists because of the potential benefits of improving efficiency of plant growth and of extending nitrogen-fixing symbionts to nonleguminous plants such as corn. In 1960, scientists at the DuPont Laboratory first isolated the nitrogenase complex from a bacterium, *Clostridium pasteurianum*. They measured its activity by incorporation of radiolabeled nitrogen, $^{15}N_2$, into $^{15}NH_3$. Since then, the detailed structure of nitrogenase has been solved (**Fig. 15.17**).

The active nitrogenase complex includes two kinds of subunits encoded by different genes: Fe protein (shaded green in **Fig. 15.17**), containing a 4Fe-4S center, and FeMo protein (shaded cyan), containing iron and molybdenum. The Fe protein contains a typical 4Fe-4S structure to facilitate electron transfer. As we learned in Chapter 14, metal atoms help to transfer electrons because their orbitals are closely spaced and transitions between these orbitals involve relatively small amounts of energy. The electrons are funneled through a second FeS cluster (the P cluster) to the FeMo (iron-molybdenum) cluster. The FeMo cluster is an unusual structure characteristic of nitrogenase, in which trios of sulfur atoms alternate with trios of iron atoms. One end of the cluster is capped with another iron, and the other end is capped with an atom of molybdenum (Mo). A consequence of the nitrogenase structure is that most nitrogen-fixing organisms (and their plant hosts, for leguminous symbionts) require the element molybdenum for growth. Some bacteria make an alternative nitrogenase that substitutes vanadium for molybdenum.

Four cycles of reduction. Nitrogen fixation requires four reduction cycles through nitrogenase (**Fig. 15.18**).

To initiate the first cycle of N_2 reduction, Fe protein acquires $2e^-$ from an electron transport protein such as a ferredoxin or a flavodoxin (step 1). Energy is provided by spending four molecules of ATP. The reduced Fe protein then transfers each electron to the FeMo center. The FeMo protein binds $2H^+$, which is reduced to H_2 (step 2). Only then does N_2 bind to the active site, by displacing the H_2 (step 3).

In the next reduction cycle, two electrons are transferred to Fe protein, where they reduce the iron. The reduced Fe protein transfers each electron to the FeMo center, near the binding site for N_2. The electron transfer requires expenditure of 2ATP per electron, or 4ATP per $2e^-$. Two hydrogen ions join the N_2 and receive the two electrons, forming HN=NH.

A third pair of electrons enters the Fe protein, which then joins another $2H^+$, reducing N_2 to $H_2N–NH_2$. The cycle again requires hydrolysis of 4ATP. A final cycle of electron transfer and H^+ uptake reduces $H_2N{-}NH_2$ to $2NH_3$. At typical cytoplasmic pH values (near pH 7), NH_3 is protonated to NH_4^+.

The loss of H_2 during nitrogen fixation is puzzling because it represents lost energy in a highly energy-intensive process. The actual fate of the H_2 varies among species. *Klebsiella pneumoniae*, a gram-negative organism in which nitrogen regulation has been much studied, gives off the H_2 without further reaction. On the other hand, *Azotobacter* uses an irreversible hydrogenase enzyme to convert H_2 back to $2H^+$ and recover the transferred electrons. In leguminous rhizobial symbionts such as *Sinorhizobium* species, H_2 recovery varies surprisingly among strains and can affect the efficiency of plant growth.

The process of nitrogen fixation is expensive, both in terms of protein synthesis and in terms of reducing energy and ATP. Even bacteria capable of nitrogen fixation repress the process in the presence of other nitrogen sources, such as nitrate (NO_3^-), nitrite (NO_2^-), ammonia (NH_3), or nitrogenous organic molecules acquired from dead cells.

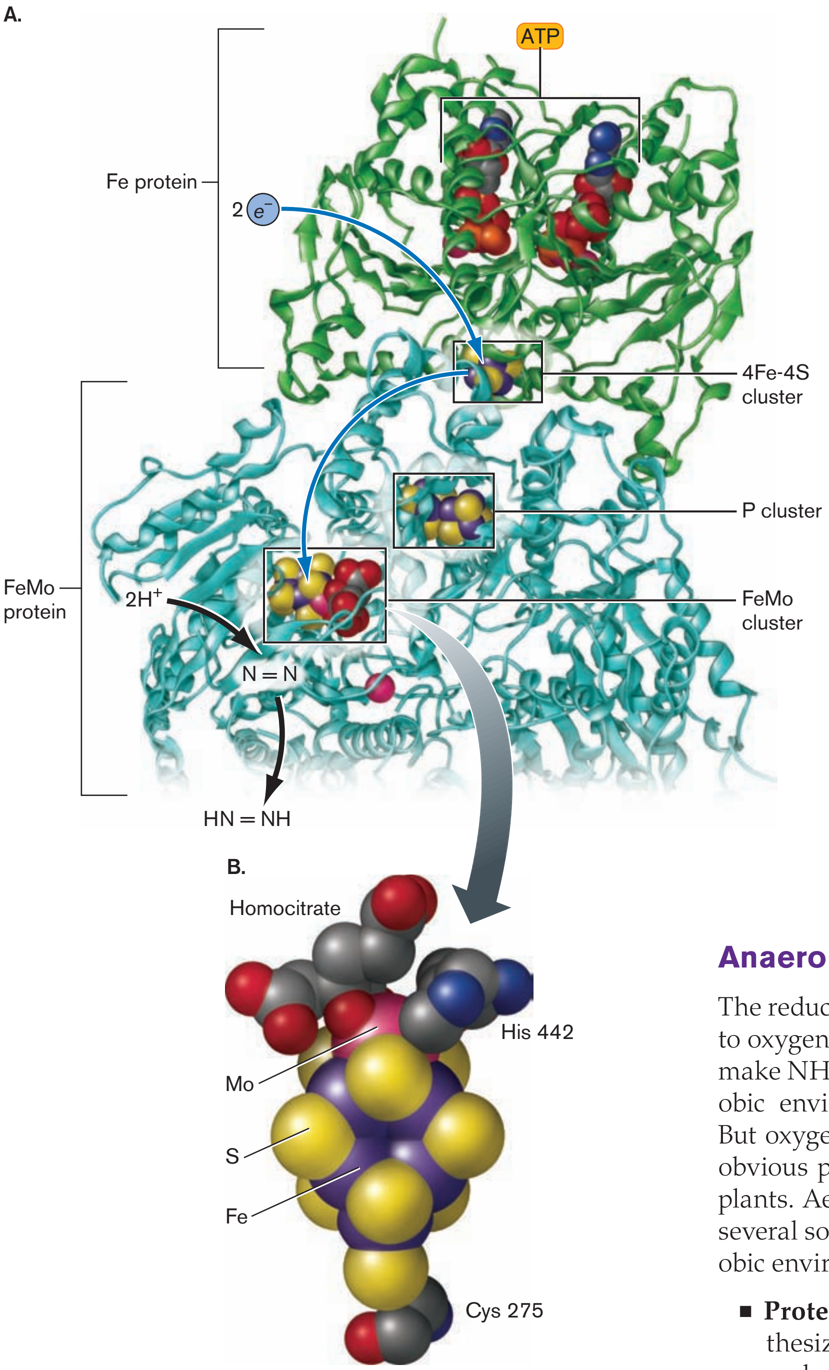

Figure 15.17 Structure of the nitrogenase complex. **A.** In each active site of the Fe-protein-FeMo-protein, the Fe protein binds ATP and receives electrons from the electron donors. The electrons are subsequently channeled down through the 4Fe-4S cluster and the P cluster (FeS cluster) to the FeMo cluster, where they reduce the N_2. (PDB code: 1N2C) **B.** The metal cluster (Fe_7S_9Mo) is held in place by coordination with a molecule of homocitrate plus two amino acid residues of nitrogenase, His 442 and Cys 275.

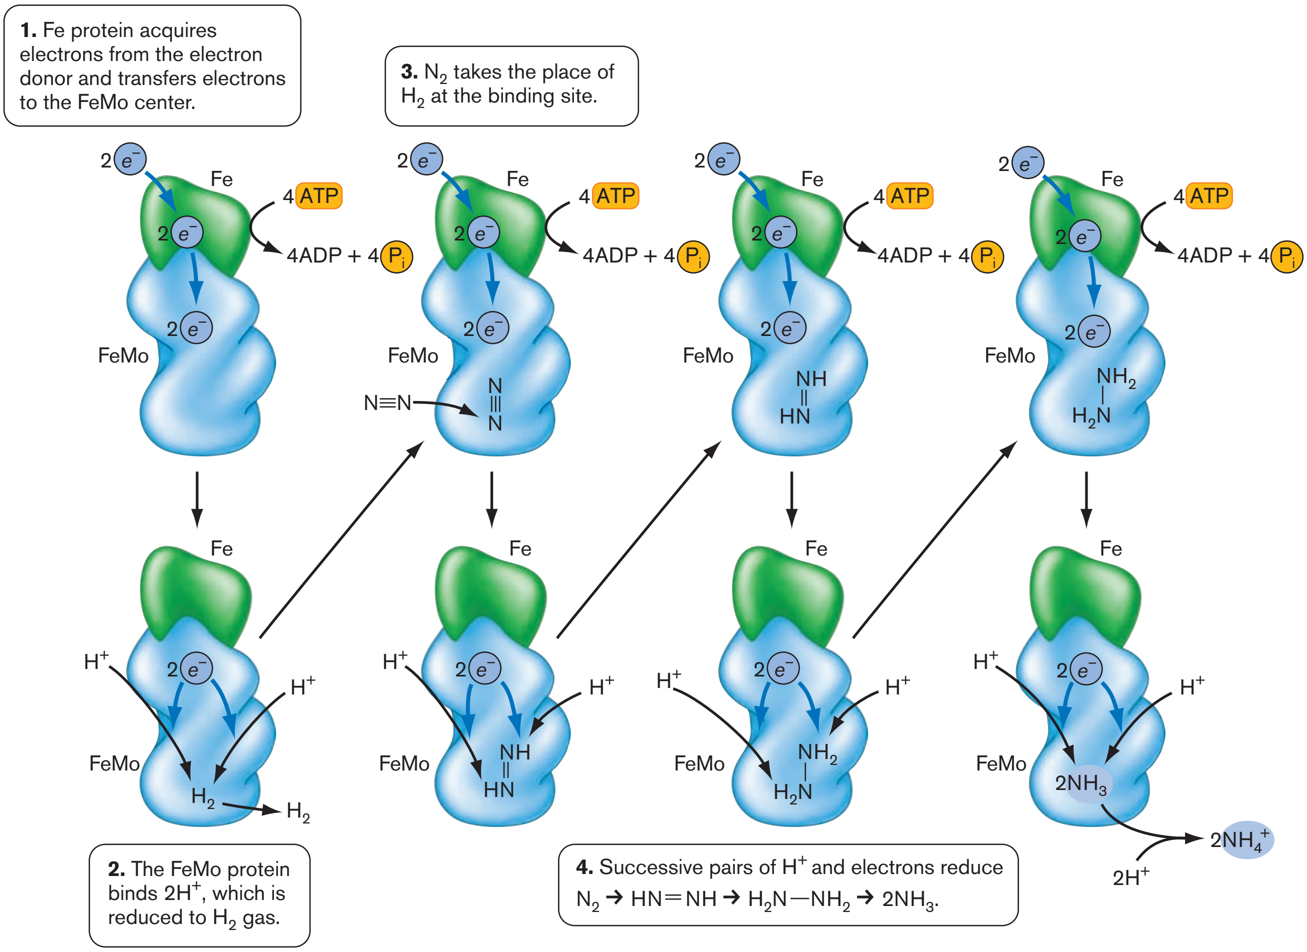
Anaerobiosis and N_2 Fixation

The reductive action of nitrogenase is extremely sensitive to oxygen because of the large reducing power needed to make NH_4^+. Thus, cells can fix nitrogen only in an anaerobic environment. This is no problem for anaerobes. But oxygenic phototrophs such as cyanobacteria face an obvious problem, as do bacterial symbionts of oxygenic plants. Aerobic and oxygenic organisms have developed several solutions to the problem of fixing nitrogen in aerobic environments.

- **Protective proteins.** Aerobic *Azotobacter* species synthesize protective proteins that stabilize nitrogenase and prevent attack by oxygen. For rhizobia, on the other hand, their plant hosts produce leghemoglobin (named for "legume" plants), a form of hemoglobin that sequesters oxygen away from the bacteria.
- **Temporal separation of photosynthesis and N_2 fixation.** Some species of cyanobacteria fix nitrogen only at night, when photosynthesis does not occur and thus no oxygen is made.
- **Specialized cells for N_2 fixation.** Filamentous cyanobacteria form specialized nitrogen-fixing cells called **heterocysts** (**Fig. 15.19**). The heterocysts lose their photosynthetic capacity entirely and specialize in



1. Fe protein acquires electrons from the electron donor and transfers electrons to the FeMo center.

2. The FeMo protein binds $2H^+$, which is reduced to H_2 gas.

3. N_2 takes the place of H_2 at the binding site.

4. Successive pairs of H^+ and electrons reduce $N_2 \rightarrow HN{=}NH \rightarrow H_2N{-}NH_2 \rightarrow 2NH_3$.

Figure 15.18 Nitrogen fixation by nitrogenase. The enzyme nitrogenase successively reduces nitrogen by electron transfer, ATP hydrolysis, and H^+ incorporation. The nitrogenase complex includes two classes of subunits encoded by different genes: Fe protein (shaded green) and MoFe protein (shaded blue).

Figure 15.19 Cyanobacteria form heterocysts to fix nitrogen under anaerobic conditions. A. *Anabaena spiroides*, a filamentous cyanobacterium, segregates N_2 fixation in heterocysts, cells that do not photosynthesize and thus maintain anoxic conditions. **B.** Autofluorescence reveals chlorophyll, which is absent in the heterocyst.

© 1997 Microbial Diversity, Tom Lie and Rolf Schauder nitrogen fixation; their loss of photosynthesis is revealed by the absence of chlorophyll autofluorescence (**Fig. 15.19B**). Heterocyst development is directed by a complex genetic program, induced by nitrogen starvation. In natural environments, the heterocysts leak organic acids that attract heterotrophic bacteria, which use up all the oxygen around the heterocyst, generating ideal anaerobic conditions for nitrogen fixation.

Molecular Regulation of N_2 Fixation by NtrC and Sigma-54

Nitrogen fixation costs substantial energy, and therefore the process is highly regulated. Oxygen and NH_4^+ availability regulate expression of the *nif* genes (*nifHDKTY*) encoding nitrogenase and other nitrogen-fixation proteins. Regulation of *nif* is mediated by several molecular regulators, including a nitrogen starvation sigma factor (sigma N) and the NtrB-NtrC two-component signal transduction system (discussed in Chapter 10). The NtrB-NtrC system has been dissected in *Klebisiella pneumoniae* by Sydney Kustu and colleagues at the University of California, Berkeley (**Fig. 15.20**).

The NtrC protein regulates nitrogenase expression in response to NH_4^+ concentration (**Fig. 15.20B**). When cellular levels of NH_4^+ are high, no activators bind the *nifHDKTY* promoter, and the nitrogen fixation genes are not expressed. When NH_4^+ is low, however, NtrC is phosphorylated by NtrB. The NtrC-P phosphoprotein now binds its DNA site to activate expression of *nifLA*, making NifL and NifA proteins. Expression of *nifLA* is coactivated by the sigma 54. Sigma 54 and the NifA protein together activate expression of *nifHDKTY*. Thus, low NH_4^+ concentration turns on nitrogen fixation.

Nitrogen fixation cannot occur with oxygen, so high oxygen levels block nitrogenase expression. When oxygen is high, NifA binds NifL and is prevented from binding the nitrogenase promoter. Low oxygen allows NifA to bind the promoter and express nitrogenase to fix nitrogen. Overall, NtrC governs response to NH_4^+, whereas NifA governs response to oxygen. Response to multiple environmental signals is typical of energy-expensive biosynthetic pathways.

TO SUMMARIZE:

- **Oxidized or reduced forms of nitrogen**, such as nitrate, nitrite, and ammonium ions, can be assimilated by bacteria and plants. Assimilation competes with dissimilatory reactions that obtain energy.

Figure 15.20 Regulation of nitrogen fixation. **A.** Sydney Kustu has made important discoveries about NtrC and other forms of nitrogen regulation in the gram-negative soil bacterium *Klebsiella pneumoniae*. **B.** When cellular levels of NH_4^+ are low, NtrC is phosphorylated and activates expression of *nifLA*. Expression is coactivated by the nitrogen starvation sigma factor, sigma 54. The NifA protein (and sigma 54) activate expression of *nif* genes encoding nitrogenase. When oxygen levels are high, however, nitrogen fixation cannot occur, so NifA is blocked by binding NifL. (Numbers refer to positions upstream of the translation site.)

- **Nitrogen gas (N_2) is fixed into ammonium ion** only by some species of bacteria and archaea, never by eukaryotes.
- **Nitrogenase enzyme** includes a protein containing an iron-sulfur core (Fe protein) and a protein containing a complex of molybdenum, iron, and sulfur (FeMo protein). Electrons acquired by Fe protein (with energy from ATP) are transferred to FeMo protein to reduce nitrogen.
- **Four cycles of reduction by NADPH** or an equivalent reductant are required to reduce one molecule of N_2 to two molecules of NH_3. At neutral pH, NH_3 is protonated to NH_4^+.
- **Oxygen inhibits nitrogen fixation**. Bacteria and plants have various means of separating nitrogen fixation from aerobic respiration, such as heterocyst development or temporal separation.
- **Regulation of nitrogen fixation** by nitrogen and oxygen levels occurs via NtrC and sigma 54 regulation of transcription.

15.6 Biosynthesis of Amino Acids and Nitrogenous Bases

Microbes need amino acids to make proteins and cell walls, as well as nitrogenous bases to form nucleic acids. When possible, they obtain these molecules from their environment through membrane-bound transporters. But competition for such valuable nutrients is high, especially for free-living microbes in soil or water. Most free-living microbes and plants possess the ability to make all the standard amino acids and bases of the genetic code, as well as nonstandard variants used for cell walls and transfer RNAs. Microbial biosynthesis of amino acids "essential" for animals is used for industrial production of food supplements.

Diversity and Complexity in Amino Acid Synthesis

Like fatty acid biosynthesis, synthesis of amino acids and nitrogenous bases requires the input of large amounts of reducing energy. These compounds pose additional challenges because of their unique and diversified forms, which cannot be made by the cyclic processes that generate molecules from repeating units. Synthesis of complex, asymmetrical molecules such as amino acids requires many different conversions, each mediated by a different enzyme. Nevertheless, some economy is gained by arrangement of branched pathways in which early intermediates are utilized to form several products (**Fig. 15.21**). For example, oxaloacetate is converted to aspartate, which can be converted to five other amino acids.

Figure 15.21 **Major pathways of amino acid biosynthesis.** Some amino acids arise from key metabolic intermediates (highlighted), whereas others must be synthesized out of other amino acids. Note alternative pathways (see Figure 15.2).

Amino Acids Arise from Metabolic Intermediates

The carbon skeletons of amino acids arise from diverse intermediates of metabolism (see **Fig. 15.21**). Note that certain amino acids arise directly from key metabolic intermediates (for example, glutamate from 2-oxoglutarate), whereas others must be synthesized from preformed

Rodney Start/Museum Victoria, Melbourne Museum

Figure 15.22 The Murchison meteorite. Fragments of a meteorite that fell in Murchison, Australia, in 1969 were shown to contain the five fundamental amino acids of biosynthetic pathways (glutamate, aspartate, valine, alanine, and glycine).

amino acids (for example, glutamine, proline, and arginine from glutamate). Some amino acids can arise from more than one source; for example, leucine and isoleucine can be made from succinate as well as from pyruvate.

It has been hypothesized that the amino acids that arise in just one or two steps from central intermediates are more ancient in cell evolution than those requiring more complex pathways. Five of these "ancient" amino acids—glutamate, aspartate, valine, alanine, and glycine—are the same as those detected in meteorites, whose composition resembles that of prebiotic Earth (**Fig. 15.22**). These same five amino acids also appear in early-Earth simulation experiments in which methane, ammonia, and water are heated under reducing conditions and subjected to electrical discharge. Thus, we speculate that the first amino acids that early cells evolved to make were the same as those that arose spontaneously in the prebiotic chemistry of our planet.

As in fatty acid biosynthesis, precursor molecules are channeled into amino acid biosynthesis by specialized cofactors and reducing energy carriers such as NADPH. Unlike fatty acids, however, amino acids must assimilate another key ingredient: nitrogen.

Amino Acids Form through Assimilation of NH_4^+

The NH_4^+ produced by N_2 fixation or by nitrate reduction is the key source of nitrogen for biosynthesis. But NH_4^+ always exists in equilibrium with NH_3, which is toxic to cells. Moreover, NH_3 travels freely through membranes, making it difficult to store NH_4^+ within a cell. Deprotonation to NH_3 increases as pH rises; by pH 9.2, deprotonation reaches 50%. Even at neutral pH, a very small equilibrium concentration of NH_3 can drain NH_4^+ out of the cell. Thus, cells avoid storing high levels of NH_4^+; instead, it is incorporated immediately into organic products.

2-oxoglutarate and glutamate condense with NH_4^+. In most bacteria, the main route for NH_4^+ assimilation is by condensing NH_4^+ with 2-oxoglutarate to form glutamate, or with glutamate to form glutamine (**Fig. 15.23**). Three key enzymes interconvert these substrates:

- **Glutamate dehydrogenase (GDH)**, actually named for its reverse activity, condenses NH_4^+ with 2-oxoglutarate to form glutamate. The condensation requires reduction by NADPH.
- **Glutamine synthetase (GS)** condenses a second NH_4^+ with glutamate to form glutamine, a process driven by spending one ATP.
- **Glutamate synthase (GOGAT, glutamine: 2-oxoglutarate amidotransferase)** converts 2-oxoglutarate plus glutamine into two molecules of glutamate. Different variants of this enzyme use different reducing agents: NADPH, NADH, or ferredoxin. The NADPH variant is shown.

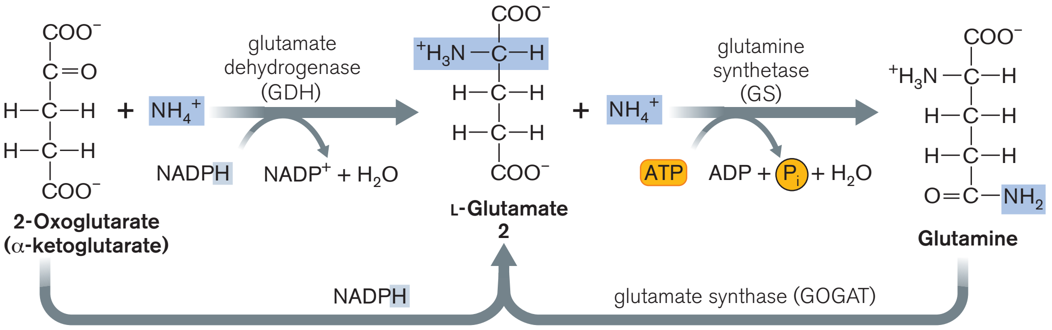

Figure 15.23 Assimilation of NH_4^+ into glutamate and glutamine. The key TCA cycle intermediate 2-oxoglutarate (alpha-ketoglutarate) incorporates one molecule of NH_4^+ at the ketone to form glutamate. Glutamine can combine with oxoglutarate to produce two molecules of glutamate. These reactions provide sources of nitrogen to feed other pathways of amino acid synthesis.

All three substrates thus exchange amino groups readily. High nitrogen levels induce GDH to take up NH_4^+, but repress GS and GOGAT. GS has a higher affinity than GDH for NH_4^+. Low nitrogen levels induce GS (to make glutamine) and GOGAT (to convert some glutamine to glutamate as needed).

Both glutamate and glutamine contribute an amine, as well as their carbon skeletons, to the synthesis of other amino acids in the biosynthetic "tree." The transfer of ammonia between two metabolites such as glutamate and glutamine is called **transamination**. Transamination also occurs between many other pairs of amino acids and metabolic intermediates. For example, glutamate transfers NH_3 to oxaloacetate, making aspartate and 2-oxoglutarate; the reaction can also be reversed. In another example, valine transfers an amine group to pyruvate, generating alanine and 2-ketoisovalerate.

THOUGHT QUESTION 15.6 Suggest two reasons why transamination is advantageous to cells.

The cellular levels of glutamate and glutamine act as indicators of nitrogen availability. When mineral forms such as NH_4^+ and nitrate are absent, some microbes seek organic sources of nitrogen in their environment. During nitrogen starvation, NtrC is phosphorylated and induces expression of glutamine synthetase as well as nitrogenase. NtrC phosphate also induces a high-affinity ammonia transporter and transporters for organic sources of nitrogen, such as amino acids, oligopeptides, and cell wall fragments containing amino sugars. All these molecules can be "scavenged" to obtain nitrogen for biosynthesis.

Building Complex Amino Acids Requires Numerous Enzymes

Seven "fundamental" amino acids show relatively simple biosynthetic pathways. Others require longer pathways involving numerous enzymes. An amino acid produced by a complex pathway is arginine (**Fig. 15.24**). Bacterial arginine biosynthesis generally involves about a dozen different enzymes distributed among four to eight operons. Operon expression is regulated by an arginine repressor that binds the promoter of each operon to prevent transcription in the presence of sufficient arginine for cell needs. In some species, the arginine repressor also activates enzymes of arginine catabolism, making the excess amino acid available as a carbon source.

THOUGHT QUESTION 15.7 Which energy carriers (and how many) are needed to make arginine from 2-oxoglutarate? (See Fig. 15.24.)

Arginine biosynthesis. Arginine synthesis begins with the condensation of glutamate with acetyl-CoA (**Fig. 15.24**, step 1). Three more amine groups are transferred subsequently by glutamine and aspartate. A second glutamate transfers an amino group to the arginine precursor (step 2) while its own carbon skeleton cycles back as 2-oxoglutarate (alpha-ketoglutarate). This transfer of NH_4^+ between two organic intermediates is an example of transamination. The original acetyl group from acetyl-CoA is then hydrolyzed, producing ornithine. Ornithine is a central intermediate, used by cells to synthesize proline and various polyamines, as well as arginine.

Ornithine receives a third amino group (step 3) from glutamine via conversion of CO_2 to carbamoyl phosphate $[H_2N\text{-}CO(PO_4)^-]$:

$$CO_2 + H_2O \longrightarrow H^+ + HCO_3^-$$

$$HCO_3^- + ATP + \text{glutamine} \longrightarrow H_2N\text{-}CO(PO_4)^{2-} + ADP + \text{glutamate}$$

Carbamoyl phosphate provides a way to assimilate one nitrogen plus one carbon into a structure.

The fourth nitrogen is acquired from aspartate in a two-step process requiring ATP release of pyrophosphate (PPi) (step 4). The release of fumarate, a TCA cycle intermediate, yields arginine.

Aromatic amino acids. The complexity of aromatic amino acids requires particularly energy-expensive biosynthesis. The number of different enzymes required, however, is minimized by the presence of a common core pathway branching to several different amino acids (**Fig. 15.25**).

The three aromatic amino acids, phenylalanine, tyrosine, and tryptophan, each require a common precursor, chorismate. The pathway to chorismate starts with simple glycolytic intermediates (phosphoenolpyruvate and erythrose 4-phosphate), but its synthesis requires 10 enzymes encoded in a single operon, *aroABCDEFGHKL*. From chorismate to phenylalanine or tyrosine requires an additional three enzymatic steps. From chorismate to tryptophan, the most complex amino acid specified by the genetic code, requires another 5 enzymes, expressed by *trpABCDE*. Thus, a total of at least 15 enzymes encoded by different genes are required to make tryptophan out of simple substrates.

Not surprisingly, the presence of tryptophan in the cell effectively represses expression of its own biosynthetic enzymes. Repression of the *trp* operon includes two mechanisms: the Trp repressor, effective over moderate to high levels of tryptophan; and an RNA loop mechanism called attenuation, sensitive to lower levels of tryptophan (discussed in Chapter 10). Attenuation involves the destabilization of the transcription complex by formation of a specific stem loop on the nascent *trp* mRNA. The mechanism of attenuation in *E. coli* was discovered in 1981 by Charles Yanofsky, winner of the National Medal of Science. Several other amino acids commonly show

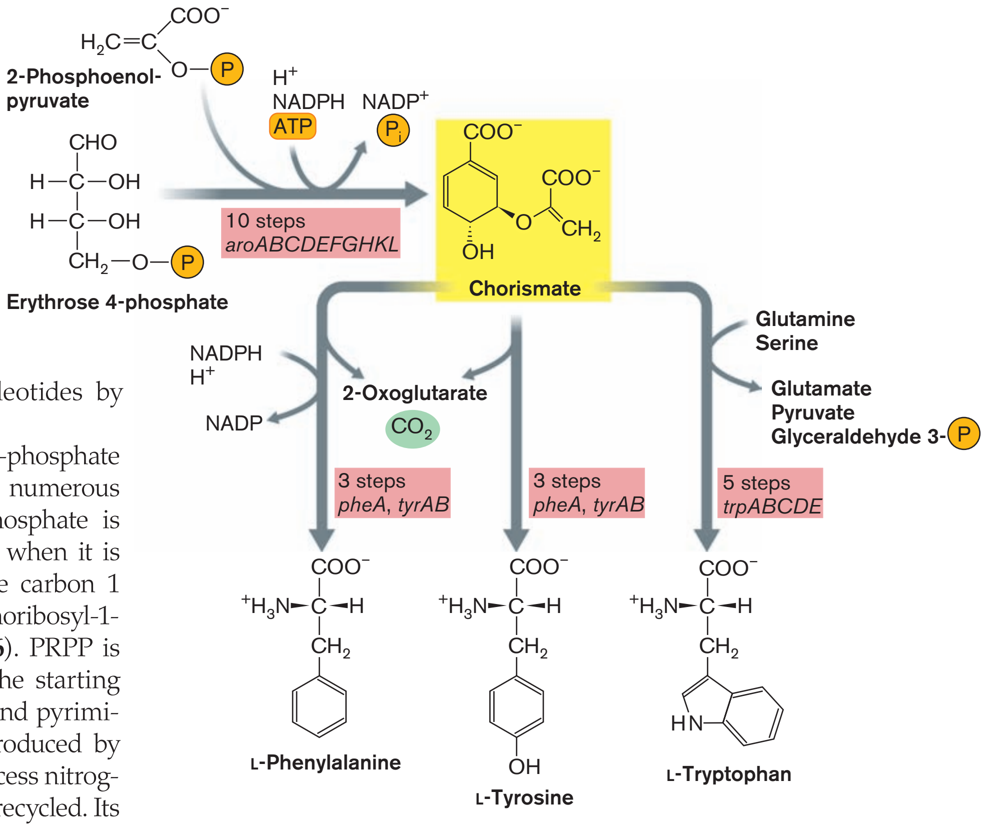
Purine and Pyrimidine Synthesis Requires Multiple Enzyme Pathways

Nitrogenous bases include purines and pyrimidines, the essential coding components of DNA and RNA. The accuracy of the entire genetic code requires accurate synthesis of these bases. Besides their role in nucleic acids, purine and pyrimidine nucleotides such as ATP serve as energy carriers.

Bases are built onto ribose 5-phosphate. The purine and pyrimidine bases are not built as isolated units; rather they are constructed on a ribose 5-phosphate substrate, forming a nucleotide (sugar-base-phosphate). Note that ribonucleotides are synthesized first and that these are

Figure 15.25 Biosynthesis of aromatic amino acids. Aromatic amino acids are assembled out of various carbon skeletons. In *E. coli*, the pathways to chorismate and tryptophan are encoded by operons of contiguous genes, *aro* and *trp*.



then converted to deoxyribonucleotides by enzymatic removal of the 2′ OH.

As we have seen, ribose 5-phosphate and related sugars participate in numerous metabolic pathways. Ribose 5-phosphate is directed into nucleotide synthesis when it is tagged with pyrophosphate at the carbon 1 (C-1) position, forming 5-phosphoribosyl-1-pyrophosphate (PRPP) (**Fig. 15.26**). PRPP is a major metabolic intermediate, the starting point for the synthesis of purine and pyrimidine nucleotides. PRPP is also produced by "scavenger" pathways, in which excess nitrogenous bases are broken down and recycled. Its synthesis is regulated by feedback inhibition to avoid overproduction of purines. In humans, overproduction of PRPP leads to gout, a condition in which the purine breakdown product uric acid precipitates in the joints, causing painful swelling of wrists and feet.

Purine synthesis. The hydrolysis of PRPP releases pyrophosphate, thus spending two high-energy phosphate bonds. This irreversible reaction drives forward the subsequent reactions to make purine. To construct the purine, the pyrophosphate at carbon 1 (C-1) is replaced by an amine from glutamine. The purine is built up by addition of a series of single-carbon groups (formyl, methyl, and CO_2) alternating with nitrogens from glutamine and carbamoyl phosphate. The number of single-carbon assimilations, including assimilation of CO_2, is striking. It may reflect the ancient origin of the purine synthetic pathway, which evolved in CO_2-fixing autotrophs.

The first purine constructed is inosine monophosphate, the "wobble" purine found at the third position of transfer RNAs. Inosine monophosphate is subsequently converted to adenine monophosphate or guanine monophosphate.

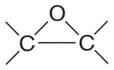
Pyrimidine synthesis. The pyrimidine is built by a slightly different route. Instead of building up the base on the ribose, the six-membered pyrimidine ring forms separately from aspartate plus carbamoyl phosphate. The pyrimidine ring then displaces the pyrophosphate of PRPP, attaching by a nitrogen to the ribosyl carbon 1. The first pyrimidine built is uracil, which can be converted to cytosine or thymine.

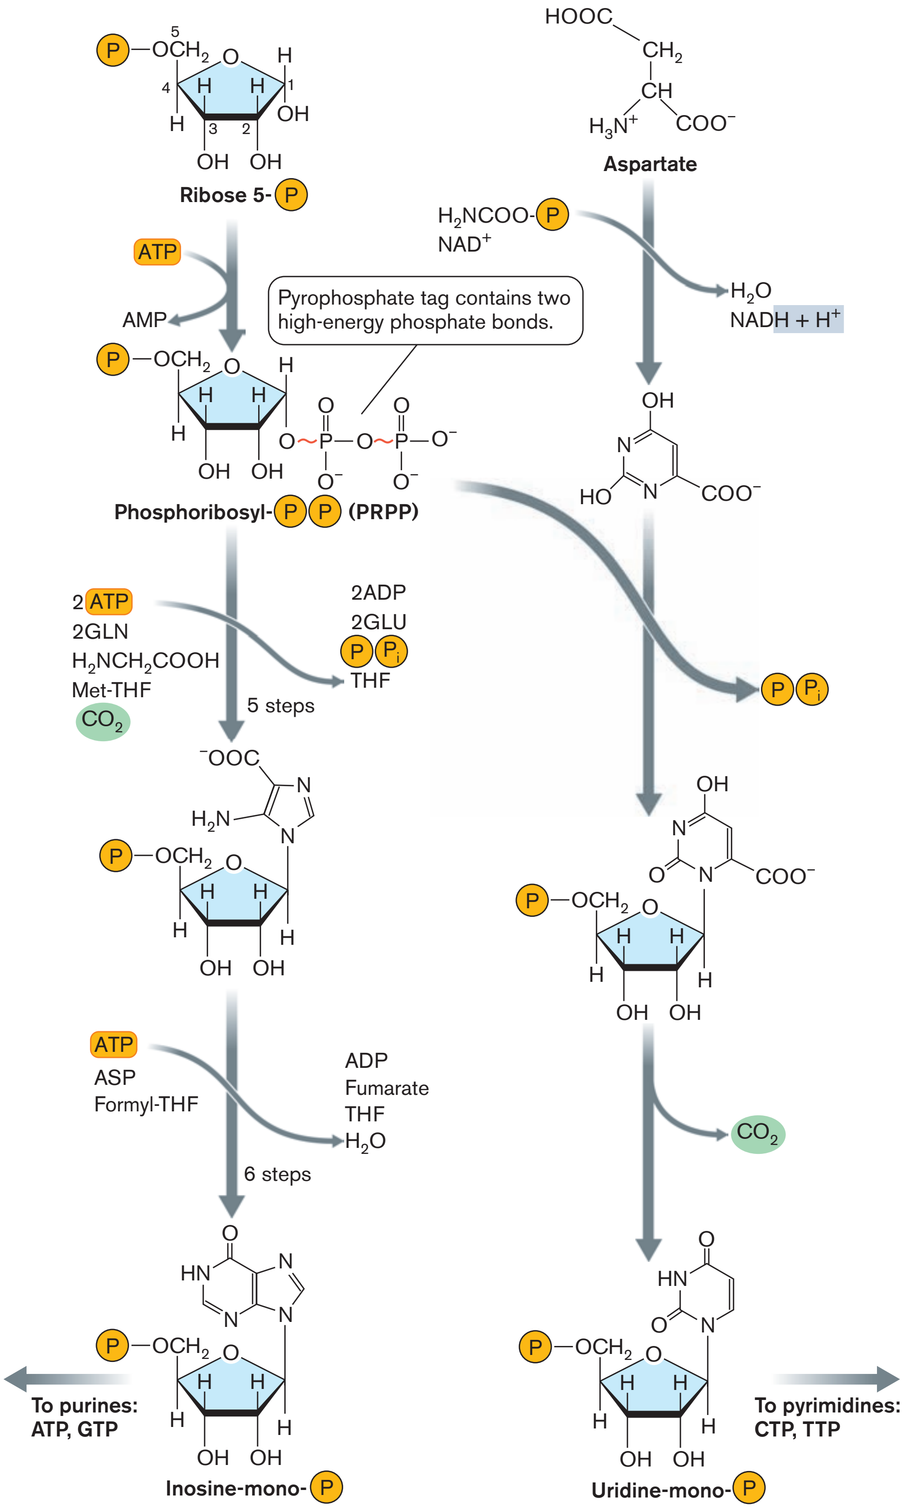
THOUGHT QUESTION 15.8 Why are purines and pyrimidines not synthesized separately from the sugar phosphate?

THOUGHT QUESTION 15.9 Why are the ribosyl nucleotides synthesized first, then converted to deoxyribonucleotides as necessary? What does this suggest about the evolution of nucleic acids?

Nonribosomal Peptide Antibiotics

In addition to the standard amino acids used by ribosomes, there exist hundreds of different amino acids used by cells for functions such as the cross-bridges of peptidoglycan (discussed in Chapter 3). Some of these are made by one-step modification of standard amino acids, such as epimerization (altering the chirality from L to D) or halogenation with chlorine or fluorine. Others have complex carbon skeletons, including unsaturated bonds and epoxides (three-membered rings):





Pyrophosphate tag contains two high-energy phosphate bonds.

Figure 15.26 Biosynthesis of purines and pyrimidines. Both purines and pyrimidines are built onto ribose 5-phosphate. Ribose 5-phosphate is directed into purine and pyrimidine biosynthesis by the activating step of ATP ⟶ AMP, converting the sugar to phosphoribosyl-PP (PRPP). The purine ring is built up out of successive additions of amines, one-carbon units, plus a formyl group from formyl tetrahydrofolate (formyl-THF). The purine ring is modified to yield the corresponding adenine and guanine compounds. Likewise, the pyrimidine ring is modified to cytidine triphosphate or thymidine triphosphate.

Both standard and nonstandard amino acids are used by actinomycetes to build secondary metabolites with antimicrobial activity. These secondary metabolites are called **nonribosomal peptide antibiotics** because their peptide backbone is constructed by an enzyme without ribosomes. Nonribosomal peptide antibiotics are synthesized by modular "assembly-line" enzymes, analogous to those that build polyketides. (See **Special Topic 15.3**, on the biosynthesis of vancomycin.)

TO SUMMARIZE:

- **Amino acid biosynthesis** requires a large number of different enzymes to catalyze many unique conversions. Structurally related amino acids branch from a common early pathway.
- **Metabolic intermediates** from glycolysis and the TCA cycle initiate amino acid biosynthetic pathways.
- **Ammonium ion is assimilated by TCA intermediates**, such as oxaloacetate into glutamate. Glutamate assimilates ammonium ion to form glutamine. Transamination is the donation of NH_4^+ from one amino acid to another, such as glutamine transferring ammonia to oxaloacetate to make aspartate.
- **Arginine biosynthesis** requires multiple steps of NH_3 transfer and carbon skeleton condensation.
- **Aromatic amino acids** are built from a common pathway that branches out. Their biosynthesis is regulated tightly at both transcriptional and translational levels.
- **Purines are built as nucleotides** attached to a ribose phosphate. Several single-carbon groups are assimilated, including CO_2, a phenomenon suggesting an ancient pathway. Pyrimidines are made from aspartate, then added onto PRPP.
- **Nonribosomal peptide antibiotics** are built by modular enzymes analogous to those that build polyketides.

Figure 15.27 Tetrapyrroles. Tetrapyrrole derivatives include hemes, chlorophylls, and coenzyme B_{12}. Different variations of the ring enable coordination to different metal atoms.

15.7 Biosynthesis of Tetrapyrroles

The **tetrapyrrole** family includes some of the best-known and essential cofactors of energy transduction and biosynthesis, such as chlorophylls, hemes of cytochromes and hemoglobin, and coenzyme B_{12} (**Fig. 15.27**). The versatility of the tetrapyrrole for redox reactions comes from its multiple conjugated double bonds, with many narrowly spaced energy transitions. The size of these transitions and the wavelength of light absorption are altered incrementally by reduction or oxidation at specific positions or by addition of particular substituents around the ring. For example, the modified ring structure of chlorophyll *a* enables the molecule to absorb red and blue light for photosynthesis. Small differences in ring structure enable different tetrapyrroles to coordinate to different metal atoms, such as iron, magnesium, or cobalt.

Of all the essential primary products that cells need to make, the tetrapyrroles are among the most complicated and require the greatest number of distinct enzymatic steps. The tetrapyrrole system consists of four five-membered rings, each including an atom of nitrogen. Its double bonds are highly conjugated around the system. The nitrogens are directed inward, where their electron pairs are well positioned to complex a metal ion.

Biosynthesis of the Tetrapyrrole Ring System

Tetrapyrroles arise from condensation of four **pyrrole** rings. The five-membered pyrrole ring has three substituent groups, one of which ($-CH_2NH_2$) serves as a linker in condensation of the tetrapyrrole. The individual pyrrole rings are generated by one of two different pathways (**Fig. 15.28**), found in different organisms: the glutamate pathway, in most bacteria as well as in plants; and the glycine-succinate pathway, in purple bacteria, animals, and fungi. The glutamate pathway is unusual in that it starts from a glutamine residue attached to a transfer RNA, generally used in protein synthesis. In either case, condensation and rearrangement generates the linear molecule 5-aminolevulinic acid (ALA). Two molecules of ALA cyclize to form the ring of porphobilinogen.

Once the pyrroles are formed, an enzyme condenses four of them in a chain, removing each amine as NH_4^+. The four linked pyrroles are conventionally labeled A through D. When the chain cyclizes, an unusual isomerization occurs in which the D pyrrole is inverted. The mechanism of the D-ring isomerization is unknown, but it imparts a critical asymmetry to the molecule as a whole. This first cyclized tetrapyrrole is called uroporphyrinogen III.

Uroporphyrinogen III forms the foundation of most biologically active tetrapyrroles. By inspection of functional tetrapyrroles, we can see the subtle modifications that distinguish them (see **Fig. 15.27**). Chlorophyll and coenzyme B_{12} (the active form of vitamin B_{12}, in which adenosine replaces cyanide) each have an extra-long side chain at the D ring, leading to completely different functional groups. The ring systems of both heme and chlorophyll are more unsaturated than the original ring system found in uroporphyrinogen III; the extra conjugated double bonds facilitate energy transitions in these electron carriers. The cobalamin core of coenzyme B_{12} has a more hydrogenated D ring and one less carbon (a carbon is lost in the connection between rings A and D).

The synthesis of tetrapyrroles is highly regulated by nutritional needs. For example, purple photoheterotrophs such as *Rhodospirillum rubrum*, switch off synthesis of bacteriochlorophylls and other photopigments in the presence of oxygen, preferring aerobic respiration to phototrophy. Thus, when exposed to oxygen, the bacteria change color from purple-red to white.

Figure 15.28 **Biosynthesis of tetrapyrroles.** The fundamental tetrapyrrole ring arises from simple TCA intermediates and amino acids. Two amino acids condense to form 5-aminolevulinic acid (ALA), which cyclizes to form porphobilinogen, a pyrrole ring with three substituents—two ending in COOH, one in NH_2. Four of the pyrroles link together, then cyclize to form the corrin ring system. The final step of cyclization includes reversal of the D-ring linkage to yield uroporphyrinogen III, which enters various pathways to form different products.

Riboswitch Regulation

Biosynthesis of tetrapyrroles is enormously energy intensive and subject to sensitive means of regulation. An interesting form of regulation is the **riboswitch** mechanism of regulating the biosynthesis of coenzyme B_{12}. A riboswitch is an RNA sequence capable of forming an elaborate stem loop structure at the sequence upstream of a biosynthetic operon (**Fig. 15.29A**). The stem loop structure is stabilized by the operon's product, in this case coenzyme B_{12}. Riboswitch regulation occurs for several ancient cofactors, including riboflavin, thiamin, and S-adenosylmethionine. It is unusual in requiring no protein repressor. The riboswitch suggests a way of regulating gene expression in the earliest cells of the proposed "RNA world," cells that lacked DNA as well as protein. (The RNA world theory of the origin of life is discussed in Chapter 17.)

Riboswitches can act either to block translation or to prematurely terminate transcription. **Figure 15.29B** shows one example: translational repression of the cobalamin operon by coenzyme B_{12}. When coenzyme B_{12} levels are high, the riboswitch stem loop structure allows formation of a neighboring stem loop, called the sequestrator. The sequestrator contains the translational start site, consisting of the Shine-Dalgarno sequence plus AUG (discussed in Chapter 8). In effect, the start site is "sequestered" by hybridization within the stem loop. When B_{12} is scarce, however, it dissociates from the riboswitch. The riboswitch stem loops come apart, exposing new sequences for potential hybridization. The exposed sequences form a new stem loop, longer and more stable than that of the sequestrator. The Shine-Dalgarno and AUG sequences are now exposed to bind the ribosome and initiate translation of biosynthetic enzymes for cobalamin.

Figure 15.29 The B_{12} riboswitch. **A.** A riboswitch upstream of the cobalamin operon. Formation of the riboswitch stem loops requires coenzyme B_{12}. **B.** The B_{12} riboswitch allows formation of the sequestrator stem loop, which sequesters the translation start site, preventing translation of cobalamin biosynthesis genes. In the absence of coenzyme B_{12}, the antisequestrator stem loops form instead of the sequestrator, permitting the ribosome to bind and translate genes.

Special Topic 15.3 Modular Biosynthesis of Vancomycin

A major nonribosomal peptide antibiotic is vancomycin, the drug of last resort for life-threatening *Clostridium difficile* and for "flesh-eating" methicillin-resistant staphylococcal infections (MRSA) (**Fig. 1**). Vancomycin has a peptide backbone (shaded) equivalent to that of ribosomal peptide, but its aminoacyl residues are nonstandard and show atypical secondary connections.

Vancomycin is produced by *Streptomyces orientalis*, an actinomycete isolated from the soil of India and Indonesia. Like polyketides, polypeptide antibiotics are synthesized by a modular enzyme complex. The vancomycin peptide backbone is built by a nonribosomal peptide synthetase (NRPS) containing seven repeating modules. Each module includes the following key domains (**Fig. 2**):

- **Domain A: Adenylation and transfer.** The A domain catalyzes adenylation (addition of adenosine monophosphate, AMP) to the carboxylate of the amino acid. The adenylation reaction is driven by ATP releasing pyrophospate (PP_i). Next, release of AMP drives transfer of the aminoacyl group onto a sulfur atom of polypeptide carrier protein (S-PCP). Each S-PCP recognizes only one specific aminoacyl group.

In subsequent rounds, the nascent peptide is transferred onto the next amino acid. *Source:* Christopher Walsh. 2003. *Antibiotics: Actions, Origins, Resistance.* ASM Press.

- **Domain C: Condensation and elongation.** The C domain catalyzes transfer of the peptidyl-S-PCP from one module onto the amine of the next aminoacyl-S-PCP. In each subsequent round, the nascent peptide is transferred onto the amino group of the next aminoacyl PCP. As each peptide travels down all seven modules, it accretes seven aminoacyl groups in all.
- **Domain E: Epimerization.** Some (not all) modules include an E domain to epimerize the aminoacyl group (change its configuration from L to D).

The vancomycin NRPS comprises three multidomain proteins (CepA, B, C), each providing one to three modules for chain extension (**Fig. 3**). The seven aminoacyl groups include leucine, asparagine, three tyrosines, and two hydroxyphenylglycines; hydroxyphenylglycine is a nonstandard derivative of glycine. Once the seven-member peptide is formed, additional enzymes (not shown) catalyze chlorination, cross-linking of hydroxyls, and sugar transfer to complete the structure shown in **Figure 1**. In all, vancomycin biosynthesis requires about 30 different genes, as predicted by bioinformatic analysis of the vancomycin gene cluster.

TO SUMMARIZE:

- **Tetrapyrroles** are conjugated ring systems made up of pyrroles, each five-membered ring including one nitrogen positioned to coordinate a central metal ion. Tetrapyrrole derivatives include chlorophylls, hemes, hemoglobin, and cyanocobalamin.
- **The glutamate pathway or the glycine-succinate pathway** condenses eight molecules of 5-aminolevulinic acid into four linked pyrroles. The linked pyrroles are cyclized to uroporphyrinogen III, the foundation of most biologically active tetrapyrrole derivatives.
- **Riboswitch regulation** limits the synthesis of the tetrapyrrole derivative cobalamin (vitamin B_{12} precursor). A riboswitch is an regulatory RNA sequence (upstream of the operon) that forms a stem loop structure stabilized by the operon's product. A riboswitch limits transcription or translation of genes encoding biosynthetic enzymes.

Concluding Thoughts

In living cells, no enzymatic pathway occurs in isolation. All pathways of energy acquisition and biosynthesis occur together, sharing common substrates and products. For example, acetyl-CoA is produced by glycolysis or by fatty acid degradation; it is then utilized by pathways that synthesize fatty acids, amino acids, bases, and tetrapyrroles. Tetrapyrrole biosynthesis requires products of the TCA cycle. At the same time, the TCA cycle is needed to provide energy through catabolism. The microbial cell regulates these competing needs on an extremely rapid timescale; within seconds of the disappearance or appearance of a nutrient, such as an amino acid, its biosynthesis is turned on or shut off.

A given microbe needs to build as much biomass as it can by the most efficient means available. For a pathogen growing within a host, this means utilizing preformed host compounds for rapid growth and replication. On the other hand, free-living microbes face intense competition for organic nutrients; they need to fix essential elements into readily accessible forms. Many soil and marine microbes build the most complicated biological molecules out of single-carbon and single-nitrogen sources, although they scavenge preformed organic substrates when available.

Microbial metabolism has many applications in food preparation and preservation, and in industrial production of antibiotics and other pharmaceuticals. The principles of food and industrial microbiology are discussed in Chapter 16. Later, in Chapters 21 and 22, we see how microbial metabolism within populations and communities contributes to global cycles of Earth's biosphere.

CHAPTER REVIEW

Review Questions

1. What are the sources of substrates for biosynthesis? From what kind of pathways do they arise?
2. How do microbial species economize by synthesizing only the products they need? Cite long-term as well as short-term mechanisms.
3. Compare and contrast the different cycles of carbon dioxide fixation. What classes of organisms conduct each type?
4. How was carbon isotope labeling used to identify intermediates of the Calvin cycle?
5. How is ribulose 1,5-bisphosphate consumed and re-formed through the Calvin cycle? What key products emerge to form sugars and amino acids?
6. How do oxygenic phototrophs maintain CO_2 at sufficient levels to conduct the Calvin cycle?
7. Explain the cyclic process of chain extension in fatty acid biosynthesis. Explain the generation of occasional unsaturated "kinks" in the chain.
8. Explain the different kinds of regulation of fatty acid biosynthesis.
9. What are the different environmental sources of nitrogen? Explain how and why microbes use these different sources.
10. Explain the process of nitrogenase converting N_2 to $2NH_4^+$. Why is H_2 produced?
11. Explain the different ways that microbes maintain anaerobic conditions for nitrogenase.
12. Explain the molecular basis of regulation of nitrogen fixation and nitrogen scavenging.
13. Compare and contrast the general scheme of biosynthesis of amino acids with that of fatty acids.
14. Outline the interconversions of 2-oxoglutarate, glutamate, and glutamine that provide nitrogen for amino acid biosynthesis.
15. Compare and contrast the processes of purine and pyrimidine biosynthesis. What is the role of the sugar ribose in each case?
16. How does the biosynthesis of tetrapyrroles generate diverse products from common small organic substrates?

Chapter 16

Food and Industrial Microbiology

16.1 Microbes as Food
16.2 Fermented Foods: An Overview
16.3 Acidic and Alkaline Fermented Foods
16.4 Ethanolic Fermentation: Bread and Wine
16.5 Food Spoilage and Preservation
16.6 Industrial Microbiology

Microbes have nourished humans for centuries, generating cheese, bread, wine and beer, tempeh, and soy sauce. And yet, from the moment of harvest, we humans compete with microbes for our food. Microbes from the food's surface or from the air colonize food, and their uncontrolled growth can render the food rancid or putrid. Historically, the need for food storage and preservation has led to practices such as drying, smoking, and adding spices, all of which retard microbial growth.

The principles of food microbiology have been extended to a much broader field of industrial microbiology. Industrial microbiology includes the development of microbial products such as antibiotics and enzymes, as well as transgenic microbes that produce human proteins such as insulin and growth hormones. Many products derive from extremophiles, organisms adapted to extreme environments, whose enzymes can withstand industrial conditions. Industrial microbiology faces special challenges with regard to microbial growth conditions, scaled-up fermentation, genetic optimization of production, and safety testing.

Chocolate production requires fermentation of cocoa beans by yeasts, lactic acid bacteria, and acetic acid bacteria, a process analyzed by Rosane Schwan at the Federal University of Lavras, Brazil. The beans are fermented by microbes naturally present in pulp of the cocoa fruit. The fermented beans are dried and processed to make cocoa and cocoa butter. (Schwan, R. F., and A. E. Wheals. 2004. *Critical Reviews in Food Science and Nutrition* 44:205)
Source: Alain Caste/Stockford.

The fermentation industry reaches back to 5000 BCE, the date of pottery jars excavated from a Neolithic mud-brick kitchen in the Zagros Mountains of modern Iran (**Fig. 16.1A**). The jars contain residue showing chemical traces of grapes fermented to wine. Besides winemaking, Neolithic people leavened bread, another staple food requiring microbial growth. For thousands of years, microbial fermentation has been a daily part of human life and commerce.

Today, microbial growth drives companies such as Genencor International, now earning $400 million in annual revenues from engineering industrial enzymes. Genencor delivers 250 products ranging from contact lens cleansing agents to new fashion finishes for denim at manufacturing centers in the United States, Europe, Argentina, and China. Most of Genencor's product enzymes are made by bacteria grown in giant fermentation vessels (**Fig. 16.1B**). Founded as a joint venture by Genentech and Corning, Genencor's success heralded a growing investment by biotech start-ups as well as traditional chemical companies in the fermentation industry—the use of microbes to produce industrial products.

The fermentation industry is based on long-standing microbial associations with human food. Until the relatively recent invention of steam-pressure sterilization, all foods contained live microbes. Microbial metabolism could spoil food; or it could improve the food by adding flavor, preserving valuable nutrients, and preventing growth of pathogens. As we learned in Chapter 1, one of the first great microbiologists, Louis Pasteur, began his career as a chemist investigating fermentation in winemaking. In Chapter 16, we see how the many kinds of microbial biochemistry presented in Chapters 13–15 give rise to the characteristics of food so familiar to us, from the taste of cheese and chocolate to the rising of bread dough and the physiological effects of alcoholic beverages. Industrial research continues to improve food through the fields of food biochemistry, discovering the molecular basis for the flavor and texture of microbial foods; food preservation, eliminating undesirable microbial decay by preservative methods; and food engineering, improving the quality, shelf life, and taste of microbial foods.

Beyond food, the commercial applications of microbes extend to industrial microbiology, the use of microbes to generate useful products of all kinds. Industrial microbiology generates enzymes, chemical feedstocks, fuels, and pharmaceuticals. New products are developed through genomic engineering, and the technologies presented in Chapter 12. Increasingly, research microbiologists reach beyond the laboratory bench to invent new uses for microbial products—and start their own companies to develop and market them.

16.1 Microbes as Food

Certain kinds of microbial bodies have long been eaten as food, especially the fruiting bodies of fungi and the fronds of marine algae. Single-celled algae and cyanobacteria are also used as food supplements. These microbes can provide important sources of protein, vitamins, and minerals.

Edible Fungi: From Survival Food to Gourmet Treat

In the children's classic *Homer Price*, by Robert McCloskey, settlers on the Ohio frontier save themselves from starvation when they discover "forty-two pounds of edible fungus, in the wilderness a-growin'." Fungal **fruiting bodies**, multicellular reproductive structures that generate spores, are commonly known as mushrooms (see Chapter 18). Mushrooms offer a flavorful source of protein and minerals, albeit at the risk of consuming the deadly toxins produced by a few species. The protein content of edible mushrooms can be as high as 25% dry weight, comparable to that of whole milk (percent dry weight), and includes all essential dietary amino acids.

Mushrooms contributed to the survival of pre-industrial humans, while killing those unlucky enough to consume varieties that were poisonous. Less than 1% of mushrooms are poisonous, but those few are deadly, such as the amanita, or "destroying angel," which produces toxins including the RNA polymerase inhibitor

Figure 16.1 The fermentation industry: then and now. A. A Neolithic jar that contained wine, from 5000 BCE. Excavated at Hajji Firuz Tepe, Iran. **B.** An industrial fermentation apparatus for growing microbes to produce enzyme products, at Genencor International.

alpha-amanitin. People who ingest the amanita typically die of liver failure.

On the other hand, certain mushrooms actually invite predation in order to disperse their spores. For example, the underground truffles prized in European cooking produce odorant molecules that attract animals to dig them up. Truffle odorants include sex pheromones such as androstenol, found in human perspiration.

Many varieties of edible mushrooms are farmed and marketed for human fare. **Figure 16.2** shows the culturing of *Agaricus bisporus,* the mushroom variety most commonly sold in the United States as button mushrooms and portobellos. Button mushrooms are harvested at an early stage, whereas portobellos are harvested later, when the gills are fully exposed and some of the moisture has evaporated. The decrease in moisture in portobellos concentrates the flavor and creates a dense, meaty texture; the mushrooms are often served in gourmet sandwiches as a vegetarian alternative to hamburger. *Agaricus* culture was first developed around 1700 in France, where the mushrooms were grown in underground caves. In modern mushroom farms, *Agaricus* mushrooms are cultured on composted horse manure or chicken manure in chambers controlled for temperature and humidity.

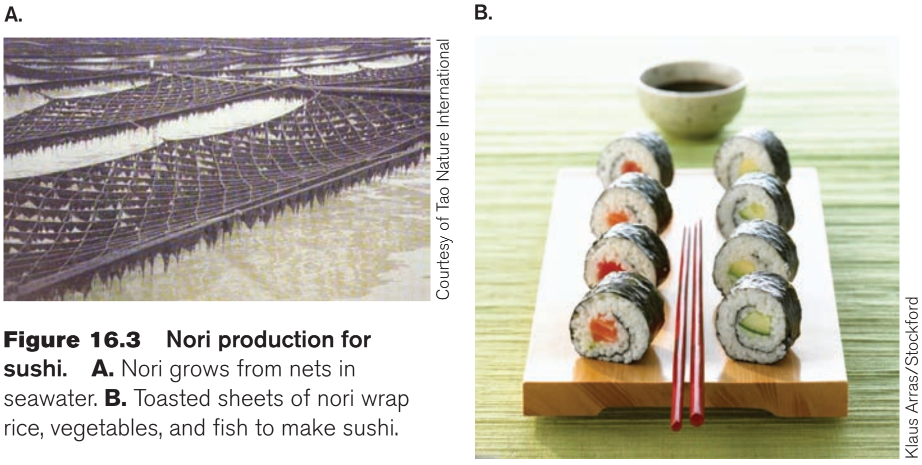
Figure 16.2 Commercial mushroom production. A. Farming of *Agaricus bisporus* mushrooms on horse manure compost, studied by Penn State graduate student Kelly Ivors. **B.** Portobello mushroom sandwich, with lettuce and tomatoes, courtesy of Middle Ground Café, Gambier, Ohio.

Other mushroom varieties from China and Japan are grown on logs or wooden blocks. Wood-grown mushrooms include the strong-flavored *Lentinula edodes* (black forest mushroom, or shiitake), *Pleurotus* (oyster mushrooms), and *Flammulina velutipes* (enoki mushrooms) with long thin white stalks and delicate flavor.

Edible Algae: Wrapping Sushi

Several kinds of seaweed (marine algae) are cultivated, most notably in Japan. The red alga *Porphyra*, a eukaryotic "true alga" (discussed in Chapter 20), forms large multicellular fronds cultured for **nori** (**Fig. 16.3**). Nori is best known for its use in wrapping rice, fish, and vegetables to form sushi.

For nori production, the red algae are grown as "seeds," or starter cultures, in enclosed tanks. The starter cultures are then distributed on nets in a protected coastal area, usually an estuary. The cultures grow until they hang heavy from the nets, when they are harvested for processing into sheets. The sheets are toasted, turning dark green.



Courtesy of Tao Nature International

Klaus Arras/Stockford

Figure 16.3 Nori production for sushi. A. Nori grows from nets in seawater. **B.** Toasted sheets of nori wrap rice, vegetables, and fish to make sushi.

Another group of seaweeds, the "brown algae," or kelp, are grown for food or to extract food additives. Kelp of the genus *Laminari* are cultured as a source of the flavor additive monosodium glutamate (MSG). A different genus, the giant kelp *Macrocystis,* is grown off the coast of California for production of the polymer alginate, a common thickener for ice cream, salad dressings, and paints. Another additive produced from brown algae is carrageenan, an emulsifier (combiner of oil and water solutions) used in commercial pies and toothpastes.

Edible Bacteria and Yeasts: Single-Celled Protein and Vitamins

Since prehistoric times, consumption of single-celled fungi or yeasts has provided a supplemental source of

Figure 16.4 **Single-celled protein from *Spirulina*.** **A.** Farming *Spirulina*. **B.** *Spirulina* processed into protein-rich food supplements. **C.** *Spirulina* cells (LM ×250).

protein and vitamins. Yeasts such as *Saccharomyces* species were grown to high concentration in fermented milks and grain beverages. Traditional beers contained only a low percentage of alcohol with a thick suspension of nutrient-rich yeasts. Especially important was the content of vitamin B_{12}, an essential substance for the human diet that cannot be obtained from plant sources.

Few bacteria are edible as isolated organisms, mainly because their small cells contain a relatively high proportion of DNA and RNA. The high nucleic acid content is a problem because nucleic acids contain purines, which the human digestive system converts to uric acid. Because we humans lack the enzyme urate oxidase, the uric acid cannot be metabolized. Consumption of more than 2 g per day of nucleic acids causes uric acid to precipitate, causing painful conditions such as gout and kidney stones. For this reason, most bacteria cannot be consumed in quantity, except as a minor component of food mass, as in fermented foods.

An exception is the cyanobacterium *Spirulina* (**Fig. 16.4**). *Spirulina* consists of spiral-shaped cells that grow photosynthetically in fresh water. *Spirulina* is sold as a food additive, rich in protein, vitamin B_{12}, and minerals. It also contains antioxidant substances that may prevent cancer. *Spirulina* is grown with illumination in special ponds lined for food production. The final product is collected and vacuum-dried to form a dark green powder of flour-like consistency.

In the food industry, *Spirulina* is classified as a form of **single-celled protein**, a term for edible microbes of high food value. Other kinds of single-celled protein include eukaryotes such as yeast and algae. The twentieth century saw the development of single-celled protein as a food source for impoverished populations. The yeast *Saccharomyces cerevesiae* was grown for protein by Germany during World War I, using inexpensive molasses for culture; and during World War II, *Candida albicans* was grown on paper mill wastes. Single-celled protein was later promoted by Western countries as a food for rapidly expanding populations of developing countries. This idea inspired the science fiction film *Soylent Green* (1973), in which people of a future overpopulated Earth are forced to eat "Soylent," a food supposedly based on soybeans and single-celled protein though its true source was recycled humans (**Fig. 16.5**).

MGM/The Kobal Collection; All rights reserved

Figure 16.5 ***Soylent Green* (1973).** Science fiction film about a future Earth whose overgrown population is forced to eat a form of food called "Soylent," supposedly based on soybeans and single-celled protein.

TO SUMMARIZE:

- **Fungal fruiting bodies** such as mushrooms and truffles are consumed as a protein-rich food.
- **Edible algae** include nori (toasted red algae), used to wrap sushi, and kelp (brown algae), which provides food additives.
- ***Spirulina*** is edible cyanobacteria, a source of single-celled protein. Most bacteria, however, are inedible because of their overly high concentration of nucleic acids.
- **Yeasts** have been grown as an economical protein and vitamin supplement.

16.2 Fermented Foods: An Overview

Virtually all human cultures have developed varieties of **fermented foods**, food products that are modified biochemically by microbial growth. The purposes of food fermentation include:

- **To preserve food.** Certain microbes, particularly the lactobacilli, metabolize only a narrow range of nutrients before their waste products build up and inhibit further growth. Typically, the waste fermentation products that limit growth are carboxylic acids, ammonia (alkaline), or alcohol. Buildup of these substances renders the product stable for much longer than the original food substrate.
- **To improve digestibility.** Microbial action breaks down fibrous macromolecules and tenderizes the product, making it easier for humans to digest. Meat and vegetable products are tenderized by fermentation.
- **To add nutrients and flavors.** Microbial metabolism generates vitamins, particularly vitamin B_{12}, as well as flavor molecules such as esters and sulfur compounds.

Different societies have devised thousands of different kinds of fermented foods. Examples are given in **Table 16.1**. Fermented foods that are produced commercially include dairy products such as cheese and yogurt, soy products such as miso (from Japan) and tempeh (from Indonesia), vegetable products such as sauerkraut and kimchi, and various forms of cured meats and sausages. Alcoholic beverages are made from grapes and other fruits (wine), grains (beer and liquor), and cacti (tequila). Other kinds of foods require microbial treatment for special purposes, such as leavening by yeast (for bread), or cocoa bean fermentation (for chocolate). Besides commercial production, numerous fermented products are homemade by traditional methods thousands of years old. Such products are known as **traditional fermented foods**. Occasionally, a traditional fermented food enters commercial production and becomes widespread. For example, soy sauce, a traditional Japanese product, was marketed by the Kikkoman company and achieved global distribution in the twentieth century.

The nature of fermented foods depends on the quality of the fermented substrate as well as on the microbial species and the type of biochemistry performed. Traditional fermented foods usually depend on **indigenous flora**, that is, microbes found naturally in association with the food substrate; or on starter cultures derived from a previous fermentation, as in yogurt or sourdough fermentation. Commercial fermented foods use highly engineered microbial strains to inoculate their cultures, although in some cases indigenous flora still participate. For example, wines and cheeses aged in the same caves for centuries often include fermenting organisms that persist in the air and the containers used.

Major classes of fermentation reactions are summarized in **Figure 16.6**. The most common conversions involve anaerobic fermentation of glucose, as discussed in Chapter 13. Glucose is fermented to lactic acid (**lactic acid fermentation**) in cheeses and sausages, primarily by lactic acid bacteria such as *Lactobacillus*. A second-stage fermentation of lactic acid to propionic acid (**propionic acid fermentation**) by *Propionibacterium* generates the special flavor of Swiss and related cheeses. Some kinds of vegetable fermentation, as in sauerkraut, involve production of lactic acid, ethanol, and carbon dioxide (**heterolactic fermentation**) by *Leuconostoc*. Fermentation to ethanol plus carbon dioxide without lactic acid (**ethanolic fermentation**) is conducted by yeast during bread leavening and production of alcoholic beverages.

In some food products, particularly those fermented by *Bacillus* species, proteolysis and amino acid catabolism generate ammonia in amounts that raise pH (**alkaline fermentation**). For example, alkaline fermentation forms the soybean product natto. Other products require the growth of mold, such as the mold-spiked Roquefort cheese and the soy product tempeh. Mold growth requires some oxygen for aerobic respiration. Respiration must be limited, however, to avoid excessive decomposition of food substrate and loss of food value.

Note that the conversions cited here include only the major reactions in achieving the food product. In addition, thousands of minor or secondary reactions occur, some of

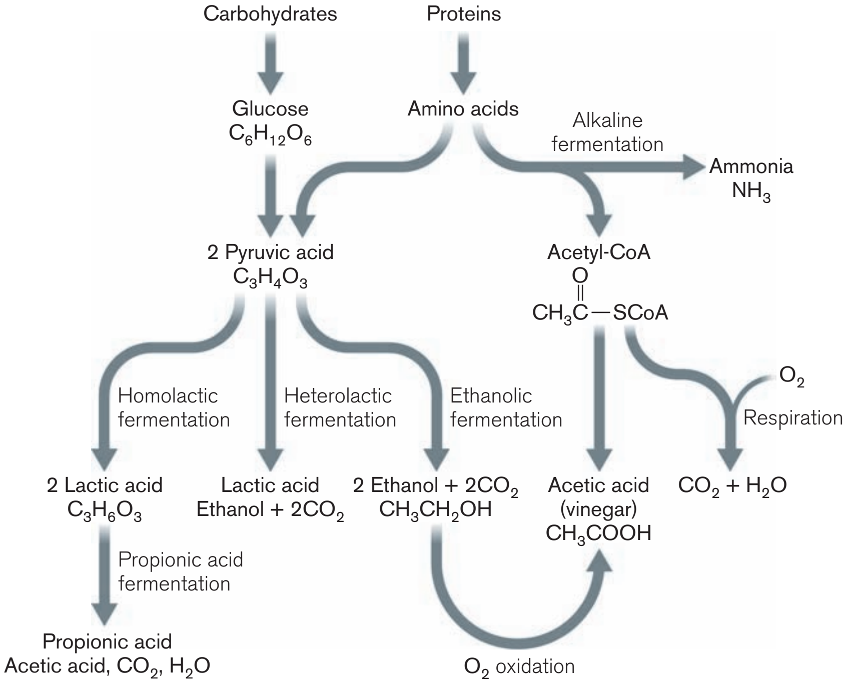

Figure 16.6 Major chemical conversions in fermented foods.

Table 16.1 Fermented foods and beverages.

Product	Description	Microbial genera	Geographic origin
Acidic fermentation of dairy, meat, and fish			
Buttermilk	Bovine milk, lactic fermented	Lactococcus	Europe, Asia
Yogurt	Bovine milk, lactic fermented and coagulated	*Lactobacillus, Streptococcus*	Europe, Asia
Kefir	Bovine or sheep milk, mixed fermentation, acidic with some alcohol	*Lactobacillus, Streptococcus,* yeasts, others	Eastern Europe, Russia
Sour cream	Bovine cream, lactic fermented	*Lactococcus*	Europe, Asia
Cheese (many kinds)	Milk (bovine, sheep, or goat) lactic fermented, coagulated, and pressed; in some cases cooked; mold ripened (spiked or coated)	Acid fermentation: *Lactobacillus, Streptococcus, Propionibacterium* Mold ripening: *Penicillium*	Europe, Asia
Sausage	Ground beef and/or pork encased with starter culture, lactic fermented, dried, or smoked	*Lactobacillus, Pediococcus, Staphylococcus,* others	Europe, Asia
Fermented fish	Many kinds of fish, mixed fermentation, acid and amines produced	Unknown	Africa, Asia
Acidic fermentation of vegetables			
Tempeh	Soybean cakes, fungal fermentation	*Rhizopus oligosporus*	Indonesia
Miso	Soy and rice paste, fungal fermentation	*Aspergillus*	Japan
Soy sauce	Extract of soy and wheat, fungal fermentation, brined, bacterial fermentation	*Aspergillus*, followed by halotolerant bacteria	China, Japan
Kimchi	Cabbage, peppers, and other vegetables, with fish paste, brined; container is buried	*Leuconostoc*, other bacteria	Korea
Sauerkraut	Cabbage fermented, making lactic and acetic acids and CO_2	*Leuconostoc, Pediococcus, Lactobacillus*	Europe
Pickled foods	Cucumbers, carrots, fish; brined, then fermented	*Leuconostoc, Pediococcus, Lactobacillus*	Europe, Asia
Kenkey	Maize, fermented, wrapped in banana leaves and cooked	Unknown	Western Africa
Chocolate	Cocoa beans soaked and fermented before processing to chocolate	*Lactobacillus, Bacillus, Saccharomyces*	South America
Alkaline fermentation			
Pidan	Duck eggs, coated in lime (CaO), aged, producing ammonia and sulfur odorants	*Bacillus*	Japan, China
Natto	Whole soybeans, fermented	*Bacillus natto*	Japan, China
Dawadawa	Locust beans, fermented	*Bacillus*	Africa
Ogiri	Melon seed paste, fermented	*Bacillus*	Africa
Leavened bread dough			
Yeast breads	Ground grain, dough leavened by yeast	*Saccharomyces*	Europe, Asia, America
Sourdough	Ground grain, dough leavened by starter culture from previous dough	*Saccharomyces, Torulopsis, Candida*	
Injera	Ground *teff* grain, dough leavened and fermented three days by organisms from the grain	*Candida*	Ethiopia
Alcoholic fermentation			
Wine	Grape juice, yeast fermented, followed by malolactic fermentation	*Saccharomyces, Oenococcus*	Europe, Asia, America
Beer	Barley and hops, yeast fermented	*Saccharomyces*	Europe, Asia, America
Sake	Rice extract, yeast fermented	*Saccharomyces*	Japan
Tequila	Blue agave, yeast fermented and distilled	*Saccharomyces*	Mexico
Whiskey	Barley or other grains or potatoes, fermented and distilled	*Saccharomyces*	United Kingdom, America, Japan

which produce tiny amounts of potent odorants and flavors. While these flavor molecules have less nutritional consequence than the main fermentation products, they are responsible for the complex, "sophisticated" taste for which fine cheeses, wines, and soy products are known.

THOUGHT QUESTION 16.1 Why do the lipid components of food experience relatively little breakdown during fermentation?

THOUGHT QUESTION 16.2 Why does oxygen allow excessive breakdown of food, compared with anaerobic processes?

TO SUMMARIZE:

- **Fermentation of food** enhances preservation, digestibility, nutrient content, and flavor.
- **Acidic fermentations** lead to organic acid fermentation products, such as lactate and propionate.
- **Alkaline fermentations** produce ammonia and break down proteins to peptides.
- **Ethanolic fermentation** produces ethanol and carbon dioxide.
- **Lipids are relatively stable** under anaerobic conditions of fermentation.

16.3 Acidic and Alkaline Fermented Foods

Many food fermentations produce acids or bases. An acid or base serves as an effective preservative because the pH change is unlikely to be reversed, and because animal or plant bodies grown at near-neutral pH are unlikely to support growth of acidophiles or alkaliphiles, which grow at extreme pH conditions.

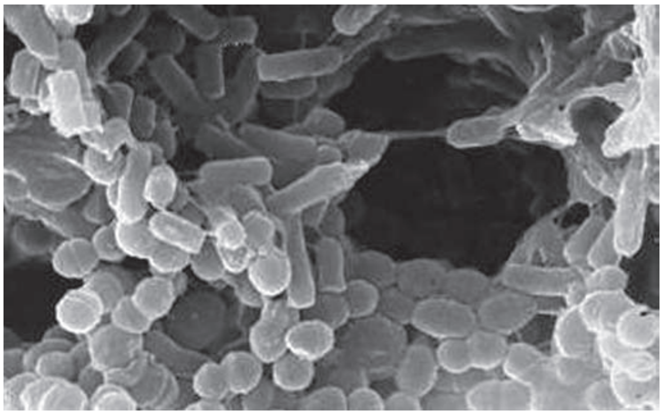
Acidic Fermentation of Dairy Products

The conversion of milk to solid or semisolid fermented products dates far back in human civilization. The practice of milk fermentation probably arose among herders who collected the milk of their pack animals but had no way to prevent the rapid growth of bacteria. The milk had to be stored in a portable container such as the stomach of a slaughtered animal. After hours of travel, the combined action of lactic acid-producing bacteria and stomach enzymes caused the coagulation of milk proteins into **curd**. The curd naturally separated from the liquid portion, called **whey**. Both "curds and whey" can be eaten, as in the nursery rhyme "Little Miss Muffet." The curds, however, are particularly valuable for their concentrated protein content.

Curd formation. A **cheese** is any milk product from a mammal (usually cow, sheep, or goat) in which the milk protein coagulates to form a semisolid curd. Curd formation results from two kinds of processes: acidification, usually as a result of the microbial production of lactic acid, and treatment by proteolytic enzymes such as rennet. The curd may then be separated and processed to varying degrees, depending on the type of cheese.

How does milk coagulate? The major organic components of cow's milk are milk fat (about 4% unless skimmed), protein (3.3%), and the sugar lactose (4.7%). Milk starts out at about pH 6.6, very slightly acidic. At this pH, the milk proteins are completely soluble in water; otherwise, they would clog the animal's udder as the milk comes out. Fermentation generally begins with bacteria such as *Lactobacillus* and *Streptococcus* (**Fig. 16.7**). As bacteria ferment lactose to lactic acid, the pH starts to decline. The dissociation constant of lactic acid ($pK_a = 3.9$) allows greater deprotonation than other fermentation products such as acetate ($pK_a = 4.8$). Thus, lactic acid rapidly acidifies the milk product to levels that halt further growth of bacteria. Halting bacterial growth minimizes the oxidation of amino acids, thus maintaining food quality.

Milk contains micelles (suspended droplets) of hydrophobic proteins called **caseins**. As the pH of milk declines below pH 5, the acidic amino acid residues of caseins become protonated, eventually destablilizing the tertiary structure. As the casein molecules unfold (or "denature"), they expose hydrophobic residues that regain stability by interacting with other hydrophobic molecules. The intermolecular interaction of caseins generates a gel-like network throughout the milk, trapping other substances such as droplets of milk fat. This protein network is responsible for the semisolid texture of **yogurt**, a simple product of milk acidified by lactic acid bacteria.



Sylvie Lortal, *Handbook of Food and Beverage Fermentation Technology*

Figure 16.7 Bacterial community within Emmentaler cheese (SEM). Bacterial species include *Lactobacillus helveticus* (rods, 2.0–4.0 μm in length) and *Streptococcus thermophilus* (cocci).

In most kinds of cheese formation, a further step of casein coagulation is accomplished by proteases such as **rennet**. Rennet derives from the fourth stomach of a calf, although modern versions are made by genetically engineered bacteria. Calf rennet includes two proteolytic enzymes, chymosin and pepsin. Chymosin specifically cleaves casein into two parts, one of which is charged and water-soluble, the other hydrophobic. The hydrophobic portion forms a firmer curd than intact casein and is responsible for the harder texture of solid cheeses. The water-soluble portion, about one-third of the total casein, enters the whey and is lost from the curd. Processing of some cheese varieties includes heating to high temperature, which denatures even the whey protein so it is retained in the curd.

Varieties of cheese. An extraordinary number of cheese varieties have been devised (**Fig. 16.8**). These fall into several categories, based on particular steps in their production.

- **Soft, unripened cheeses**, such as cottage cheese and ricotta, are coagulated by bacterial action, without rennet. The curd is cooked slightly, and the whey is partly drained, but their water content is 55% or greater. These cheeses spoil easily; there are no steps of aging, or **ripening**.
- **Semihard, ripened cheeses**, such as Muenster and Roquefort, include rennet for firmer coagulation, and the curd is cooked down to a water content of 45–55%. The cheese is aged for several months.
- **Hard cheeses**, such as Swiss cheese and cheddar, are concentrated to even lower water content. Extra-hard varieties, such as Parmesan and Romano, have a water content as low as 20%. These cheeses are aged for many months, even several years.
- **Brined cheeses**, such as feta, are permeated with brine (concentrated salt), which limits further bacterial growth and develops flavor. Harder cheeses, such as Gouda, may be brined at the surface.
- **Mold-ripened cheeses** are inoculated with mold spores that germinate and grow during the ripening, or aging, process to contribute texture and flavor. The mold may be inoculated on the surface, to form a crust (as in Brie and Camembert), or it may be spiked deep into the cheese (as in blue cheese or Roquefort).

Cheese production. Commercial production of cheese involves a standard series of steps (**Fig. 16.9**). At each of these steps, choices of treatment lead to very different varieties. Key steps are illustrated for the example of Gouda cheese in **Fig. 16.10**.

In the first step, the milk is filtered to remove particulate objects, such as straw, and microfiltered or centrifuged to remove potentially pathogenic bacteria and spores. Most modern production includes flash pasteurization (brief heating to 72°C), although some traditional cheeses continue to be made from unpasteurized milk. Unpasteurized milk in cheese has been linked to illness, particularly from *Listeria*, bacteria that grow at typical refrigeration temperatures.

The fermenting microbes are added as a **starter culture**. The starter was traditionally derived from a sample of previous fermentation, in which case the flora are undefined. Commercial cheese production now uses defined species. In all but the soft cheeses, bacterial coagulation and curd formation are supplemented by rennet or by genetically engineered proteases.

The solid curd is then cut, or **cheddared** (hence the name "cheddar" cheese). The finer the pieces, the more whey can be pressed out and the harder the cheese produced. Curd is then heat treated, with or without the whey; if whey is included, more protein is retained. Brining at this stage leads to a salty cheese, such as feta.

The pressed curd is then shaped into a mold, which determines the ultimate shape of the cheese. Before ripening (or aging), the cheese may be floated in brine to generate a rind; or it may be coated or spiked with a *Penicillium* mold. The ripening period then allows development of flavor. Texture also changes; for example, where fermentation has produced CO_2, the trapped gas forms "eyes," or holes.

The cheese then dries and ripens on the shelf.

Flavor generation in cheese. In all fermented foods, microbial metabolism generates by-products that confer a characteristic aroma and flavor. In some cases, particular species confer distinctive flavors; for example, *Propionibacterium* ferments lactate or pyruvate to propionate, a distinctive flavor component of Swiss cheese. All bacteria generate a surprising range of side reactions, forming trace products that confer distinctive flavors. For example, while *Lactobacillus* converts most of the lactose to lactic acid, a small fraction of the pyruvate is converted to acetoin, acetaldehyde, or acetic acid, which contribute flavor. Most amino acids are retained intact; but traces are converted to flavorful alcohols, esters, and sulfur compounds (**Fig. 16.11**). For example, methanethiol (CH_3SH) contributes to the desirable flavor of cheddar cheese. Lipids are not significantly metabolized by *Lactobacilli*, but in mold-ripened cheeses such as Camembert, *Penicillium* oxidizes a small amount of the lipids to flavorful methylketones, alcohols, and lactones.

Figure 16.11 Flavor generation from amino acid catabolism. Casein catabolism generates flavor molecules (highlighted). Extracellular enzymes break down casein into peptides and amino acids, which are taken into the bacterial cell by membrane transporters. The amino acids are fermented to volatile alcohols and esters. In some cases, they combine with sulfur to form methanethiol and other sulfur-containing odorants characteristic of cheese.

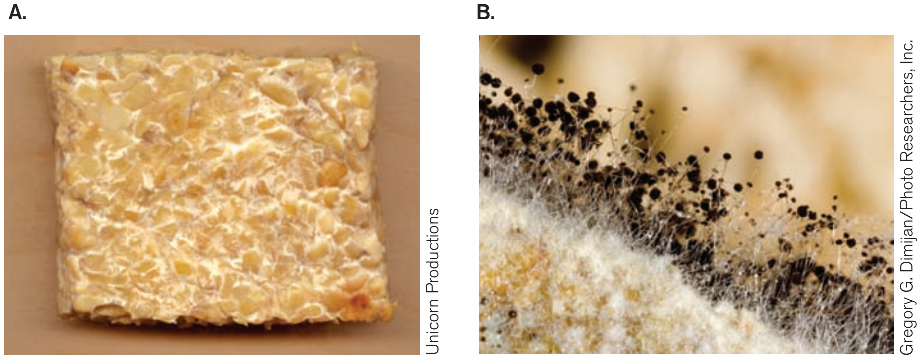
Acid Fermentation of Vegetables

Many kinds of vegetable products are based on microbial fermentation. Commercial products marketed globally include pickles, soy sauce, and sauerkraut. Other products provide staple foods for particular nations or regions, such as Indonesian tempeh and Korean kimchi.

Soy fermentation. Soybeans offer one of the best sources of vegetable protein and are indispensable for the diet of millions of people, particularly in Southeast Asia. In North America, soy products are important for vegetarian consumption and as a milk substitute, as well as for animal feed. But soybeans also contain substances that decrease their nutritive value. Phytate, or inositol hexaphosphate, chelates minerals, such as iron, inhibiting their absorption by the intestine. Lectins are plant glycoproteins that bind to cell surface glycoproteins within the human body. At high concentration, lectins may upset digestion and induce autoimmune diseases. Protease inhibitors interfere with chymotrypsin and trypsin, thus decreasing the amount of protein that can be obtained from the soy food.

All of these drawbacks of soybeans are diminished by microbial fermentation, while the protein content remains comparable to that of the unfermented bean (40%). A variety of fermented soy foods have been developed. Most soy fermentation involves mold growth, supplemented by bacteria that contribute vitamins, including vitamin B_{12}.

A major fermented soy product is **tempeh**, a staple food of Indonesia, the world's fifth most populous country, as well as of other countries of Southeast Asia (**Fig. 16.12**). Tempeh consists of soybeans fermented by *Rhizopus oligosporus*, a common bread mold. Besides decreasing the negative factors of soy, the mold growth breaks down proteins into more digestible peptides and amino acids. During World War II, tempeh was fed to American prisoners of war held by the Japanese. The tempeh was later credited with saving the lives of prisoners whose dysentery and malnutrition impaired their ability to absorb intact proteins.



Unicorn Productions

Gregory G. Dimijan/Photo Researchers, Inc.

Figure 16.12 Tempeh, a mold-fermented soy product. A. Fried tempeh. **B.** *Rhizopus oligosporus* mold, used to make tempeh.

Tempeh is commonly produced in home-based factories in Indonesia. The soybeans are soaked in water overnight, allowing initial fermentation by naturally present lactic acid bacteria; in some cases, a crude "starter" may be introduced from the water of soybeans soaked previously. This pre-fermentation allows bacterial generation of vitamins and produces mild acid that promotes growth of mold. The soaked beans are then dehulled, cooked, and cooled to room temperature for inoculation with *R. oligosporus* spores or with a previous tempeh culture. The inoculated beans are wrapped in banana leaves or in perforated plastic bags, then allowed to incubate for two days. The mold grows as a white mycelium that permeates the beans, joining them into a solid cake. The final product has a mushroom-like taste and is often served fried or grilled like a hamburger.

Other soy products undergo acidic fermentation by the mold *Aspergillus oryzae*. The Japanese condiment **miso** is made from ground soy and rice, salted and fermented for two months by *A. oryzae*. **Soy sauce** is made from jiang, a Chinese condiment similar to miso in which the rice starter culture is replaced by wheat. The fermentation generates glutamic acid, a flavor-enhancing compound known popularly in the form of its salt—monosodium glutamate, or MSG.

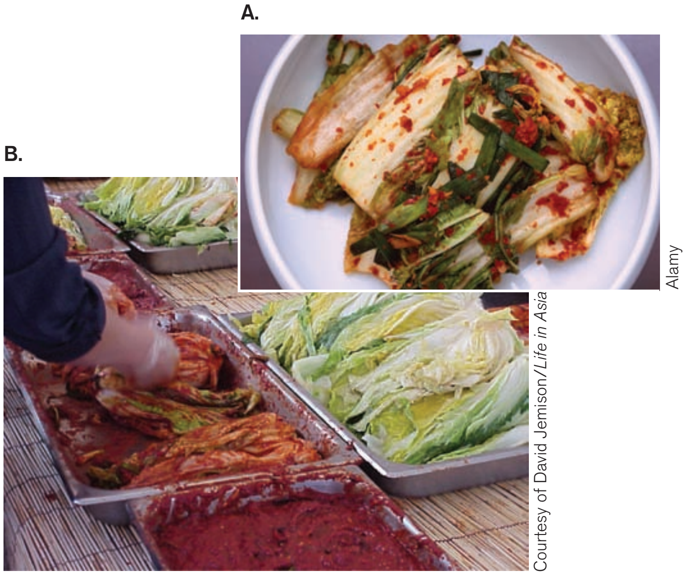
Fermentation of cabbage and other vegetables. Various leaf vegetables are fermented by traditional societies, originally as a means of storage over the winter months. In Europe and North America, the best-known fermented products include sauerkraut and pickles. Sauerkraut production involves heterolactic fermentation by *Leuconostoc mesenteroides*. In heterolactic fermentation, each fermented sugar molecule yields lactic acid as well as ethanol and carbon dioxide. The culture is used to inoculate shredded cabbage, which is layered in alternation with salt. The salt helps limit the species and extent of microbial growth. A similar brine-enhanced fermentation process is used to pickle cucumbers, olives, and other vegetables.

An important food based on brine-fermented cabbage is Korean **kimchi** (**Fig. 16.13**). Kimchi is prepared from Chinese cabbage, salted and layered with radishes, peppers, onions, and other vegetables. The vegetables are covered with a paste of fish, rice, and chili peppers. Pickled seafoods such as shrimp or oysters may be included. The entire mixture is stored in a pot, traditionally buried underground for several months. The main fermentation organism is *Leuconostoc mesenteroides*, although *Streptococcus* and *Lactobacillus* species participate.

One of the most complex of all food fermentations is that of cocoa beans. Cocoa and coffee beans both require fermentation within the juice of the fruit before the beans are dried and processed. In the case of cocoa, at least three different kinds of fermentation must be performed by three different kinds of microorganisms (see **Special Topic 16.1**).

Alkaline Fermentation: Natto and Pidan

In Western countries, food-associated fermentation is almost synonymous with acidification. In Southeast Asia and in Africa, however, many food products involve



Alamy

Figure 16.13 Kimchi. A. To make kimchi, cabbage leaves are layered alternating with chili paste containing salted fish and vegetables. **B.** The salted layers are packed to be buried and aged for two months.

Special Topic 16.1 Chocolate: The Mystery Fermentation

Chocolate, the product of the cocoa bean *Theobroma cacao*, or "food of the gods," requires one of the most complex fermentations of any food. For all the commercialization of chocolate production, totaling 2.5 billion kilos per annum worldwide, no "starter culture" has yet been standardized to ferment the cocoa bean. Instead, the beans harvested in Africa or South America are heaped in mounds upon plantain leaves for fermentation by indigenous microorganisms, essentially the same way cocoa has been processed for thousands of years (**Fig. 1**). The fermentation must occur immediately where the beans are harvested; they cannot be exported and fermented later.

The microbial fermentation actually occurs outside the cocoa bean, within the pulp that clings to the beans after they are removed from the cocoa fruit. The pulp contains 1% pectin, a complex branched polysaccharide, plus a rich supply of amino acids and minerals. These nutrients support growth of many kinds of microbes. Brazilian microbiologist Rosane Schwan, of

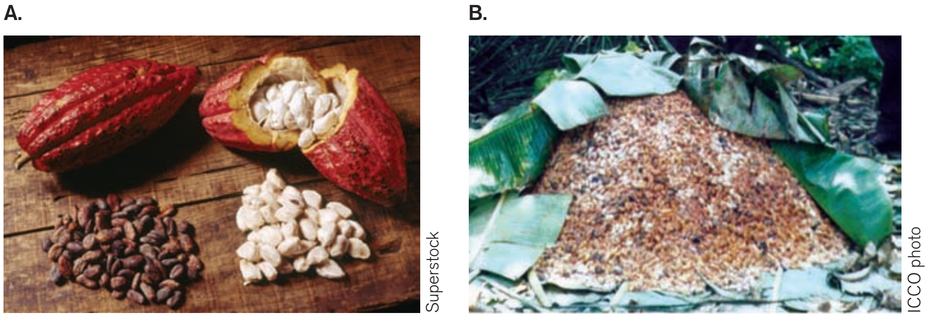

Figure 1 Cocoa beans. **A.** Cocoa fruit, showing beans encased in mucilage. **B.** Heap of beans covered by plantain leaves. Fruit pulp ferments, liquefies, and drains away, while the beans acidify and turn brown.

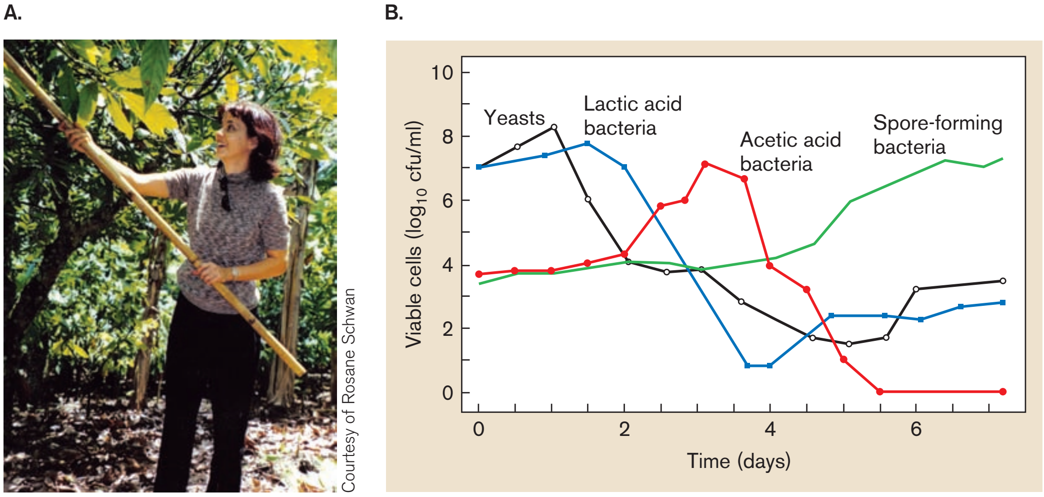

Figure 2 Microbial succession during cocoa pulp fermentation. **A.** Rosane Schwan harvests cocoa beans for her research on cocoa fermentation. **B.** Yeasts generate alcohol, which lactic acid bacteria convert to lactate, and acetic acid bacteria oxidize to CO_2. *Source*: B. From R. Schwan.

increased pH. Such fermentations typically release small amounts of ammonia, which raises the pH to about 8, retarding growth of all but alkali-tolerant bacteria. The fermenting bacteria are usually *Bacillus*, aerobic species tolerant of moderate alkali and capable of extensive proteolysis and amino acid decomposition. The fermentation needs to be controlled to limit the loss of protein content, but the end result is a highly stable food product.

Natto. The Japanese soybean product **natto** is prepared by a process similar to that for tempeh. Soybeans are washed, prefermented, and cooked briefly before incubation with the starter organism *Bacillus natto*. The fermenting beans are incubated in a shallow, ventilated container at a slightly raised temperature (40°C).

B. natto secretes numerous extracellular enzymes, including proteases, amylases, and phytases. These enzymes the Federal University of Lavras, Brazil, analyzed the microbial community (**Fig. 2**). Schwan defined three stages of succession: yeasts, lactic acid bacteria, and acetic acid bacteria.

Yeast fermentation (anaerobic). The pulp initially is full of citric acid (pH 3.6). The acidity favors growth of yeasts, including *Candida, Kloekera*, and *Saccharomyces*. The yeasts consume citric acid, increasing pH. They also degrade pectin into glucose and fructose, allowing the pulp to liquefy.

As the liquefied pulp drains, its remaining sugars are fermented to ethanol, CO_2, and acetate. These products eventually rise to levels that inhibit yeast growth. The ethanol and acetate penetrate the bean embryo, preventing germination and disrupting cell membranes. The disrupted cells release enzymes that generate key flavor molecules of chocolate by hydrolysis of proteins to produce hydrophobic peptides. Other products include psychoactive molecules, such as theobromine, a stimulant similar to caffeine, and 2-phenylethylamine, a neurotransmitter associated with the pleasure response (**Fig. 3**).

Lactic acid bacteria (anaerobic). The consumption of citric acid by yeast increases the pH to pH 4.2, encouraging growth of lactic acid bacteria. *Lactobacillus* species convert citric acid to acetate, CO_2, and lactic acid. As fermentable substrates disappear, however, lactic acid bacteria are inhibited.

Acetic acid bacteria (aerobic). After one or two days, the beans are overturned and mixed periodically to permit access to oxygen. Aerobic bacteria such as *Acetobacter* now convert the ethanol and acids to CO_2. The consumption of acids neutralizes undesirable acidity. The bean is also penetrated by oxygen, which oxidizes key cocoa components, such as polyphenols. Polyphenol oxidation generates the brown color of cocoa and contributes flavor.

Oxidative respiration within the mound of beans generates heat faster than it can dissipate, causing temperature to rise as high as 50°C, which halts fermentation. After fermentation and pulp drainage, the beans are dried and roasted. The roasting process completes the transformation of cocoa substances that contribute flavor. Without the preceding fermentation process, no flavor would develop. Cocoa liquor and cocoa butter are extracted from the beans, then recombined with sugar and other components to make "cocoa mass" (**Fig. 4**). The cocoa mass is stirred for several days to achieve a smooth texture; then it is molded into the decorative forms known as chocolate.

The quality of chocolate rests largely on the original process of pulp fermentation, whose details remain poorly understood. Schwan is working to develop a defined starter culture, a community of microbes to produce a predictable high quality of flavor. At present, however, one of the world's most refined and highly prized commercial food products still depends on the indigenous microbial fermentation of cocoa pulp.

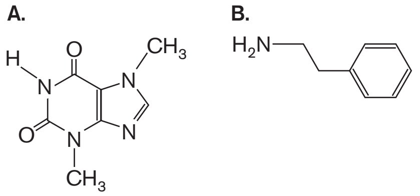

Figure 3 **Psychoactive products of cocoa fermentation.** **A.** Theobromine, a stimulant. **B.** 2-Phenylethylamine, an antidepressant.

decrease the undesirable components of soy, such as phytates and lectins, while liberating more easily digestible peptides and amino acids. Some of the amino acids are deaminated, generating ammonia; a well-ventilated natto chamber allows most of this gas to escape. In addition, *B. natto* synthesizes extracellular polymers such as polyglutamate (a peptide chain consisting exclusively of glutamic acid residues). Polyglutamate generates long elastic strings that bind the beans together. The stretching of these strings from chopsticks is considered a sign of a good natto (**Fig. 16.14A**).

Alkaline fermented vegetables. In Africa, numerous vegetable products are based on alkaline fermentation predominantly by *Bacillus* species. An example is dawadawa, a paste of fermented locust beans common in western Africa. The locust beans are washed and supplemented with potash, or potassium hydroxide, originally obtained from wood ashes. This addition of alkali retards growth of bacteria other than *Bacillus* species, which predominate at higher pH. The beans are fermented by indigenous bacteria (bacteria already present in the beans). The fermented beans are sun-dried, releasing most of the ammonia, and pounded into cakes for storage. Similar alkali-fermented vegetables include ogiri, from melon seeds, and ugba, from oil beans.

Eleanor Nakama-Mitsunaga, Honolulu Star-Bulletin

Figure 16.14 Alkaline-fermented foods. **A.** Natto consists of soybeans fermented by *Bacillus natto*. The fermentation generates long strings of polyglutamate. **B.** Pidan, or "thousand-year egg," consists of duck eggs coagulated by sodium hydroxide and fermented by *Bacillus* species. One egg is cut open, revealing the transformed yolk, which develops a greenish color.

Pidan. An ancient means of preserving eggs has produced the famous Chinese delicacy pidan, or "thousand-year egg," now a favorite at dim sum restaurants (**Fig. 16.14B**). To make pidan, duck eggs are covered with a mixture of brewed tea, lime (CaO), and sodium carbonate (Na_2CO_3). The lime and sodium carbonate react to form NaOH, which penetrates the eggshells, raising pH and coagulating the egg white proteins. The eggs are buried in mud for several months, during which time the combined action of alkali and *Bacillus* fermentation generates dark colors and interesting flavors. Hydrogen sulfide and acetaldehyde contribute to flavor generation.

THOUGHT QUESTION 16.5 In traditional fermented foods, without pure starter cultures, what determines the kind of fermentation that occurs?

TO SUMMARIZE:

- **Milk curd** forms by lactic acid fermentation and rennet proteolysis, rendering casein insoluble. The cleaved peptides coagulate to form a semisolid curd. The main fermentative organisms are lactic acid bacteria.
- **Cheese varieties** include unripened cheese; semihard and hard cheeses that are cooked down and ripened; brined cheeses; and mold-ripened cheeses.
- **Cheese flavors** are generated by minor side products of fermentation, such as alcohols, esters, and sulfur compounds.
- **Soy fermentation** to tempeh and other products improves digestibility and decreases undesirable soy components such as phytates and lectins. The fermentative agent of tempeh is the bread mold *Rhizopus oligosporus*.
- **Vegetables** are fermented and brined to make sauerkraut and pickles. Cabbage and supplementary foods are fermented and brined to make kimchi.
- **Alkaline fermented vegetables** include the soy product natto, the egg product pidan, and the locust bean product dawadawa. The main fermenting organisms are *Bacillus* species.

16.4 Ethanolic Fermentation: Bread and Wine

Some of our most nutritionally significant and culturally important foods, including most bread and alcoholic beverages, derive from ethanolic fermentation by yeast fungi. Ethanolic fermentation converts pyruvate to ethanol and carbon dioxide:

$$C_3H_4O_3 \longrightarrow CH_3CH_2OH + CO_2$$

The most prominent yeast used is *Saccharomyces cerevisiae*, known as baker's yeast or brewer's yeast (**Fig. 16.15**). A hardy organism, *S. cerevisiae* easily survives on a grocery shelf for home use and is genetically tractable for fundamental research. The yeast has been studied since the time of Pasteur, who used it to prove the biological basis of fermentation. *S. cerevisiae* today is a major model system of cell biology, yielding the molecular secrets of human cancer and other diseases.

Bread making depends on carbon dioxide to generate air spaces that **leaven** the dough, making its substance easier to chew and digest. The small amount of ethanol produced is eliminated during baking. For alcoholic bever-

Figure 16.15 **Baker's yeast, the "champion" fermenter.** **A.** *Saccharomyces cerevisiae* cells budding; some show bud scars (SEM). **B.** *S. cerevisiae* is used to study the function of human proteins such as α-synuclein (green fluorescence), which plays a role in Parkinson's disease. ages, however, ethanol is the key product, accompanied by carbon dioxide bubbles for "fizz," known as carbonation.

Bread Dough Is Leavened by Microbial CO_2

Bread is made in many different forms (**Fig. 16.16**) and from diverse kinds of flour, or ground grain. The earliest breads probably arose from grain mush naturally contaminated by yeast. Later, bread makers learned to include yeast left over from wine or beer production as a starter culture.

Yeast bread production. The preparation of all forms of yeast bread requires the same fundamental steps. A starter culture of yeast is included in the dough. The yeast can be commercial baker's yeast, or it can be **sourdough** starter, an undefined yeast population derived from a previous batch of dough. The dough is kneaded to develop a fine network of air pockets and allowed to rise, expanding with production of the carbon dioxide gas (**Fig. 16.17**). The finest-textured breads are made from wheat flour, which contains gluten, a substance that forms a fine molecular network supporting the rising dough.

Modern bread sold commercially is produced on an industrial scale. The dough is made in huge vats, then cut into regular chunks that are placed into the bread pans. The loaves are baked under hot-air convection, a system that greatly decreases the baking time. In the United States, most commercial bread is sliced mechanically, an invention that

Guy Cali and Associates/Stockford

dates back to 1912. Sliced bread requires preservative chemicals to prevent growth of mold on the exposed interior.

THOUGHT QUESTION 16.6 Compare and contrast the role of fermenting organisms in the production of cheese and bread.

Injera: extended fermentation. Most kinds of bread involve only a short fermentation period, just long enough to produce enough gas for leavening. A prolonged fermentation, with more extensive microbial activity, occurs in the dough for an Ethiopian bread called **injera** (**Fig. 16.18**). The high microbial content provides a substantial source of vitamins not found in quick-rising breads.

Injera is made from teff, a grain with small, round kernels that grows in Ethiopia at high altitude. Teff contains no gluten, so it cannot rise as much as wheat flour, but it makes a kind of flatbread. The dough is spread into a wide pancake, then allowed to ferment for three days, based on organisms present in the grain and air. The fermentation includes a succession of species, usually dominated by the yeast *Candida*. The extended fermentation generates a complex range of by-products that confer exceptional flavors in the baked product. Injera forms the basis of an entire Ethiopian meal, served with other food items placed upon it as an edible tablecloth. Diners wrap samples of each food in a fold of injera and consume them together.

Alcoholic Beverages: Beer and Wine

Ethanolic fermentation of grain or fruit was important to early civilizations because it provided a drink free of waterborne pathogens. Traditional forms of beer also provided essential vitamins in the unfiltered yeasts.

Ethanol is unique among fermentation products in that it provides a significant source of caloric intake, but it is also a toxin that impairs mental function. A modest level of ethanol enters the human circulation naturally from intestinal flora, equivalent to a fraction of a drink per day. The human liver produces the enzyme **alcohol dehydrogenase**, which detoxifies ethanol. This enzyme in a healthy liver can metabolize small amounts of alcohol without harm. However, excess alcohol consumption can overload the liver's capacity for detoxification and permanently damage the liver and brain.

Beer: alcoholic fermentation of grain. Beer production is one of the most ancient fermentation practices and is depicted in the statuary of ancient Egyptian tombs dated to 5,000 years ago (**Fig. 16.19A**). The earliest Sumerian beers were made from bread soaked in water and fermented. Today, most beer is produced commercially by fermenting barley using giant vats (**Fig. 16.19B**). Production of high-quality beer involves complex processing with many steps, including the germination of barley grains, the mashing in water and cooking, and the introduction of hops for flavor (**Special Topic 16.2**).

Before fermentation, the barley starch is broken down to maltose by enzymes from the grain. Most of the maltose is fermented by yeast to ethanol and carbon dioxide. However, minor side products contribute flavors—or unpleasant off-flavors if present in too great an amount (**Fig. 16.20**). Some of the off-flavors result from the presence of oxygen, which is needed because yeast is not a true anaerobe; it requires aerobic metabolism to synthesize some of its cell components. The presence of oxygen diverts some pyruvate into acetaldehyde, most of which converts to ethanol. Some of the acetaldehyde, however, remains unconverted, and some is converted to diacetyl. Both acetaldehyde and diacetyl cause off-flavors.

Most pyruvate undergoes ethanolic fermentation, but a small fraction is drawn off to make amino acids via TCA cycle intermediates, as discussed in Chapter 15. The 2-oxo

acids of the TCA cycle are analogous to pyruvate, with the methyl group replaced by extended carbon chains (R group). A tiny amount of the 2-oxo acids is converted to long-chain alcohols, which add desirable flavor to beer.

THOUGHT QUESTION 16.7 Compare and contrast the role of low-concentration by-products in the production of cheese and beer.

Wine: alcoholic fermentation of fruit. The fermentation of fruit gives rise to wine, another class of alcoholic products of enormous historical and cultural significance. Grapes produce the best-known wines, but wines and distilled liquors are also made from apples, plums, and other fruits. The key difference between fermentation of fruits and fermentation of grains is the exceptionally high monosaccharide content in fruits. Grape juice, for example, can contain concentrations of glucose and

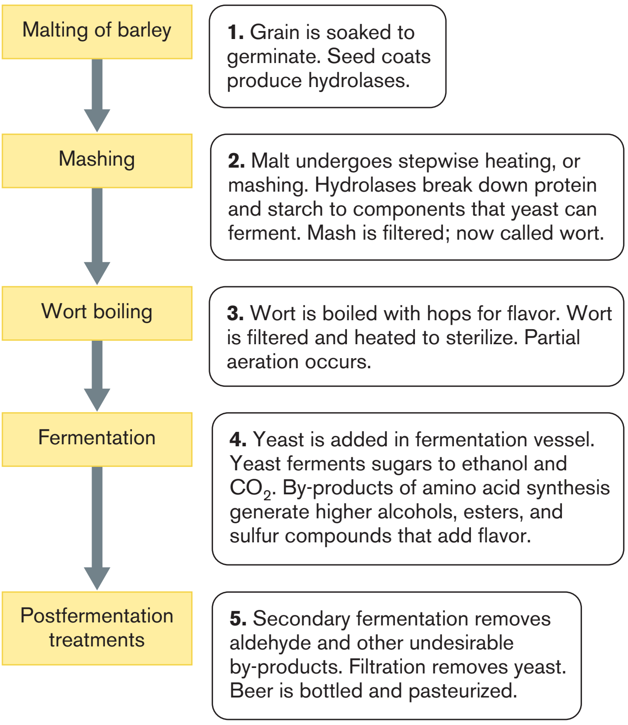
Special Topic 16.2 Beer Is Made from Barley and Hops

Beer production encompasses five main stages (**Fig. 1**). These include malting, the germination of barley grains; mashing, a stepwise heating process to promote starch hydrolysis; wort boiling with hops; fermentation; and postfermentation treatments.



1. Grain is soaked to germinate. Seed coats produce hydrolases.

2. Malt undergoes stepwise heating, or mashing. Hydrolases break down protein and starch to components that yeast can ferment. Mash is filtered; now called wort.

3. Wort is boiled with hops for flavor. Wort is filtered and heated to sterilize. Partial aeration occurs.

4. Yeast is added in fermentation vessel. Yeast ferments sugars to ethanol and CO_2. By-products of amino acid synthesis generate higher alcohols, esters, and sulfur compounds that add flavor.

5. Secondary fermentation removes aldehyde and other undesirable by-products. Filtration removes yeast. Beer is bottled and pasteurized.

Figure 1 Process of beer production. Barley is malted, milled, and mashed to break down long-chain sugars and proteins into short chains and monomers that yeast can digest, forming wort. The wort is fermented by yeast to make beer.

Malting of barley. The barley grains are malted, or soaked in water, to encourage germination (**Fig. 2**). During germination, the endosperm (stored food) of the grain secretes gibberellin, a hormone that stimulates the growth of rootlets and the emerging stem. Gibberellin induces the aleurone (lining of the endosperm) to produce hydrolases, enzymes that break down starch to maltose and proteins to amino acids for use by the growing plant. The hydrolases actually become activated during the second stage, called mashing, when the grains are crushed and stirred in huge vats of water.

Mashing. While the grain is mashed, the temperature is raised in steps, each of which optimizes the activity of a different hydrolase (**Fig. 3**). At 52°C, the protein hydrolases are activated. Then at 68°C, the starch hydrolases convert long-chain sugars to the disaccharide maltose, which can support yeast fermentation. The final temperature (77°C) inactivates all enzymes; then the mash is cooled, pressed, and filtered. The liquid filtrate of the mash is called wort.

Wort boiling. The wort is supplemented with hops, a traditional herb used for centuries in Europe to contribute a distinctive flavor of beer. After boiling with hops, the wort is again filtered.

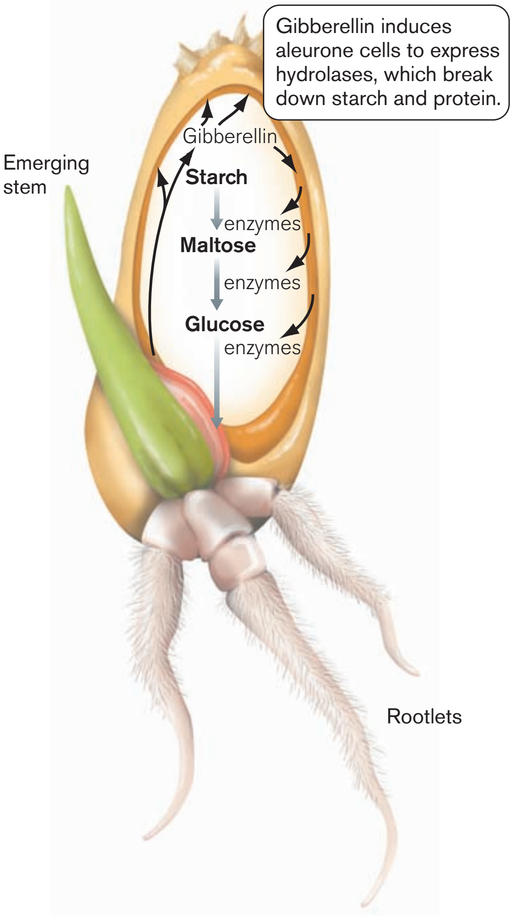
Fermentation. The wort is inoculated with a special strain of *Saccharomyces cerevisiae* known as brewer's yeast. The yeast conducts ethanolic fermentation on the maltose from hydrolyzed starch. At the same time, minor by-products, such as long-chain alcohols, impart good flavors. The time of fermentation is a key factor in the quality of the beer.

fructose as high as 15%. With simple sugars available, yeast can set to fermentation immediately, without need for preliminary breakdown of long-chain carbohydrates, as in the malting and mashing of beer.

Most modern wine production uses strains of the grape *Vitis vinifera*. The grapes are crushed to release juices, usually in the presence of antioxidants such as sulfur dioxide (**Fig. 16.21**). For white wine, the skins are removed before juice is fermented. For red wine, the skins are included in early fermentation to extract the red and purple anthocyanin pigments as well as phenolic flavor compounds. The first few days of fermentation are dominated by indigenous species of yeast naturally present on the grapes, such as *Kloeckera* and *Hanseniaspora* species. Commercial producers usually inoculate with standard *S. cerevisiae*, whose population dominates the late stage of fermentation (6–20 days). The yeast growth ends once the ethanol level reaches about 15%; to achieve higher alcohol content, distillation is required.

After fermentation, the wine is drained, or "racked," from the sediment of grape and yeast material, the lees. The liquid may be further clarified by centrifugation. Then it is stored for 2–3 weeks in tanks or barrels. During storage, a second stage of fermentation may be performed, called **malolactic fermentation**. In malolactic fermentation, the wine is seeded with *Oenococcus oeni* bacteria, which ferment L-malate (deprotonated L-malic acid), a side product from glucose fermentation. The L-malate is decarboxylated to L- or D-lactate:

$$^{-}OOC{-}CHOH{-}CH_2{-}COO^{-} \longrightarrow CH_3{-}CHOH{-}COO^{-} + CO_2$$



Gibberellin induces aleurone cells to express hydrolases, which break down starch and protein.

Figure 2 **Malting the grain.** Malting involves germination of the grain to induce expression of hydrolase enzymes.

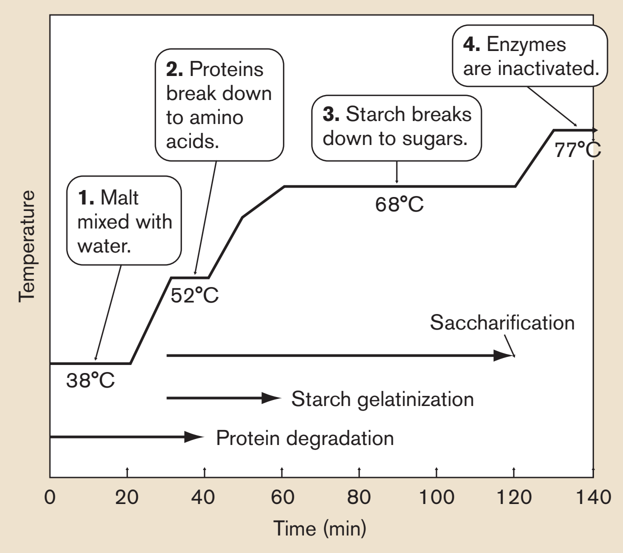

Figure 3 **Mashing the wort.** During mashing, stepwise heating activates the hydrolases to break down carbohydrates and proteins.

Postfermentation treatment. This includes filtering of the wort to remove the bulk of the yeast. The product, now recognizably beer, still contains undesirable levels of acetaldehyde and diacetyl generated by partial oxidation. These oxidized by-products can be reduced by the few remaining yeast cells during a period of secondary fermentation. During secondary fermentation, oxygen is completely excluded and the temperature is decreased to 15°C or lower. The best German beers are aged at 2°C for several months.

By removal of a carboxylate group as CO_2, malolactic fermentation decreases acidity of the wine, improving flavor. It also removes a potential carbon source whose later fermentation by undesirable organisms could spoil the wine.

As in the case of beer production, yeast fermentation of wine produces numerous minor products contributing flavor, such as long-chain alcohols and esters. At the same time, overgrowth of yeast or the growth of undesired species can produce excess amounts of these compounds, such as sulfides and phenolics, giving rise to off-flavors. Some undesired species require oxygen exposure, whereas others can grow during storage and bottling. The balance of microbial populations is challenging to control and has a major role in determining the quality of a given wine vintage.

TO SUMMARIZE:

- **Bread is leavened** by yeasts conducting limited ethanolic fermentation, producing enough carbon dioxide gas to expand the dough.
- **Injera** bread dough undergoes more extensive fermentation by indigenous organisms, and as a result generates multiple flavors.
- **Beer** derives from alcoholic fermentation of grain. Barley grains are germinated, allowing enzymes to break down the starch to maltose for yeast fermentation.
- **Secondary products of grain fermentation**, such as long-chain alcohols and esters, generate the special flavors of beer.
- **Wine** derives from alcoholic fermentation of fruit, most commonly grapes. The grape sugar (glucose) is

fermented by yeast to alcohol. A secondary product, malate, undergoes malolactic fermentation by *Oenococcus oeni* bacteria.

For white wine, the skins are removed before addition of yeast starter, and the temperature is kept low to retain volatile flavors. Both kinds of wine usually undergo malolactic fermentation by *Oenococcus oeni*, special lactic acid bacteria that consume malic acid. *Source:* G. H. Fleet. Wine. Chapter 37 in *Food Microbiology*, ASM Press.

16.5 Food Spoilage and Preservation

We humans have always competed with microbes for our food. When early humans killed an animal, microbes commenced immediately to consume its flesh. Because meat perished so fast, it made economic sense to share the kill immediately and consume all as soon as possible. Vegetables might last longer, but eventually succumbed to mold and rot. Later societies developed preservation methods, such as drying, smoking, and canning, that enabled humans to survive winters and dry seasons on stored food.

Modern food preservation depends on **antimicrobial agents**, chemical substances that either kill microbes or slow their growth, as well as physical preservative measures, such as treatment with heat and pressure. These general principles of microbial control are described in Chapter 5. Here we focus on microbial contamination and food preservation from the perspective of the food industry.

Food Spoilage and Food Contamination

After food is harvested, several kinds of chemical changes occur. Some begin instantly, whereas others take several days to develop. Some changes may be considered desirable, such as meat tenderizing, whereas others, such as putrefaction, render food unfit for consumption. The major classes of food change include:

- **Enzymatic processes.** Following the death of an animal, its flesh undergoes proteolysis by its own enzymes. Limited proteolysis tenderizes meat. Plants after harvest undergo other changes; for example, in harvested corn, the sugar rapidly converts to starch.
- **Chemical reactions with the environment.** The most common abiotic chemical reactions involve oxidation by air—for example, lipid autoxidation, which generates rancid odors.
- **Microbiological processes.** Microbes from the surface of the food begin to consume it, some immediately, others later in succession, generating a wide range of chemical products. In meat, internal organs of the digestive tract are an important source of microbial decay.

Microbial activity can aid food production, but it can also have various undesirable effects. Two different classes of microbial effects are distinguished: food spoilage and food contamination with pathogens.

Food spoilage refers to microbial changes that render a product obviously unfit or unpalatable for consumption.

For example, rancid milk or putrefied meats are unpalatable and contain metabolic products that may be deleterious to human health, such as oxidized fatty acids or organic amines. Even in these cases, however, the definition of spoilage partly depends on cultural practice. What is sour milk to one person may be buttermilk to another; what one society considers spoiled meat, another considers merely aged.

Different pathways of microbial metabolism lead to different kinds of spoilage. Sour flavors result from acidic fermentation products, as in sour milk. Alkaline products generate bitter flavor. Oxidation, particularly of fats, causes **rancidity**, whereas general decomposition of proteins and amino acids leads to **putrefaction**. The particularly noxious odors of putrefaction derive from amino acid breakdown products that often have apt names, such as the amines cadaverine and putrescine and the aromatic product skatole.

Food contamination, or **food poisoning**, refers to the presence of microbial pathogens that cause human disease; for example, rotaviruses that cause gastrointestinal illness. Pathogens usually go unnoticed as food is consumed because their numbers are very low, and they may not even grow in the food. Even the freshest-appearing food may cause serious illness if it has been contaminated with a small number of pathogens.

How Food Spoils

Different foods spoil in different ways, depending on their nutrient content, the microbial species, and environmental factors such as temperature. **Table 16.2** summarizes common forms of spoilage.

Dairy products. Milk and other dairy products contain carbon sources, such as lactose, protein, and fat. In fresh milk, the nutrient most available for microbial catabolism is lactose, which commonly supports anaerobic fermentation to sour milk. Fermentation by the right mix of microbes, however, leads to yogurt and cheese production, as previously described.

Under certain conditions, bitter off-flavors may be produced by bacterial degradation of proteins. The release of amines causes a rise in pH. Protein degradation is most commonly caused by psychrophiles, species that grow well at cold temperatures, such as those of refrigeration.

Cheeses are less susceptible than milk to general spoilage because of their solid structure and lowered water activity. However, cheeses can grow mold on their surface. Historically, the surface growth of *Penicillium* strains led to invention of new kinds of cheeses. Other kinds of mold, however, such as *Aspergillus*, produce toxins and undesirable flavors.

Meat and poultry. Meat in the slaughterhouse is easily contaminated with bacteria from hide, hooves, and intestinal contents. Muscle tissue offers high water content, which supports microbial growth as well as rich nutrients, including glycogen, peptides, and amino acids. The breakdown of peptides and amino acids produces the undesirable odorants that define spoilage (for example, cadaverine and putrescine).

Meat also contains fat, or adipose tissue, but the lipids are largely unavailable to microbial action because they consist of insoluble fat (triacylglycerides). Instead, meat lipids commonly spoil abiotically by autoxidation (reaction with oxygen) of unsaturated fatty acids, independent of microbial activity. Thus, when meat is exposed to air during storage, it turns rancid, particularly meats such as pork, which contains highly unsaturated lipids. Autoxidation can be prevented by anaerobic storage, such as vacuum packing, which also prevents growth of aerobic microorganisms. The absence of the suppressed organisms, however, favors growth of lactic acid bacteria and anaerobes such as *Brochothrix thermosphacta*. These organisms generate short-chain fatty acids, which taste sour.

In industrialized societies, the most significant determinant of microbial populations in meat spoilage is the practice of refrigeration. Refrigeration prolongs the shelf life of meat because contaminating microbes are predominantly mesophilic (grow at moderate temperatures, as discussed in Chapter 5). But ultimately, the few psychrotrophs initially present do grow; typically, these are *Pseudomonas* species. The pseudomonads are also favored by the low pH of meat (pH 5.5–7.0), which results from the accumulation of lactic acid in the muscle.

Seafood. Fish and other seafood contain substantial amounts of protein and lipids, as well as amines such as trimethylamine oxide. Fish spoils more rapidly than meat and poultry for several reasons. First, fish do not thermoregulate, and they inhabit relatively low-temperature environments. Because fish grow in low-temperature environments, their surface microorganisms tend to be psychrotrophic and thus grow well under refrigeration. In addition, marine fish contain high levels of the osmoprotectant trimethylamine oxide (TMAO), which bacteria reduce to trimethylamine, a volatile amine responsible for the "fishy" smell of seafood. Finally, the rapid microbial breakdown of proteins and amino acids leads to foul-smelling amines and sulfur compounds, such as hydrogen sulfide and dimethyl sulfide.

THOUGHT QUESTION 16.8 Why would bacteria convert trimethylamine oxide (TMAO) to trimethylamine? Would this kind of spoilage be prevented by exclusion of oxygen?

Table 16.2 Food spoilage (examples).

Food product	Signs of spoilage	Microbial cause
Milk and dairy products		
Milk	Sour flavor	Lactic acid bacteria produce lactic and acetic acids.
Milk	Coagulation	Lactic acid bacteria produce proteases that destabilize casein and lower pH, causing coagulation.
Milk	Bitter flavor	Psychrophilic bacteria degrade proteins and amino acids.
Cheese	Open texture, fissures	Lactic acid bacteria produce carbon dioxide.
Cheese	Discoloration and colonies	Molds such as *Penicillium* and *Aspergillus* grow on the cheese.
Meat and poultry		
Meat and poultry	Rancid flavor	Psychrotrophic bacteria produce free fatty acids, which become oxidized.
Meat and poultry	Putrefaction	*Pseudomonas* and other aerobes degrade amino acids, producing amines and sulfides.
Meat and poultry	Discolored patches	Molds such as *Mucor* and *Penicillium* grow on the surface.
Eggs	Pink or greenish egg white	*Pseudomonas* and related bacteria grow on albumin, producing water-soluble pigments.
Eggs	Sulfurous odor	Bacterial growth on albumin releases hydrogen sulfide.
Seafood		
Fish	Fishy smell	Anaerobic psychrophiles such as *Photobacterium* convert trimethylamine oxide (TMAO) to trimethylamine.
Fish	Odor of putrefaction	*Pseudomonas* and other gram-negative species degrade amino acids, producing amines and sulfides.
Shellfish	Odor of putrefaction	*Vibrio* and other marine bacteria decompose the protein.
Fruits, vegetables, and grains		
Plants before harvest	Rotting or wilting	Plant pathogens, most commonly fungi such as *Alternaria*, *Aspergillus*, and *Penicillium*
Stored plant foods	Rotting or wilting	Molds or bacteria produce degradative enzymes, such as pectinases and cellulases.
Apples, pears, cherries	Geosmin off-flavor	*Penicillium* mold
Peeled oranges	Discoloration and off-flavor	*Enterobacter* and *Pseudomonas* spp.
Pasteurized fruit juices	Medicine-like phenolic off-flavor	Acid- and heat-tolerant spore former, *Alicyclobacillus* sp., produces 2-methoxyphenol (guaiacol).
Bread	Ropiness	*Bacillus* spp.
Bread	Red discoloration	*Serratia marcescens*

Plant foods. Fruits, vegetables, and grains spoil differently than animal foods because of their high carbohydrate content and their relatively low water content. The low water content of plant foods usually translates into considerably longer shelf life than for animal-based foods. Carbohydrates favor microbial fermentation to acids or alcohols that limit further decomposition, and this microbial action can be managed to produce fermented foods, as described in Section 16.2.

A distinctive role is assigned to plant pathogens, which rarely infect humans but may destroy the plant before harvest. Most plant pathogens are fungi, although some are bacteria, such as *Erwinia* species. Historically, plant pathogens have caused major agricultural catastrophes, such as the Irish potato famine, caused by a fungus-like pathogen. Plant pathogens continue to devastate local economies and cause shortages worldwide; a contemporary example is the witches' broom fungus *Crinipellis perniciosa*, which causes a serious fungal disease of cocoa trees that has drastically cut Latin American cocoa production.

After harvest, various molds and bacteria can soften and wilt plant foods by producing enzymes that degrade the pectins and celluloses that give plants their structure. In general, the more processed the food, the greater the opportunities for spoilage. For example, citrus fruits generally last for several weeks, but peeled oranges are susceptible to spoilage by gram-negative bacteria.

Baked bread usually resists spoilage except for surface molds. However, in rare cases, improperly baked bread can show contamination. The appearance of red bread, caused by the red bacterium *Serratia marcescens*, is believed to have been responsible for the "blood" observed in communion bread during a Catholic mass in the Italian town of Bolsena in 1263, an event that became known as the Miracle of Bolsena.

Human Pathogens Spread through Food

The U.S. Centers for Disease Control and Prevention estimate that there are 76 million cases of gastrointestinal illness a year, usually spread through water or food. Thus, one in four Americans experiences gastrointestinal illness in a given year. Intestinal pathogens spread readily because many pathogens can be transmitted through food without any outward sign that the food is spoiled.

Food-borne pathogens typically arise from a range of sources; see, for example, the diagram of transmission of *Listeria monocytogenes*, a psychrotrophic pathogen that invades the cells of the intestinal epithelium, causing listeriosis (**Fig. 16.22**). (Psychrotrophic organisms grow optimally at moderate temperatures but also grow slowly at lower temperatures, typically 0–30°C.) *Listeria* can be transferred from soil and feed to cattle, whose manure then cycles it back to soil. From cattle, the pathogen contaminates milk and meat, where it can eventually infect human consumers. Because *Listeria* is a psychrotroph, it outcompetes other food-borne bacteria under refrigeration.

The U.S. Public Health Service judges the importance of food-borne illnesses based on their incidence and/or severity (**Table 16.3**). For example, the Norwalk-type viruses, or noroviruses, infect 180,000 Americans per year; their spread is very difficult to control, especially in close quarters, such as a cruise ship, where an outbreak can easily infect a large proportion of passengers. Fortunately, the course of illness, however unpleasant, is short, with few complications.

On the other hand, the spore-forming pathogen *Clostridium botulinum* causes only about 100 cases of botulism per year. The incidence is relatively low, but if untreated, the fatality rate is 50%. In this case, the low incidence of botulism actually enhances its danger because the condition is likely to go undiagnosed.

What distinguishes a pathogen from a spoilage organism? Pathogens possess highly specific mechanisms for host colonization, as discussed in Chapter 25. **Figure 16.23** shows intestinal crypt cells covered with *Escherichia coli* O157:H7 bacteria, an emergent pathogen first recognized in fast-food hamburgers.

Bacterial factors that contribute to disease are often encoded together in the genome in a region known as a **pathogenicity island**. A pathogenicity island consists of a set of genes and operons that function coordinately (as discussed in Chapter 9). The colocalization of the genes enables transfer of virulence capability to other species as pathogens evolve. **Figure 16.24** shows an example of a pathogenicity island in *Salmonella*. Four of its operons contribute to the Type III secretion complex, which

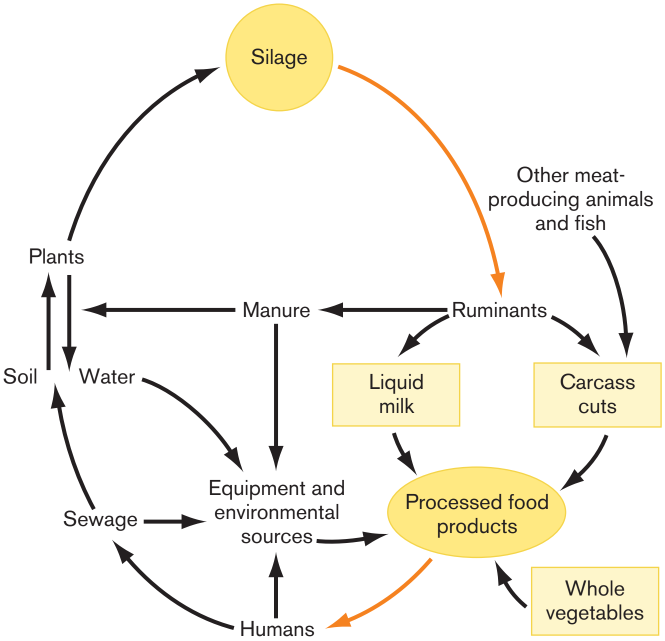

Figure 16.22 **Transmission of *Listeria monocytogenes*.** Transmission occurs through various routes, including passage through food products. Colored arrows indicate transmission of disease.

Table 16.3 Food-borne pathogens in the United States[a].

Pathogen	Incidence and transmission	Course of illness
Norovirus (Norwalk and Norwalk-like viruses)	Most common cause of diarrhea; also called "stomach flu" (no connection with influenza). 180,000 cases per year are estimated. Transmitted mainly by virus-contaminated food and water. Infection rates are highest under conditions of crowding in close quarters, such as inside a ship or a nursing home.	Disease lasts for 1 or 2 days. Includes vomiting, diarrhea, and abdominal pain; headache and low-grade fever may occur.
Salmonella sp.	Most common food-borne cause of death; more than 1 million cases per year; estimated 600 deaths per year. Transmission nearly always through food—raw, undercooked, or recontaminated after cooking, especially eggs, poultry, and meat; also contaminates dairy products, seafood, fruits, and vegetables.	Causes gastrointestinal disease that includes diarrhea, fever, and abdominal cramps lasting 4–7 days. Fatal cases are most common in immunocompromised patients.
Campylobacter	More than 1 million cases of campylobacteriosis per year; estimated 100 deaths per year. Grows in poultry without causing symptoms. Transmission is mainly through raw and undercooked poultry; contaminates half of poultry sold. Occurs less often in dairy products or in foods contaminated after cooking.	In humans, usually causes severe bloody diarrhea, fever, and abdominal cramps lasting 7 days. Fatal cases are most common in immunocompromised patients.
Escherichia coli O157:H7	An emerging pathogen, first recognized in a hamburger outbreak in 1982; now known to infect 73,000 yearly, including 60 deaths per year. Grows in cattle without causing symptoms. Transmitted most often through ground beef; also through unpasteurized cider and from salad items.	In humans, usually causes severe bloody diarrhea and abdominal cramps lasting 5–10 days. About 5% of patients, especially children and elderly, develop hemolytic uremic syndrome, in which the red blood cells are destroyed and the kidneys fail.
Clostridium botulinum	Causes about 100 cases per year of botulism, with a 50% fatality rate if untreated. *C. botulinum* grows in improperly home-canned foods, more rarely in commercially canned low-acid foods and improperly stored leftovers such as baked potatoes. Spores occur in honey, endangering infants under 2 years of age.	Botulinum toxin from growing bacteria causes progressive paralysis, with blurred vision, drooping eyelids, slurred speech, difficulty swallowing, and muscle weakness. Infant botulism causes lethargy and impaired muscle tone, leading to paralysis.
Listeria monocytogenes	*Listeria* bacteria grow in animals without symptoms. Animal feces may contaminate water, which is then used to wash vegetables. Transmission occurs mainly through vegetables washed in contaminated water and through soft cheeses. *Listeria* is psychrotrophic, growing at refrigeration temperatures.	Listeriosis involves fever, muscle aches, and sometimes gastrointestinal symptoms. In pregnant women, symptoms may be mild but lead to serious complications for the unborn child.
Shigella	*Shigella* infects about 18,000 people a year in the United States; in developing countries, *Shigella* infections are endemic in most communities. Transmission occurs through fecal-oral contact or from foods washed in contaminated water.	Shigellosis involves gastrointestinal symptoms such as diarrhea, fever, and stomach cramps, usually lasting 7–10 days. Complications are rare.
Staphylococcus aureus	*S. aureus* is best known as a skin infection transmitted through open wounds. However, *S. aureus* can also be transmitted through high-protein foods such as ham, dairy products, and cream pastries.	*S. aureus* causes toxic shock syndrome. Can also cause food poisoning via pre-formed toxins.
Toxoplasma gondii	*T. gondii* is a parasite believed to infect 60,000 people annually, most with no symptoms. In a few cases, serious disease results. *T. gondii* is transmitted through contact with feces of infected animals, particularly cats, or through contaminated foods such as pork.	Toxoplasmosis causes mild flu-like symptoms; but in pregnant women, its transmission to the unborn child can lead to severe neurological defects, including death. Neurological complications also occur in immunocompromised patients.
Vibrio vulnificus	*V. vulnificus* is a free-living marine organism that contaminates seafood or open wounds. About 40 cases per year are reported.	*V. vulnificus* can infect the bloodstream, causing septic shock. Mainly threatens people with preexisting conditions such as liver disease.

secretes toxins and host colonization factors (discussed in Chapter 25). Other genes encode outer membrane proteins that counteract host defenses, as well as regulators of virulence gene expression.

The most dangerous consequence of infection by food-borne pathogens is the production of a potentially fatal toxin. For example, *E. coli* O157:H7 infection of the intestines can be overcome, but the bacteria produce Shiga toxin, which can destroy the kidneys. In cases of adult botulism, *Clostridium botulinum* does not usually grow within the patient; the botulinum toxin comes from bacteria that grew previously in improperly sterilized food. The botulinum toxin has a highly specific effect, inhibiting synaptic vesicle fusion in the terminal of peripheral motor neurons (**Fig. 16.25**). Synaptic inhibition prevents activation of muscle cells, causing paralysis. Microbial toxins are discussed further in Chapter 25.

Food Preservation: Physical and Chemical Methods

Cultural practices and cuisines have long evolved so as to limit food spoilage. Such practices include cooking (heat treatment), addition of spices (chemical preservation), and fermentation (partial microbial digestion). In modern commercial food production, spoilage and contamination are prevented by numerous methods based on fundamental principles of physics and biochemistry that limit microbial growth (discussed in Chapter 5).

Physical means of preservation include:

- **Dehydration and freeze-drying.** Removal of water prevents microbial growth. Water is removed either by application of heat or by freezing under vacuum (known as **freeze-drying**, or **lyophilization**). Drying is especially effective for vegetables and pasta. The disadvantage of drying is that some nutrients are broken down.
- **Refrigeration and freezing.** Refrigeration temperature (typically –2°C to 16°C) slows microbial growth, as shown in an experiment comparing bacterial growth in ground beef at different temperatures (**Fig. 16.26**). Nevertheless, refrigeration also selects for psychrotrophs. Freezing halts the growth of most microbes, but preexisting contaminant strains often survive to grow again when the food is thawed. This is why deep-frozen turkeys, for example, can still

cause *Salmonella* poisoning, especially if the interior is not fully thawed before roasting.

- **Controlled or modified atmosphere.** Food can be packed under vacuum, or stored under atmospheres with decreased oxygen or increased CO_2. Controlled atmospheres limit abiotic oxidation as well as microbial growth. For example, CO_2 storage is particularly effective for extending the shelf life of apples.
- **Pasteurization.** Invented by Louis Pasteur, pasteurization is a short-term heat treatment designed to decrease microbial contamination with minimal effect on food value and texture. For example, milk is commonly pasteurized at 63°C for 30 minutes followed by quick cooling to 4°C. Pasteurization is most effective for extending the shelf life of liquid foods with consistent, well-understood microbial flora, such as milk and fruit juices.
- **Canning.** In canning, the most widespread and effective means of long-term food storage, food is cooked under pressure to attain a temperature high enough to destroy endospores (typically 121°C). Commercial canning effectively eliminates microbial contaminants, except in very rare cases. The main drawback of canning is that it incurs some loss of food value, particularly that of labile biochemicals such as vitamins, as well as loss of desirable food texture and taste.
- **Ionizing radiation.** Exposure to ionizing radiation, known as food irradiation, effectively sterilizes many kinds of food for long-term storage. The main concerns about food irradiation are its potential for unknown effects on food chemistry and the hazards of the irradiation process itself for personnel involved in food processing. Nevertheless, irradiation has proved highly effective at eliminating pathogens that would otherwise cause serious illness.

Often, two or more means of preservation are used in combination, such as acid treatment and refrigeration. For example, **Figure 16.27** shows results of a typical experiment measuring the effect of pH on microbial survival in refrigerated food—in this case, *E. coli* O157:H7 in Greek eggplant salad. Note the critical threshold pH required to decrease bacterial counts. At pH 4, about the pH of lemon juice, the bacteria show a steep exponential death curve, whereas at pH 4.5, the bacteria remain viable for many days.

Many kinds of chemicals are used to preserve foods. Major classes of chemical preservatives include:

- **Acids.** While microbial fermentation can preserve foods by acidification, an alternative approach is to add acids directly. Organic acids commonly used to preserve food include benzoic acid, sorbic acid, and propionic acid. The acids are generally added as salts: sodium benzoate, potassium sorbate, sodium propionate. These acids act by crossing the cell membrane in the protonated form, then releasing their protons at the higher intracellular pH. For this reason, they work best in foods that already have moderate acidity (pH 5–6), such as dried fruits and processed cheeses.
- **Esters.** The esters of organic acids often show antimicrobial activity, whose basis is poorly understood. Examples include fatty acid esters and parabens (benzoic acid esters). They are used to preserve processed cheeses and vegetables.
- **Other organic compounds.** Numerous organic compounds, both traditional and synthetic, have antimicrobial properties. For example, cinnamon and cloves contain the benzene derivative eugenol, a potent antimicrobial agent.

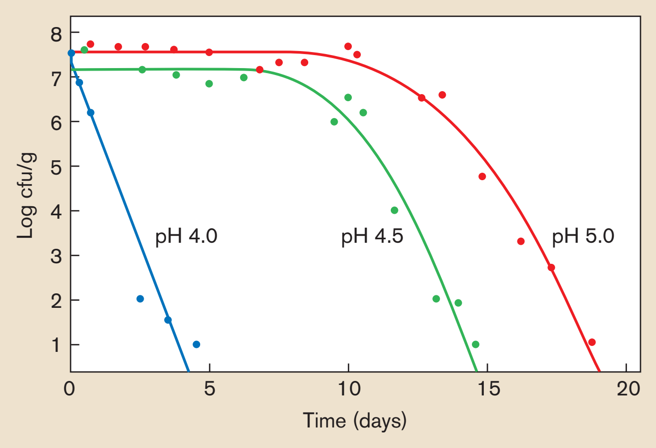

Figure 16.27 Bacteria die sooner at lower pH. Survival curves of *E. coli* O157:H7 in eggplant salad stored at 5°C at pH 4.0 (•), pH 4.5 (•), and pH 5.0 (•). *Source*: Panagiotis N. Skandamis and George-John E. Nychas. 2000. *Applied and Environmental Microbiology* 66:1646.

- **Inorganic compounds.** Inorganic food preservatives include salts, such as phosphates, nitrites, and sulfites. Nitrites and sulfites inhibit aerobic respiration of bacteria, and their effectiveness is enhanced at low pH. These substances, however, may have harmful effects on humans; nitrites can be converted to toxic nitrosamines, and sulfites cause allergic reactions in some people.

THOUGHT QUESTION 16.9 Is it possible for physical or chemical preservation methods to completely eliminate microbes from food? Explain.

TO SUMMARIZE:

- **Food spoilage** refers to chemical changes that render food unfit for consumption. Food spoils through degradation by enzymes within the food, through spontaneous chemical reactions, and through microbial metabolism.
- **Food contamination, or food poisoning**, refers to the presence of microbial pathogens that cause human disease, or toxins produced by microbial growth. Food harvesting, processing, and shared consumption are all activities that spread pathogens.
- **Dairy products** can be soured by excessive fermentation or made bitter by bacterial proteolysis.
- **Meat and poultry** are putrefied by decarboxylating bacteria, which produce amines with noxious odors.
- **Fish and other seafood** spoil rapidly because their unsaturated fatty acids rapidly oxidize; they harbor psychrotrophic bacteria that grow under refrigeration; and their TMAO is reduced by bacteria to the fishy-smelling trimethylamine.
- **Vegetables** spoil by excess growth of bacteria and molds. Plant pathogens destroy food crops before harvest.
- **Food preservation** includes physical treatments, such as freezing and canning, as well as the addition of chemical preservatives, such as benzoates and nitrites.

16.6 Industrial Microbiology

The production and preservation of food is only one field of **industrial microbiology**, the commercial exploitation of microbes. Industrial microbiology is commonly understood to include a broad range of commercial products relevant to microbes, including vaccines and clinical devices; industrial solvents and pharmaceuticals; bioinformatic analysis of genomes; and genetically modified plants and animals using microbial vectors. Another growing field of industrial microbiology is bioremediation and environmental engineering, covered in Chapters 21 and 22.

Industrial Microbiology Aims for Commercial Success

The practical application of a microbial product or device may arise out of an industrial laboratory, or it may be conceived by a research scientist with the aim of meeting a compelling need in society. For example, **Special Topic 16.3** profiles a biotechnology company formed to develop innovative products for the prevention, testing, and treatment of tuberculosis. In all cases, however, the key goal is success in the marketplace—that is, to generate a product that achieves adoption by customers in preference to alternative technologies. The product's sales must cover the costs of raw materials and production and (in a for-profit company) generate a profit for the shareholders. Success requires:

- **Identifying a useful product.** Possible products include small molecules, such as antibiotics; human proteins from cloned genes; or proteins from microbes with useful properties, such as thermostability.
- **Isolating a microbe to produce the product.** A novel product, such as an antibiotic, is generally discovered in a naturally occurring microbe. The genes encoding product biosynthesis are then cloned into an industrial vector.
- **Scaling up production in quantity.** The engineered microbial strain containing the vector with its cloned genes must be grown on an industrial scale, and the product must be isolated and purified.
- **Developing a business plan.** The scientist-entrepreneur must obtain partners skilled at industrial management, finance, and marketing. Patents must be filed to protect the intellectual property rights.
- **Safety and efficacy testing.** Human consumption or consumer use require many levels of clinical testing for approval by government agencies.
- **Effective marketing.** The benefits of the new product must be communicated effectively to convince customers of its superiority to current products or processes.

Failure at any of the preceding tasks spells doom for the product. Thus, a prudent business plan includes multiple alternative products in development. Although the failure rate of new products is high, all the products we use had to overcome these risks.

Molecular Products from Human or Microbial Sources

Increasingly, microbes are grown to produce a commercially valuable chemical substance, such as a vitamin, an

Special Topic 16.3 Start-Up Companies Take On Tuberculosis

In the 1990s, newspaper headlines announced the resurgence of tuberculosis (TB) in American cities. Carol Nacy was then a chief scientific officer at a small biotechnology firm, following a research career at the Walter Reed Army Institute of Research and a term as president of the American Society for Microbiology (**Fig. 1**). In 1996, Nacy was invited by the National Institutes of Health to assist in a review of tuberculosis research grant support to U.S. universities. She was surprised to discover the lack of attention to TB, a disease that is the world's number one killer of women aged 15–44 and the leading killer of men after traffic accidents. The United States spends $1 billion yearly to treat 16,000 active cases; yet the standard antibiotics for tuberculosis were developed before 1970, and the main diagnostic test available (the tuberculin skin test) dates to 1880, the time of Robert Koch. The best available vaccine, the bacille Calmette-Guérin (BCG) attenuated-live vaccine, is only 50% effective.

Despite the clear needs, tuberculosis has been of little interest to industrial research or development. So Nacy decided to found two new companies to address TB: a nonprofit medical research company to develop vaccines and conduct clinical trials and a for-profit company to develop innovative drugs and treatment devices.

Figure 1 Carol Nacy developed two companies to fight tuberculosis.

© Joanne Lawton/Washington Business Journal

A nonprofit company for vaccine development. The nonprofit company Aeras Global TB Vaccine Foundation, now directed by Jerald Sadoff, received $100 million in grants from the Bill and Melinda Gates Foundation—more than doubling the amount spent worldwide on TB vaccines in 1999. Additional funding came from the U.S. Centers for Disease Control and Prevention and from the government of Denmark. The Aeras foundation established a clinical trial site in Cape Town, South Africa. South Africa has the highest rate of pediatric TB in the world: over 500 cases per 100,000 persons. Aeras trained South African investigators and support staff in the art of clinical trials, while helping community health care workers to serve the local community. They helped test and counsel the community for HIV, a major risk factor for tuberculosis, and they vaccinated thousands of babies with BCG vaccine.

By 2005, Aeras had 12 different experimental TB vaccines in clinical and preclinical trials. The experimental vaccines are based on leading-edge principles of molecular biology, such as a recombinant vaccinia virus expressing antigenic proteins from *Mycobacterium tuberculosis*; recombinant fusion proteins from *M. tuberculosis*; and a mutant strain of the bacterium deleted for genes encoding two transcriptional sigma factors. An advanced "DNA vaccine" was developed consisting of a recombinant DNA vector designed to express antigenic proteins within host cells. The fundamental principles behind these experimental vaccines are introduced in Chapters 11 and 12.

A for-profit company develops drugs and devices. Nacy's for-profit company, Sequella, Inc., targeted innovative ideas with high risk but high potential to improve performance, rapidity, and safety of diagnosing and treating TB infections. Nacy and her cofounders scanned the academic community for novel ideas that had succeeded against TB in "proof of principle" animal models. The most promising ideas were developed for improved antibiotics, rapid and less invasive tests for TB exposure, and devices to measure the extent of pulmonary infection. Because any one idea had a high risk of failure, multiple prospects were pursued in each category.

industrial solvent, or an enzyme (**Table 16.4**). Each product requires a gene or operon of genes encoding either the product itself or the enzymes for the product's biosynthesis. We may distinguish between two fundamentally different sources of products: cloned genes from human, animal, or plant sources; and native microbial products, often from newly discovered species in extreme environments. Cloned human genes typically encode a protein of valuable function in the human body. For example, the Claragen company produces the recombinant human protein CC10, a lung development protein often deficient in the lungs of premature infants. The recombinant protein, produced and purified from a recombinant bacterium, can be provided to the infant to reduce lung inflammation.

Cloning of gene products in recombinant organisms is discussed in Chapter 12. Here we discuss obtaining

Several Sequella products have since reached advanced clinical trials. Their lead product is the Transdermal Patch Test, a diagnostic transdermal patch to distinguish between active TB and prior TB infection or BCG vaccination (**Fig. 2**). Prior to the transdermal patch, it has been difficult to determine whether an individual who tests positive for TB antibodies actually has active infection or has simply been exposed to the bacillus in the past. The transdermal product allows antigens to penetrate the skin without needle injection, and it produces results more reliable than the standard tuberculin skin test.

For treatment of TB, several promising new antibiotics are in the pipeline. The most promising antibiotic, SQ109, was discovered by high through-put screening of a chemical library, in collaboration with Clifford Barry at the National Institutes of Health. The chemical library consisted of over 60,000 analogs of a known TB antibiotic, ethambutol (**Fig. 3**). Ethambutol is part of the current standard course of treatment for TB, whose six-month time course has a poor compliance rate. It is hoped that improved drugs will shorten the time course and improve compliance, thereby decreasing the appearance of drug-resistant strains.

The analog molecules were selected based on a common diamine core, with different combinations of side chains. The 60,000 compounds in the library were subjected to combinatorial screening, a mathematically intensive analysis based on numerous tests. Of the compounds tested, 2,796 showed activity against *M. tuberculosis* in the test tube. The 69 best compounds were tested for cytotoxicity in tissue culture, activity in TB-infected macrophages, and activity in infected animals. The compound with the greatest efficacy and fewest side effects was SQ109, a molecule with an unusual cage-like side group of three fused rings. SQ109 is now in preclinical trials for toxicology and dose range. With these products, Sequella has positioned itself to develop more effective vaccines, diagnostics, and treatments to alleviate the global burden of tuberculosis—and to make a handsome profit for investors.

products from native microbial sources. For example, the Dutch company Novozymes markets over 600 microbial enzymes, including Stainzyme, a laundry detergent acting at lower temperatures, an oxidase to control bleaching of paper pulp, and proteases for leather treatment. Novozymes also produces numerous enzymes as biocatalysts for "green chemistry." Green chemistry refers to environmentally friendly procedures for reactions in organic chemistry, typically using water solution in place of petroleum-derived organic solvents.

Bioprospecting. To identify new microbial products, chemical companies screen thousands of microbial strains from diverse ecosystems. The search for organisms with potential commercial applications is called **bioprospecting**. Bioprospecting can be done anywhere,

Table 16.4 Commercial products from microbes.

Class of product	Product	Producer microbe[a]
Agricultural products	Gibberellin (plant hormone)	*Fusarium moniliforme* (fungus)
	Fungicides	*Coniothyrium minitans* (fungus)
	Insecticides (live pathogens)	*Bacillus thuringiensis*
Enzymes	Alpha-amylase	*Bacillus subtilis*
	Amyloglucosidase	*Aspergillus niger*
	Lactase (beta-galactosidase)	*Kluyveromyces lactis* (fungus)
	Lipases	*Candida cylindraceae* (yeast)
	Alkaline protease	*Aspergillus oryzae* (fungus)
Food supplements	L-Lysine	*Brevibacterium lactofermentum*
	L-Tryptophan	*Klebiella aerogenes*
	Monosodium glutamate (MSG)	*Corynebacterium ammoniagenes*
	Vitamin B_{12}	*Pseudomonas denitrificans*
	Vitamin C (ascorbic acid)	*Acetobacter suboxidans*
Fuels and solvents	Acetone	*Clostridium* spp.
	Butanol	*Clostridium acetobutylicum*
	Glycerol	*Zygosaccharomyces rouxii*
	Methane (natural gas)	Methanogens (archaea)
Organic acids	Acetic acid	*Acetobacter xylinum*
	Citric acid	*Aspergillus niger* (fungus)
	Lactic acid	*Lactobacillus delbruckii*
Pharmaceuticals: antibiotics	Streptomycin	*Streptomyces griseus*
	Penicillin	*Penicillium chrysogenum* (fungus)
	Erythromycin	*Saccharopolyspora erythraea*
	Tetracycline	*Streptomyces aureofaciens*
Pharmaceuticals: other drugs	Lysergic acid (LSD, hallucinogen)	*Claviceps paspali* (fungus)
	Cyclosporin (immunosuppressant)	*Trichoderma polysporum*
	Steroids	*Arthrobacter* spp.
Pharmaceuticals: cloned human proteins	Insulin	Recombinant *Escherichia coli*
	Interferon	Recombinant *E. coli* or *Saccharomyces cerevisiae*
	Human growth hormone	Recombinant *E. coli*
	CC10 lung development protein	Recombinant *E. coli*
	Antibodies	Baculovirus-infected caterpillars
	Cancer regulators	Baculovirus-infected caterpillars

[a] Bacteria, unless stated otherwise

from one's backyard to Yellowstone National Park. Unique, endangered ecosystems are the most promising sources of previously unknown microbial strains with valuable properties. Extreme environments, such as the hot springs of Yellowstone, are particularly promising because their products may tolerate conditions of temperature or pH required for industrial use. Psychrophiles from extremely cold environments, such as Antarctica, are a useful source for enzymes that do not require heating for activity, such as the Stainzyme laundry detergent.

An important aspect of bioprospecting is "mining the genome." Once a promising source strain is obtained, its genome is sequenced to investigate the genetic sequences that encode the useful product and regulate its expression. The operons encoding the product (or enzymes for its production) can then be cloned for optimal production (see Chapter 12). The cloned genes are transferred into an **industrial strain**, a strain whose growth characteristics are well studied and optimized for industrial production. An industrial strain must possess the following attributes:

- **Genetic stability and manipulation.** The industrial strain must reproduce reliably, without major DNA rearrangements. It must also have an efficient gene transfer system by which vectors can introduce genes of interest into its genome.

- **Inexpensive growth requirements.** Industrial strains grow on low-cost carbon sources with minimal special needs, such as vitamins, and at easily maintained conditions of temperature and gases.
- **Safety**. Industrial strains are nonpathogenic and do not produce toxic byproducts.
- **High level of product expression.** The strain or recombinant vector must possess an efficient gene expression system to generate the desired product as a high proportion of its cell mass.
- **Ready harvesting of product.** Either the product must be secreted by the cell or, if the product is intracellular, the cells must be easily breakable to liberate the product.

Species for industrial strains include the bacterium *Bacillus subtilis*, the yeast *Candida utilis*, and the filamentous fungus *Aspergillus niger*. Each of these species is safe, grows to high density on inexpensive carbon sources, such as molasses, and expresses desired products at high concentration.

THOUGHT QUESTION 16.10 Why would different industrial strains or species be used to express different kinds of cloned products?

Fermentation Systems

Commercial success requires optimizing every detail of the fermentation system. "Fermentation" in industrial terms refers not just to anaerobic metabolism, but to all means of growth of microbes on an industrial scale. In an **industrial fermenter**, the growth vessel and all its environmental supports, such as temperature control and oxygenation, must be scaled up to thousands of liters (**Fig. 16.28**). This increase in scale generates many problems of quality control, such as maintaining even temperature, pH, and oxygenation throughout the vessel and minimizing foaming of the culture liquid. A small change in any of the growth factors can impact production costs and profit margin. Another major concern is to avoid contamination by other organisms.

The fermenter is the core of the first half of industrial production, known as **upstream processing** (**Fig. 16.29**). Upstream processing refers to the culturing of the industrial microbe to produce large quantities of product. All aspects of the process must be controlled so as to maximize the final concentration of product, which in most cases peaks at a specific time in the microbial growth cycle. Following microbial growth, the culture must be harvested and the product purified. These processes constitute **downstream processing**. The first step of downstream processing is to separate the microbial cells from

the culture fluid, by centrifugation or by filtration. Next, the **primary recovery** of product follows one of two different pathways, depending on whether the product is maintained within the cells or secreted into the culture fluid. Many kinds of subsequent purification and finishing steps are necessary before the product has acceptable quality for its desired use. Again, failure of any detail can render the entire process unusable.

Products designed for human internal use face formidable hurdles in clinical testing and finally approval by the appropriate regulatory agency, such as the U.S. Food and Drug Administration (FDA). After millions of dollars are invested in process development, the product may still fail this final test and never come to market. Not surprisingly, a pharmaceutical company must research thousands of potential products before achieving one that makes a profit. The consumer cost inevitably includes the development costs not only of the one successful product, such as recombinant insulin, but also of all the products that failed.

Production in Animal or Plant Systems

Some kinds of products require subtle kinds of processing that occur correctly only within animal or plant cells. For example, protein products may require posttranslational modifications such as glycosylation (attachment of polysaccharide chains). In such cases, the expressed genes must be transferred from a bacterial or viral vector into an animal or plant tissue culture or to a transgenic animal or plant. The microbially transformed animal or plant may itself be the industrial product. We present two examples of microbial production involving multicellular hosts: that of the plant vector host *Agrobacterium tumefaciens* and that of the baculovirus insect vector.

***Agrobacterium tumefaciens* engineers plants.** Bacteria and viruses provide the vectors for transferring genes into multicellular organisms, as discussed in Chapter 12. A bacterium of major industrial importance is *Agrobacterium tumefaciens*, a tumor-inducing plant pathogen that conducts natural genetic engineering on dicot plants (**Fig. 16.30**►). Long before scientists invented “recombinant DNA,” *A. tumefaciens* had evolved a gene transfer system by which it induces infected plant cells to generate food molecules to feed the pathogen. This highly efficient gene transfer system is readily modified to insert genes of interest, such as herbicide resistance, into plant genomes.

Tumorigenic strains of *A. tumefaciens* possess a special plasmid for engineering plant cells, called the **Ti plasmid** (tumor-inducing plasmid). The Ti plasmid is transferred into a plant cell through a process mediated by bacterial proteins, similar to conjugation (discussed in Chapter 7). The Ti plasmid includes the *vir* operon, which encodes virulence genes, as well as T-DNA (transferable DNA), a sequence of genes that will be transferred to the host plant and recombined into its genome. T-DNA encodes tumor induction genes as well as enzymes for biosynthesis of a carbon and nitrogen source called an opine. Opines are specialized amino acids made by a one-step synthesis from arginine, typically by amination of a central metabolite such as pyruvate or 2-oxoglutarate. A given strain of *A. tumefaciens* typically provides one type of opine synthesis enzyme and has the ability to metabolize the corresponding opine.

The *vir* gene products from the Ti plasmid detect the presence of a plant host and stimulate plasmid transfer (see **Fig. 16.30**). In the cell envelope, VirA protein detects a chemical signal from a wounded plant, which is capable of being infected. VirA then activates VirG to induce expression of other *vir* genes, encoding endonucleases VirD1 and VirD2. The VirD endonucleases cleave the left and right ends of the T-DNA and direct its transfer into the plant cell. Within the plant cell nucleus, the T-DNA becomes integrated into the plant genome, where it induces opine production. The opine-producing cells proliferate, forming a tumor.

For industrial use, a recombinant strain of *A. tumefaciens* has the Ti plasmid divided into two separate plasmids. One contains the *vir* operon conducting DNA transfer, whereas the other plasmid contains T-DNA with its left and right ends intact but most of its genes substituted by a desired recombinant gene. Upon infection, the virulence system induces transfer of the T-DNA to the plant cell without any tumor-inducing genes, allowing genomic integration of the recombinant gene without tumor induction or opine production.

THOUGHT QUESTION 16.11 Why would an herbicide resistance gene be desirable in an agricultural plant? What long-term problems might be caused by microbial transfer of herbicide resistance genes into plant genomes?

Baculovirus in insects. Insect viruses such as baculovirus provide a surprisingly practical means of generating large amounts of product. The larvae, or caterpillars, grow rapidly on inexpensive substrates, accumulating large quantities of biomass. The most effective host is generally a strain of an aggressive pest such as *Trichoplusia ni*, the cabbage looper, an insect pest that feeds on the underside of cabbage leaves. Virus-infected caterpillars are used to

produce human proteins such as antibodies, growth factors, and antimicrobial peptides.

A baculovirus expression system (**Fig. 16.31**) was developed by insect virus researchers Max Summers and Gale Smith at Texas A&M University. This expression system involves two kinds of microbial vector: a bacterial plasmid carrying an engineered product gene and an insect virus. Baculoviruses are circular double-stranded DNA viruses that can infect a wide range of insects and insect cell lines in tissue culture. In the baculovirus expression system, the gene of interest, encoding, for example, a vaccine antigen, is first cloned into a standard bacterial plasmid, called the transfer vector. The transfer vector contains an antibiotic resistance gene, a cloning site for gene insertion, and a promoter from the polyhedrin gene, a baculovirus gene promoter that induces high-level expression in infected insect cells. The transfer vector plus linearized baculovirus DNA are cotransfected (introduced) into insect cells in tissue culture. For the virus to reproduce, it must recombine with the transfer vector, restoring the circularity of its genome. All the progeny virus particles now contain the recombinant gene, and when replicated, they will express it to make high levels of recombinant protein.

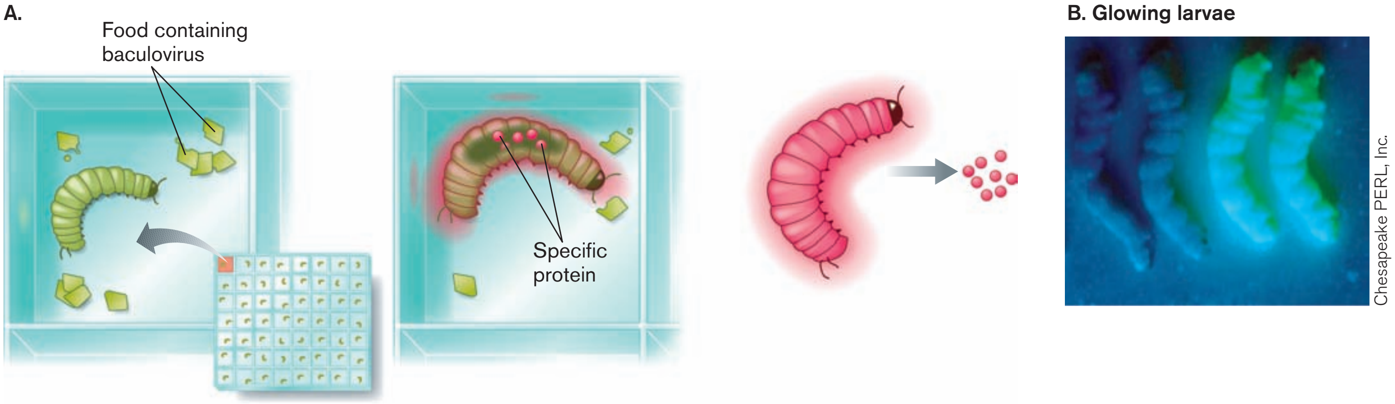
Protein expression requires growth of the recombinant virus in insect caterpillars. A remarkably efficient system of caterpillar protein production was developed by the company Chesapeake PERL, Inc. (**Fig. 16.32**). In the protein production system, *Trichoplusia* caterpillars hatch from eggs and grow within chambers full of food substrate. A recombinant baculovirus containing the desired product gene is sprayed into each chamber. The caterpillar eats the virus with its food, becoming infected. The recombinant virus then directs synthesis of its product, using the highly efficient promoter from the viral polyhedrin gene. In addition, a recombinant gene expresses a fluorescent marker protein such as DsRed. When the caterpillars glow with fluorescence, this signals that they are producing the desired protein and are ready for harvesting.

TO SUMMARIZE:

- **Industrial microbiology** includes the production of vaccines and clinical devices, industrial solvents and pharmaceuticals, and genetically modified plants and animals.
- **Microbial product molecules** may be indigenous or they may be cloned from nonmicrobial sources. Thermophiles and psychrophiles are particularly important sources of new strains with potentially interesting new properties.
- **Microbial products must be competitive** with alternative technologies. Developing a competitive new molecular product requires identifying a useful molecule, isolating and engineering a strain to produce it, scaling up for production in quantity, developing a business plan, and testing for safety.
- **Bioprospecting** is the mass screening of new microbial strains for potentially valuable protein and small-molecule products.



Week 1: Infection
The caterpillar hatches from the egg. It sits amid food in a container made of 56 individual cells, each of which contains one caterpillar. At week's end, a recombinant insect virus encoding a specific protein is sprayed into each cell.

Week 2: Production
As the caterpillar grows, it eats the virus-infested food and becomes infected. The recombinant virus directs it to produce the specific protein as well as a protein that causes it to glow.

End of week 2: Harvest
The caterpillar emits an intense glow signaling it's ready for harvesting. The caterpillars are ground up, and the specific proteins are separated and purified from caterpillar cadavers.

Figure 16.32 Insect caterpillars are engineered to produce a valuable protein. A. Caterpillars of *Trichoplusia ni* are infected with recombinant baculovirus, which produces a desired protein product as well as a fluorescent marker protein such as DsRed, indicating successful infection. **B.** The infected caterpillars ready for harvest fluoresce; compare with uninfected controls (dark).

- **Industrial strains**, commonly *E. coli* or *B. subtilis*, are used to incorporate the newly discovered genes into a host microbe.
- **Upstream processing** refers to the culturing of the industrial microbe to produce large quantities of product. **Downstream processing** involves product recovery and purification.
- **Posttranscriptional processing of human or plant genes** may be facilitated by use of a transgenic source or a virus-infected animal host.

Concluding Thoughts

Overall, we see how microbes from our environment contribute products for human use, from foods and vitamin supplements to industrial enzymes and highly specific protein therapeutics. These microbial applications incorporate much of the natural metabolism and biochemistry introduced in Chapters 13–15. Human inventiveness and industrial and financial management must meet many challenges to develop new microbial products.

CHAPTER REVIEW

Review Questions

1. What kinds of microbes are consumed as food? Why are most bacteria inedible for humans?
2. What are the advantages of fermentation for a food product?
3. What are the differences between traditional fermented foods and commercial fermented foods?
4. How do acidic fermentations contribute to the formation of different kinds of cheeses? What is the role of different kinds of metabolism performed by different microbial species?
5. Compare and contrast acidic and alkaline fermentation processes. What different kinds of foods are produced?
6. Compare and contrast the role of ethanolic fermentation in bread making and winemaking.
7. How do relatively minor fermentation reactions contribute to the flavor of food?

8. Explain the differences between food spoilage and food poisoning.

9. What are the most important food-borne pathogens, based on infection rates? Based on mortality rates?

10. What are the major means of preserving food? Compare and contrast their strengths and limitations.

11. What tasks must be accomplished to develop a microbial product for commercial marketing?

12. What are the sources of potential new microbial products? What is the difference between a source strain and an industrial strain?

13. Explain upstream processing and downstream processing.

14. Explain why genes encoding industrially useful products may be transferred into plant or animal systems for production. What are the roles of microbes in these systems?

Part 4

Microbial Diversity and Ecology

AN INTERVIEW WITH

KARL STETTER: ADVENTURES IN MICROBIAL DIVERSITY LEAD TO PRODUCTS IN INDUSTRY

Karl Stetter, professor at the University of Regensburg in Germany, was the first person to discover living organisms growing at temperatures above 100°C. Hyperthermophiles grow in hot springs and at thermal vents in the ocean floor. Such organisms possess exceptionally stable enzymes with enormous potential uses in industry. In 2004, Stetter cofounded the Diversa Company to isolate and develop such enzymes. For example, Diversa developed an enzyme for bleaching paper from a microbe isolated at a geyser in Russia. Such industrial enzymes often replace polluting processes with processes that are more environmentally friendly.

Why did you decide to make a career in microbiology?

I had been fascinated about microbes since I was a little child, when my parents had given me a simple microscope.

What enabled you to discover the hyperthermophile *Pyrodictium occultum*?

Just believe the laws of physics and chemistry and never believe prejudices (such as, "If it would exist, other people would have discovered it already"). Finding life above 100°C was a big surprise. I had to be perfectly sure about my results and confirmed them several times. It finally paid off, and this topic became my first *Nature* paper.

Would you describe the discovery that led to your 1982 paper ("Ultrathin mycelia-forming organisms from submarine volcanic areas having an optimum growth temperature of 105°C," *Nature* 300[1982]:258–260)?

This paper raised a lot of public interest; I even had to give my first (completely unexpected!) press conference. Here is how my discovery came about: During my family holidays in 1981, in order to check my hypothesis of life possibly existing above 100°C (under overpressure to keep the water liquid), I did some scuba sampling at the shallow hot vents off the coast of Vulcano, Italy. This had been my first attempt in underwater sampling. To do this, I developed some special sampling gear, which I used and improved on all my later diving expeditions (electronic waterproof thermometers with sturdy, very long probes, syringes with enlarged inlets, and so on). During our holidays, my wife and my little daughter Sabine had fun supporting me in our little rubber boat, processing the still-boiling hot samples that I brought up to the surface. The samples were kept anaerobic by injecting a reducing agent, a mixture of sodium dithionite and sodium sulfide.

Courtesy of Karl Stetter

Karl Stetter collecting samples from volcanic hot springs in Siberia.

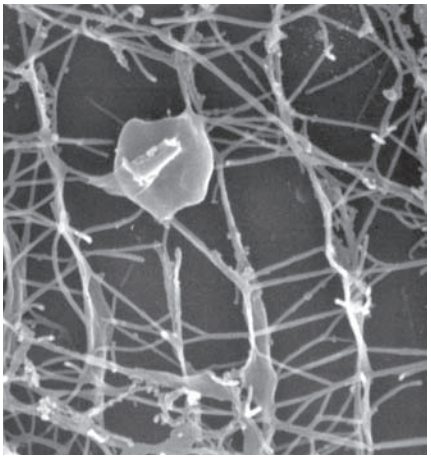
Back in the Regensburg lab, together with my technician, we began extensive cultivation attempts, which lasted for several months before the exciting bugs finally grew up. For the first time, from several samples at 100°C incubation temperature, disk-shaped cells grew up within two days. As we found out later, their fastest growth was in superheated water at 105°C, and their upper limit for growth temperature was even at 110°C!

What is it like for students working with extremophiles in the laboratory? How do you modify laboratory practice for the culture and observation of these organisms?

It's great fun for students to culture hyperthermophiles, as it is for me. It´s great to culture organisms that had been thought to be impossible. Of course, some safety briefing is essential to avoid lab accidents. Every culture bottle under pressure in my lab is housed in an explosion-safe cage. It's an incredible thrill being the first to see a novel bug growing!

What have we learned from the genome sequences of hyperthermophiles? What do they tell us about microbial evolution?

This question would require a whole book of answers. Here is my answer in a nutshell: Hyper-



Courtesy of Karl Stetter

***Pyrodictium occultum*, the first hyperthermophile discovered.** The disk-shaped archaeal cells form complex networks of interconnecting filaments. (Cell diameter, 2–4 μm.)

thermophiles harbor rather small genomes. Interestingly, their DNA double helix is not stabilized by an elevated GC/AT content of its DNA. Instead, all hyperthermophiles possess reverse gyrase to stabilize DNA. The enzymes and other proteins are structurally related to their homologs in mesophilic (moderate-growth-temperature) organisms.

A lot of horizontal gene transfer goes on in hyperthermophiles. The information-processing machinery in hyperthermophiles (small-subunit rRNA, and so on) appears to be still rather primitive. In the small-subunit rRNA–based tree of life, hyperthermophiles include all the deep-branching lineages of organisms that diverged earliest.

You also discovered the unusual hyperthermophilic symbiont *Nanoarchaeum*, which lives at marine vents at 70–98°C associated with another archaeon, *Ignicoccus*. *Nanoarchaeum* cells are only 400 nm in diameter and lack cell walls, their cell membranes covered only by a protein S-layer. They require cell-cell contact with an actively growing *Ignicoccus* cell in order to grow. What do we know about how these two organisms affect each other's growth?

Nanoarchaeum definitively needs *Ignicoccus* to grow. But *Ignicoccus* grows without *Nanoarchaeum.* This is all just under laboratory conditions. So far, we are pretty much away from a deeper understanding of this exciting symbiosis, which most likely has existed since the dawn of life.

Why is the Diversa Company so interested in your extremophiles?

From its onset, Diversa has been interested in extremophiles, with the view of developing sturdy enzymes as industrial catalysts. Diversa has already developed several promising products, such as stock food additives, enzymes for bleaching paper pulp, and oil recovery enzymes.

What do you think are the most exciting areas for students entering microbiology today? What advice do you have for today's students?

I think our hyperthermophile research at present is only the tip of a damned hot iceberg! But truly, there are so many exciting questions open in all kinds of fields in microbiology. Students should follow their passion and try to do an excellent job in whatever field they choose. And if they don't mind burning their fingers once in a while . . . well, then hyperthermophiles may be the right choice for them!

After sharing your early discoveries, how does your family relate to your work today?

My wife Heidi is a microbiologist and a high school teacher of chemistry and biology. Our oldest daughter Sabine is now an attorney in criminal law. Our son Florian is a very successful actor, on the stage and in movies.

What are your pursuits outside science?

In addition to my number one hobby—cultivating hot bugs—I grow tropical orchids in my greenhouse (about 500 species) and drive a hot car (Ferrari) at 190 miles per hour over the German Autobahn.

Chapter 17

Origins and Evolution

17.1 Origins of Life
17.2 Models for Early Life
17.3 Microbial Taxonomy
17.4 Microbial Divergence and Phylogeny
17.5 Horizontal Gene Transfer
17.6 Symbiosis and the Origin of Mitochondria and Chloroplasts

Microbial life may have appeared as early as 3.8 billion years ago, soon after our planet Earth formed out of dust from the young sun. Since then, microbes have diverged into new forms adapted to diverse ways of life, from psychrophiles beneath the ice of Antarctica to anaerobes in the human colon. Descendants of early microbes include all living plants and animals, including ourselves. How did microbes originate on Earth? How did their metabolism shape the chemistry of Earth's crust and atmosphere?

DNA sequence-based taxonomy has revealed vast numbers of previously unknown microbial species. How do we classify them? Some evidence, particularly the sequences of rRNA genes, support a traditional branched tree of life. Other gene sequences, however, support a more complex picture, including gene transfer between distant branches of the tree. Many microbes have evolved mutualistic partnerships with other living things, such as bacteria that fix nitrogen within plant cells. Still other microbes evolve as pathogens whose adaptations enable them to live at the expense of their host and cause disease.

A diver is sectioning a stromatolite, a layered community of cyanobacteria in a tidal pool in the Bahamas. Fossil stromatolites have been dated at 3.4 billion years ago, among the earliest forms of life on Earth. *Source*: Abigail C. Allwood, et al. 2006. *Nature* 441:714.

For centuries, observers of the natural world have wondered where life came from. As early as 1802, the naturalist Erasmus Darwin, grandfather of Charles Darwin, wrote:

Organic life beneath the shoreless waves
Was born and nurs'd in ocean's pearly caves;
First forms minute, unseen by spheric glass,
Move on the mud, or pierce the watery mass;
These, as successive generations bloom,
New powers acquire and larger limbs assume . . .

Thus, nineteenth-century biologists developed the idea that all living organisms had evolved from microbes, perhaps even from cells too small to be seen with the "spheric glass" of a microscope. Even without modern tools of isotope analysis and genetics, thoughtful observers recognized the overwhelming commonalities among all living cells, such as the membrane-bound compartment of cytoplasm and common metabolic pathways such as sugar metabolism. Today, lines of evidence from geology, biochemistry, and genetics overwhelmingly support the microbial origin of life.

What did early life look like? The earliest forms of life for which we have clear fossil evidence are bacterial communities called **stromatolites** (**Fig. 17.1A**). A stromatolite is a bulbous mass of sedimentary layers of limestone (calcium carbonate, $CaCO_3$) accreted by microbes over years, even centuries. Within the outer layers, microbes grow as a "microbial mat," a kind of biofilm. The outermost layers of the mat contain oxygenic phototrophs, such as diatoms and filamentous cyanobacteria, that exude bubbles of oxygen. A few millimeters below the surface, red light supports bacteria photolyzing H_2S to sulfate, which is then reduced by still lower layers of sulfate-reducing bacteria. Stromatolites today survive mainly in isolated pools whose high salt concentration excludes predators, as in Hamlyn Bay, Australia. But 3 billion years ago, in the absence of predators, stromatolites covered shallow seas all over Earth. Fossil stromatolites appear in ancient rock formations such as the 3.4-billion-year-old Strelley Pool Chert, a sedimentary formation in Pilbara Craton, Australia (**Fig. 17.1B**). Their layers preserve the wavy form of the microbial mats, remarkably similar to living stromatolites. Stromatolites are studied by NASA for clues as to how life may appear on other planets.

Questions about life's origin have long sparked controversy. In eighteenth-century Europe, the idea of "spontaneous generation" of microbes was considered so dangerous that priests and monks performed scientific experiments to disprove it (described in Chapter 1). The priests ultimately won their scientific point: All microbes today have "parents"—that is, preexisting microbes. But these experiments did not address the origin of the first living cells or how early life gave rise to modern species. This concept was so controversial that in the early twentieth century, laws forbade teaching it in American public schools. In 1929, such a law in Tennessee was put to the test by high school teacher John Scopes in what became the famous Scopes trial (**Fig. 17.2**). According to a 14-year-old student who testified at the trial, Scopes taught that "there was a little germ of one cell organism formed, and this organism kept evolving . . . and from this was man." A large body of evidence now supports the view that microbes living more than 3 billion years ago gave rise to all animals and plants as well as to all modern microbes.

Chapter 17 explores the evidence from geochemistry and molecular biology for the nature of the earliest cells, as well as the challenges in interpreting data from so long ago. We explore how molecular techniques reveal deep similarities among all life-forms: the core macromolecular apparatus of DNA, RNA, and proteins, expressed by genomes that share a common set of ancestral genes. We focus on three major concerns of microbial evolution:

- The origin of life on Earth and the nature of the earliest cells.
- The divergence of microbes from common ancestors.
- Gene transfer and symbiosis as agents of evolution.

17.1 Origins of Life

Before the first cells could evolve, several fundamental conditions were required. These conditions included:

- **Essential elements.** Because all life on Earth is composed of molecules, the origin of life required the fundamental elements that compose organic molecules.
- **Continual source of energy.** The generation of life requires continual input of energy, which ultimately is dissipated as heat. The main source of energy for life is the sun.
- **Temperature range permitting liquid water.** Above 150°C, life's macromolecules fall apart; below the freezing point of water, metabolic reactions cease. Maintaining the relatively narrow temperature range conducive to life depends on the nature of our sun, our planet's distance from the sun, and the heat-trapping capacity of our atmosphere.

Elements of Life

For life to arise and grow, elements such as carbon and oxygen needed to be available on Earth. The planet Earth coalesced during formation of the solar system 4.5 Gyr (gigayears, or billions of years) ago. Central to the solar system is our sun, a "yellow" star of medium size and surface temperature (5,770 K). The sun's surface temperature generates electromagnetic radiation across the spectrum, peaking in the range of visible light. As we learned in Chapter 13, the photon energies of visible light are sufficient to drive photosynthesis but not so energetic that they destroy biomolecules. Thus, the stellar class of our sun makes organic life possible.

NOTE: A billion means the number 10^9 in American English; but in British English, a billion is 10^{12}. For clarity, we designate 10^9 years as a gigayear, or **Gyr**. A million years (10^6) is a "megayear," or **Myr**.

The sun's surface temperature and luminosity are generated by nuclear fusion reactions in which hydrogen nuclei fuse to form helium. Yet 2% of the solar mass consists of heavier elements, such as carbon, nitrogen, and oxygen, as well as traces of iron and other metals—elements that compose Earth, including its living organisms. Where did these heavier elements come from? To answer this question, we must look to other stars in the universe at different stages of their development (**Fig. 17.3**).

Elements of life formed within stars. Throughout the universe, young stars such as our sun fuse hydrogen to form helium. As stars age, they use up all their hydrogen. With hydrogen gone, the aging star contracts and its temperature rises, enabling helium nuclei to fuse forming carbon (see **Fig. 17.3**). Carbon drives a cyclic nuclear reaction, the CNO cycle, to form isotopes of nitrogen and oxygen. Further nuclear reactions generate heavier elements through iron (Fe). Thus, the major elements of biomolecules were formed within stars that aged before the birth of our solar system.

The later nuclear reactions of aging stars generate heavier nuclei up to iron. The aging star expands, forming a red giant (see **Fig. 17.3**). When a star of sufficient mass expands (a supergiant), it explodes as a **supernova** (**Fig. 17.4**). The explosion of a supernova generates in a brief time all the heaviest elements and ejects the entire contents of the star at near-light speed. Billions of years before our sun was born, the first stars aged and died, spreading

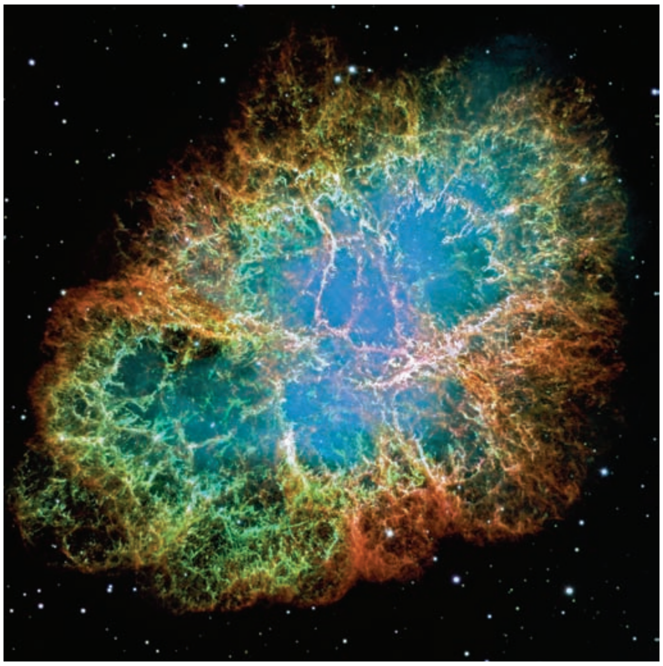
Elements formed in supernova become incorporated in new stars.

Figure 17.3 Stellar origin of atomic nuclei that form living organisms. In young stars, hydrogen nuclei fuse to form helium. In older stars, fusion of helium forms carbon, nitrogen, oxygen, and all the heavier elements up to iron. Massive stars explode as supernovae, spreading all the elements of the periodic table across space. These elements are picked up by newly forming stars, such as our own sun.



NASA/JPL-Science Faction

Figure 17.4 Crab Nebula, the remnant of a supernova. Observed by radioastronomy.

all the elements of the periodic table across the universe. Some of these elements coalesced with our sun and formed the planets of our solar system. In effect, all life on Earth is made of stardust, the remains of stars long gone.

THOUGHT QUESTION 17.1 What would have happened to life on Earth if the sun were a different stellar class, substantially hotter or colder than it is now?

Elemental composition of Earth. When our solar system formed, individual planets coalesced out of matter attracted by the force of gravity. Because of Earth's small size, most of the hydrogen gas escaped Earth's gravity very early. The most abundant dense component of Earth was iron (**Fig. 17.5**). Much of Earth's iron sank to the center to form the core. The core is surrounded by a mantle, composed primarily of iron combined with less dense crystalline minerals such as silicates of iron and magnesium, $(Fe, Mg)_2SiO_4$. The mantle is coated by Earth's thin outer crust. The crust is composed primarily of silicon dioxide, SiO_2, also known as quartz or chert. Crustal rock includes smaller amounts of numerous minerals, including the carbonates and nitrates that provided the essential elements for life. Overall, the crust shows a redox gradient, reducing in the interior and oxidizing at the surface.

The crust, also called the lithosphere, provides a habitat for microbes down to surprising depths, such as within gold mines excavated to 3 kilometer (km). Some **endolithic** microbes (microbes living within rock) metabolize by oxidizing electron donors generated through decay of radioactive metals. The discovery of endolithic organisms deep in the crust was of great interest to NASA scientists

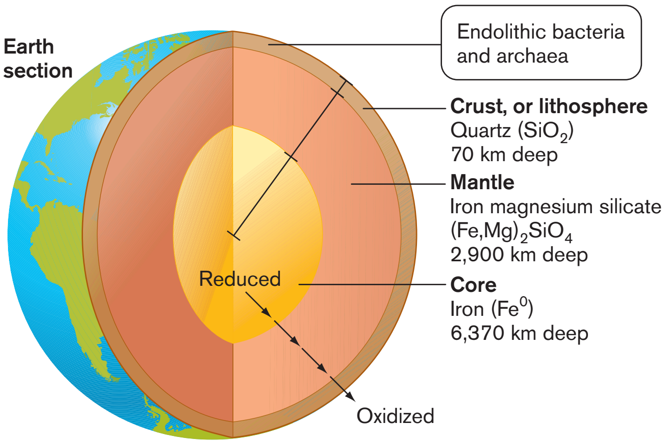


Figure 17.5 Geological composition of Earth. The cross section of Earth shows the core, the mantle, and the thin outer crust. The core and mantle are rich in iron; oxygen content increases toward the crust. The crust is composed primarily of silicates such as quartz (SiO_2). Crustal rock supports endolithic prokaryotes.

seeking life on Mars, whose crust might provide a similar habitat to Earth's.

The outer surface of the crust supports the remainder of the **biosphere**, the sum total of all life on Earth. The biosphere generates oxidants (electron acceptors), most notably O_2. Oxygen-breathing organisms can live only on the outer surface, where O_2 is produced by photosynthesis.

Earth's atmosphere. From the crust and the mantle of early Earth, volcanic activity released gases such as carbon dioxide and nitrogen, which formed Earth's first atmosphere, while volcanic water vapor formed the ocean. The composition of this first atmosphere, before life evolved, looked much like that of Mars: thin, about 1% as dense as that of Earth today, consisting primarily of CO_2. But unlike Mars, Earth developed living organisms that filled the atmosphere with gaseous N_2 and O_2 and that continue to produce these gases today. Organisms also produce CO_2, as well as fixing it into biomass. Some CO_2 and N_2 arise from geological sources such as volcanoes, but their contribution is small compared to that of biological cycles (discussed in Chapter 22). The overall composition of Earth's atmosphere is determined by living organisms, primarily microbes.

Temperature. Another important aspect of Earth's habitat, determined by the atmospheric density and composition, is temperature. Atmospheric gases absorb light and convert the energy to heat, raising the temperature of the surface and atmosphere. This rise in temperature is known as the **greenhouse effect**. Because carbon dioxide is an especially potent greenhouse gas, the CO_2-rich atmosphere of early Earth could have heated the planet to temperatures approaching that of Venus, eliminating the possibility of life. Instead, microbial consumption of CO_2 and generation of nitrogen and oxygen gases limited Earth's surface temperature to an average of 13°C. The cooling effect may have led to an ice age, possibly forestalled by rising methane from methanogens. One way or another, the history of Earth's atmosphere is intimately related to the history of microbial evolution.

Geological Evidence for Early Life

The first period of Earth's existence, ranging 4.5–3.8 Gyr ago, is designated the **Hadean eon** (**Fig. 17.6**), named for Hades, the ancient Greek world of the dead. During the Hadean eon, repeated bombardment by meteorites vaporized the oceans, which then cooled and recondensed. Meteor bombardment may have killed off incipient life more than once before living microbes finally became established. Still, scientists speculate whether some forms of life might have survived Hadean conditions, perhaps growing 3 km below the Earth's surface. Like the dead spirits imagined by the Greeks to have populated Hades, Earth's earliest cells might have reached deep enough within the crust that they were protected from the heat and vaporization at the surface. As of this writing, however, no geological evidence supports the existence of life earlier than 3.8 Gyr ago.

The Archaean era. The earliest geological evidence for life dates to 3.8–2.5 Gyr ago, in the **Archaean eon** (**Fig. 17.6**). In the Archaean, meteor bombardment was less frequent, and the Earth's crust had become solid. The Archaean marked the first period with stable oceans containing the key ingredient of life: liquid water. Water is a key medium for life because it remains liquid over a wide range of temperatures and because it dissolves a wide range of inorganic and organic chemicals. Rock strata dating to the Archaean era reveal the first evidence of living organisms and their metabolic processes.

NOTE: The term *Archaean* refers to the earliest eon in which life existed, whereas *archaeal* is the adjective referring to the taxonomic domain Archaea. The domain Archaea (originally, Archaebacteria) was named by Carl Woese based on his theory that the species of this domain most closely resembled the earliest life-forms of the Archaean eon. In fact, early life may have encompassed diverse traits later associated with archaea, bacteria, and eukaryotes.

Figure 17.6 Geological evidence for early life. The geological record shows evidence of microbial life early in Earth's history, 3 Gyr before the first multicellular forms.

How and when did living cells arise out of inert materials? Without a time machine to take us back 4 Gyr, we must rely on evidence from Earth's geology. Interpreting geology is a challenge because most forms of evidence for early life are indirect and subject to multiple interpretations. The farther back in time, the more change has occurred to the rock strata and the greater the difficulties. One way to meet this challenge, however, is to compare the results from different kinds of evidence (**Table 17.1**). If two or more kinds of evidence (such as microfossils and isotope ratios) point to life in the same location, the conclusion is strengthened.

Stromatolites. Fossil stromatolites are layers of carbonate or silicate rock that resemble modern living stromatolites. Presumably, the fossils formed as layers of phototrophic microbial communities grew and died, their form filled in by calcium carbonate or silica. Fossil stromatolites accepted by geologists date as early as 3.4 Gyr ago (see **Fig. 17.1**). These rock formations appear remarkably similar to the layered forms of stromatolites today. The ancient rock, however, is too deformed to reveal the detailed structure of cells, and the biological origin of such fossils is questioned by some researchers.

Microfossils. The most convincing evidence is the visual appearance of **microfossils**, microscopic fossils in which calcium carbonate deposits have filled in the form of ancient microbial cells (**Fig. 17.7**). Microfossils are dated based on the age of the rock formation in which they are found, which in turn is based on evidence such as radioisotope decay. Convincing microfossils need to show regular three-dimensional patterns of cells that cannot be ascribed to abiotic (nonbiological) causes.

Table 17.1 Geological evidence of early life.

Type of evidence	Advantages	Limitations
Stromatolites. Layers of phototrophic microbial communities grew and died, their form filled in by calcium carbonate or silica.	Fossil stromatolites can be observed in the oldest rock of the Archaean eon. Their distinctive shapes resemble those of modern living stromatolites.	Some layered formations attributed to stromatolites have been shown to be generated by abiotic (nonbiological) processes.
Microfossils. Early microbial cells decayed, and their form was filled in by calcium carbonate or silica. The size and shape of microfossils resemble that of modern cells.	Microfossils are visible and measurable under a microscope, offering direct evidence of cellular form.	Microscopic rock formations require subjective interpretation. Some formations may result from abiotic processes.
Isotope ratios. Microbes fix $^{12}CO_2$ more readily than $^{13}CO_2$. Thus, limestone depleted of ^{13}C must have come from living cells. Similarly, sulfate reduced by sulfate-respiring bacteria shows depletion of ^{34}S compared with ^{32}S.	Isotope ratios offer objective measurement of a highly reproducible physical quantity. They provide the best evidence for dating the earliest life. Isotope ratios generated by key biochemical reactions can calibrate the timeline of phylogenetic trees.	We cannot prove absolutely that no abiotic process could generate a given isotope ratio. Isotope ratios tell us nothing about the form of early life or how it evolved.
Biosignatures. Certain organic molecules found in sedimentary rock are known to be formed only by microbes. These molecules are used as biosignatures.	Biosignatures such as hopanoids are complex molecules and highly specific to different life-forms.	In the oldest of rocks, organic molecules are eliminated by metamorphic processes.
Oxidation state. The oxidation state of metals such as iron and uranium indicates the level of O_2 available when the rock formed. Banded iron formations (BIF) suggest oxidation by microbial phototrophs that intermittently produced oxygen.	Oxidized metals offer evidence of microbial processes even in highly deformed rock.	It is hard to rule out abiotic causes of oxidation. If biological processes were responsible, the kind of metabolism is not revealed.

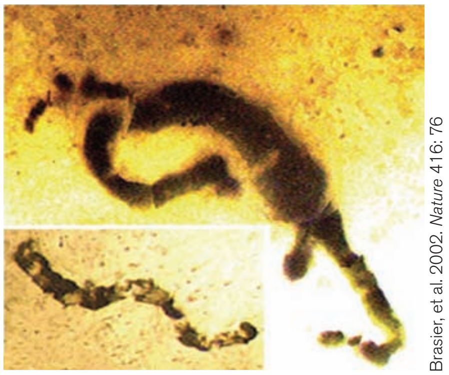
Figure 17.7 Microfossils compared with modern bacteria. **A.** Filamentous prokaryotes, 2.0 Gyr, from Gunflint formation, Ontario, Canada. **B.** Modern *Leptothrix* sp. filamentous bacteria. **C.** Colonial cyanobacteria, about 2.0 Gyr, from Belcher Islands, Canada. **D.** Modern *Entophysalis* cyanobacteria. **E.** Filamentous algae, 1.2 Gyr, from arctic Canada. **F.** Modern red algae, a eukaryote, *Bangia* species.

The earliest convincing microfossils are dated at 2.0 Gyr. Microfossils dated to 2.0 Gyr include filamentous prokaryotes in the Gunflint formation, Ontario, Canada (**Fig. 17.7A**). The Gunflint outcrops consist of chert, a kind of silicate formed by precipitation from an ancient sea. The sea was rich in carbonates and reduced iron, a good combination for redox metabolism. Some of the fossils resemble the form of filamentous iron-metabolizing bacteria today, such as *Leptothrix* species (**Fig. 17.7B**). Other microfossils dated at 2.0 Gyr resemble colonial cyanobacteria (compare **Fig. 17.7C** with **17.7D**). More recent strata, dated at 1.2 Gyr, contain larger fossil cells comparable to those of modern eukaryotes such as algae (**Figs. 17.7E** and **F**).

If life existed in more ancient times, such as the Archaean eon, where are the microfossils? Archaean rock is metamorphic, greatly modified by temperature and pressure. The macroscopic contours of stromatolites can be identified, but microfossil interpretation is highly



Brasier, et al. 2002. *Nature* 416: 76

Figure 17.8 Microfossils or artifacts? Structures originally identified as cyanobacterial microfossils from western Australia, dated to 3.85 Gyr. Further testing indicates that the structures are nonbiological artifacts.

controversial. For example, microfossils of cyanobacteria dated to 3.85 Gyr by William Schopf in the early 1990s were accepted and described in many textbooks (**Fig. 17.8**). The 3.85-Gyr fossils have since been reinterpreted by Martin Brazier and colleagues as nonbiogenic artifacts (caused by abiotic processes). The form of the proposed Archaean microfossils is less regular and convincing than the form of later specimens, particularly when observed at different angles not shown in the original publication.

Another kind of evidence is that of a **biosignature** or **biological signature**, a chemical indicator of life. Biosignatures have been found that are even earlier than the oldest fossils. Their significance is limited, however, as it is hard to rule out nonbiogenic explanations, so researchers seek additional, corroborating evidence based on independent principles.

Isotope ratios. An **isotope ratio** may serve as a biosignature if the ratio between certain isotopes of a given element is altered by biological activity. Enzymatic reactions, unlike abiotic processes, are so selective for their substrates that their rates may differ for molecules containing different isotopes. For example, the carbon-fixing enzyme rubisco, found in chloroplasts, preferentially fixes CO_2 containing ^{12}C rather than ^{13}C. The carbon dioxide fixed into microbial cells eventually is converted to calcium carbonate in sedimentary rock. Thus, the calcium carbonate deposited by CO_2-fixing autotrophs (such as cyanobacteria) shows lower ^{13}C content than calcium carbonate deposited by abiotic processes (**Fig. 17.9B**). The difference, $\delta^{13}C$, is defined by the fractional difference (in parts per thousand) between the $^{13}C/^{12}C$ ratios in a sample versus a standard inorganic rock:

$$\delta^{13}C = \frac{^{13}C/^{12}C\ (\text{experimental}) - {}^{13}C/^{12}C\ (\text{standard})}{^{13}C/^{12}C\ (\text{standard})} \times 1{,}000$$

Typical $\delta^{13}C$ values are shown in **Figure 17.9B**. Organisms on land and sea show $\delta^{13}C$ values of –10 to –30 parts per thousand, a significant ^{13}C depletion through carbon fixation. A comparable $\delta^{13}C$ is observed in fossil fuels, which formed from plant and animal bodies decomposed by bacteria.

B. ^{13}C isotope depletion

C. 2-Methylhopane

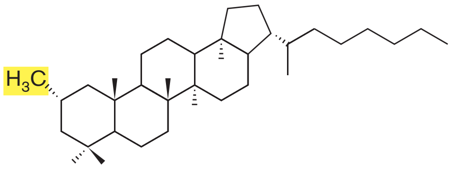

Figure 17.9 Biosignatures of early life. A. Minik Rosing (left), in Greenland, shows the Isua rocks whose carbon isotope ratios indicate photosynthesis at 3.8 Gyr. **B.** ^{13}C isotope depletion (negative $\delta^{13}C$) occurs in biomass as a result of the Calvin-Benson cycle. Negative $\delta^{13}C$ is observed at 3.7 Gyr in sedimentary graphite, which may derive from sedimented phototrophs. Little or no isotope depletion is seen in carbonate rock, which has no biological origin. **C.** 2-methylhopane, a biological signature of cyanobacteria, is found in rock strata dated at 2.5 Gyr. The 2-methyl group is highlighted.

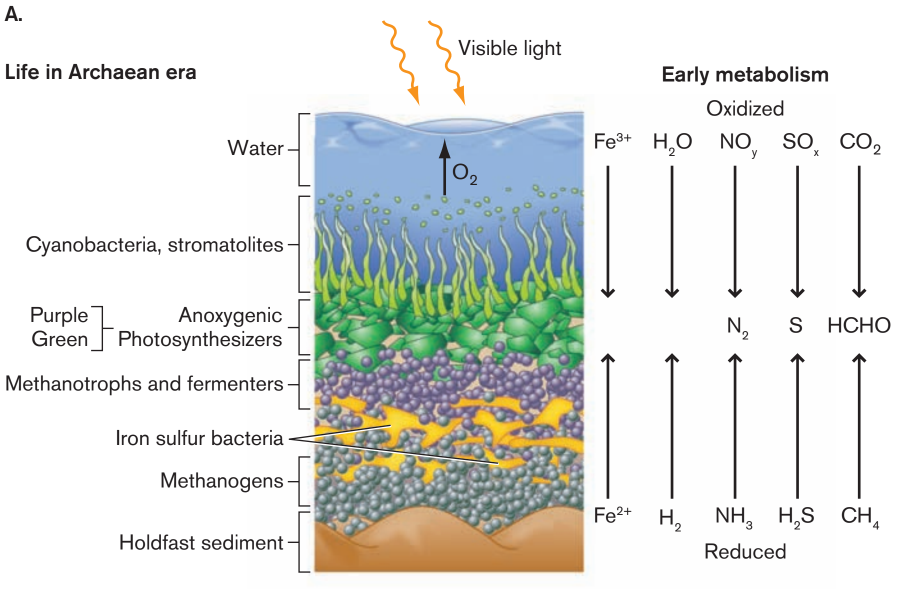

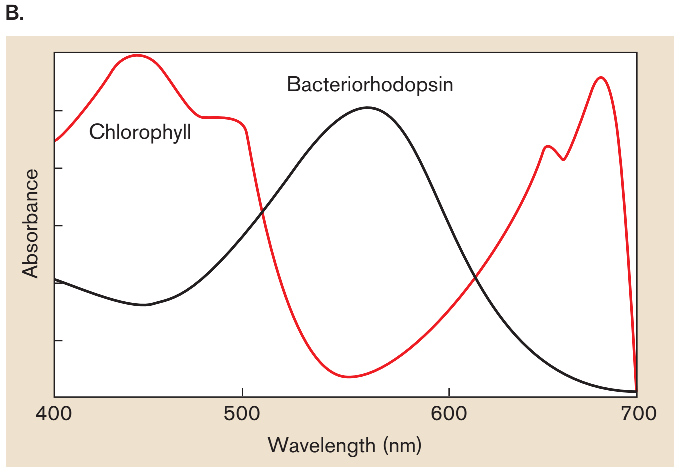

Figure 17.10 Early metabolism. **A.** Early metabolism could have been based on various reactions between oxidized minerals that diffuse down from the air and water and reduced minerals in the sediment, upwelling from hydrothermal vents. **B.** Early photosynthesis may have resembled that of haloarchaea, whose bacteriorhodopsin absorbs light in the central range of sunlight (yellow-green, 500–600 nm), in contrast to the chlorophyll of cyanobacteria and plants, which absorbs blue and red. *Source*: B. Shil DasSarma, U. Maryland.

The most ancient mineral samples showing a substantial $\delta^{13}C$ (about –18 parts per thousand) are graphite granules in the Isua rock bed of West Greenland, dated at 3.7 Gyr. The graphite granules were analyzed by Minik Rosing, a native Greenlander at the Danish Lithosphere Center (**Fig. 17.9A**). The graphite grains derive from microbial remains buried within sediment that subsequently metamorphosed, driving out the water content but leaving behind the telltale carbon. By contrast, carbonate rock of nonbiogenic origin from the same formation shows a $\delta^{13}C$ near zero.

Cyanobacterial hopanoids. A different kind of biosignature is given by organic molecules specific to a particular life form. Certain organic molecules may last within rock for hundreds of millions of years. A particularly durable class of molecules are membrane lipids. Recall from Chapter 3 that bacterial cell membranes contain steroid-like molecules called hopanoids (**Fig. 17.9C**). A hopanoid consists of four or five fused rings of hydrocarbon with variable side groups, depending on the bacterial species. The 2-methylhopanoids, containing a methyl side chain, are highly specific to cyanobacteria and are found in no other class of organism today. They are considered a biosignature of cyanobacteria.

The hopanoid derivative 2-methylhopane is found in sedimentary rock of the Hamersley Basin of Western Australia, dated to 2.5 Gyr. This highly specific biosignature is strong evidence that cyanobacteria existed by the end of the Archaean eon. Furthermore, because cyanobacterial photosynthesis is a relatively advanced form of metabolism, the finding suggests that more primitive microbes must have evolved earlier.

Metabolism of the First Cells

How did the earliest life-forms metabolize without oxygen gas to respire and without the complex machinery of photosynthesis? The nature of the first metabolism is unknown, but geochemistry and modern metabolism suggest several possibilities (**Fig. 17.10A**).

- **Oxidation-reduction reactions.** The early oceans contained oxidized forms of nitrogen, sulfur, and iron that could interact with reduced minerals from the crust. For example, nitrate (NO_3^-) or sulfate (SO_4^{2-}) could be reduced by hydrogen gas to yield energy (hydrogenotrophy, discussed in Chapter 14). The oxidized molecules were generated by reactions driven by ultraviolet radiation, which penetrated the atmosphere in the absence of the ozone layer. Sulfur isotope ratios ($^{34}S/^{32}S$) suggest the growth of sulfate-reducing bacteria as early as 3.47 Gyr ago.
- **Light-driven ion pumps.** A simple light-driven pump, such as the bacteriorhodopsin of haloarchaea (halophilic archaea), could have conducted the first kind of phototrophy. The absorption spectrum of

bacteriorhodopsin matches the peak of solar radiation reaching the upper layers of ocean (**Fig. 17.10B**), in contrast to the chlorophylls of cyanobacteria and plants, which absorb the outer ranges of blue and red. Perhaps cyanobacteria evolved in the presence of haloarchaea, filling the unexploited photochemical niches.

- **Methanogenesis.** Climate models of early Earth suggest a methane atmosphere, produced by methanogenic archaea. Methanogenesis involves reaction of H_2 and CO_2 producing CH_4 and H_2O. Methanogens show highly divergent genomes, a finding that suggests early evolution of their common ancestor. Their biochemistry and evolution (discussed in Chapter 19) are consistent with proposed models of ancient life.

Oxygen from Cyanobacteria Appeared Gradually

An extraordinary event in the planet's history was the evolution of the first oxygenic phototrophs, cyanobacteria that split water to form O_2. The entry of O_2 into Earth's biosphere is often portrayed as a sudden event that would have been disastrous to microbial populations that lacked defenses against its toxicity. In fact, geological evidence shows that oxygen arose gradually in the oceans, starting about 2 Gyr ago, and may have arisen and disappeared numerous times before reaching a high steady-state level in our atmosphere.

Banded iron formations. Evidence for oxygen in the biosphere comes from the oxidation state of minerals, particularly those containing iron. The bulk of crustal iron is in the reduced form (Fe^{2+}), which is soluble in water and reached high concentrations in the anoxic early oceans. Sedimentary rock, however, contains many fine layers of oxidized iron (Fe^{3+}), which is insoluble and forms a precipitate, such as iron oxide (Fe_2O_3). The layers of iron oxide suggest periods of alternating oxygen-rich and anoxic conditions. These layered iron minerals are called **banded iron formations (BIFs)** (**Fig. 17.11A**). A common form of banded iron consists of gray layers of silica oxide (SiO_2) alternating with layers colored red by iron oxides and iron oxyhydroxides [$FeO_x(OH)_y$]. Banded iron formations are widespread around the world and provide our major sources of iron ore (**Fig. 17.11B**).

Banded iron formations are often found in rock strata containing signs of past life such as ^{13}C depletion and other biomarkers. For example, the Isua formations (Greenland) and Hamersley formations (western Australia), which both show ^{13}C depletion, also contain extensive banded iron. Calculations show that the layers of oxidized iron could result from biological metabolism involving iron oxidation. One possibility is that the iron was oxidized by chemolithotrophs, using molecular oxygen produced by cyanobacteria. The Archaean and early Proterozoic eons experienced fluctuating levels of molecular oxygen in the atmosphere. These fluctuations could have led to oscillating levels of iron oxide thus producing bands in the sediment, as microbes used up all the oxygen.

Alternatively, Dianne Newman, at the California Institute of Technology, proposes that the iron oxides arose directly from anaerobic photosynthesis, in which the reduced iron served as the electron donor (**Fig. 17.12**). Photosynthetic oxidation of Fe^{2+} to Fe^{3+}, or "photoferrotrophy," could have occurred in cycles until the marine iron was all oxidized, generating sedimentary layers of iron oxides and iron oxyhydroxides. This argument was supported by Newman's discovery of iron phototrophy by modern purple bacteria such as *Rhodopseudomonas palustris*.

By 2.3 Gyr ago, the prevalence of oxidized iron and other minerals indicates the steady rise of oxygen from photosynthesis in Earth's atmosphere. All the dissolved Fe^{2+} from the ocean floor was oxidized, leaving the oceans in the iron-poor state that persists today. Oxygen as the most efficient electron acceptor enabled the evolution of aerobic respiratory bacteria. Aerobic bacteria gave rise to mitochondria, which enabled the evolution of eukaryotes and ultimately multicellular organisms (**Fig. 17.13**).

Remarkably, modern cells are still composed primarily of reduced molecules, highly reactive with oxygen, a relic of the time when our ancestral cells evolved in the absence of oxygen. The conditions under which such cells may have evolved can be simulated in the laboratory—conditions under which some of life's most common

molecules, such as adenine and simple amino acids, form spontaneously. These early-Earth simulation experiments can never prove the actual conditions under which life began, but they can suggest testable models with intriguing implications.

Origin and evolution of life on Earth

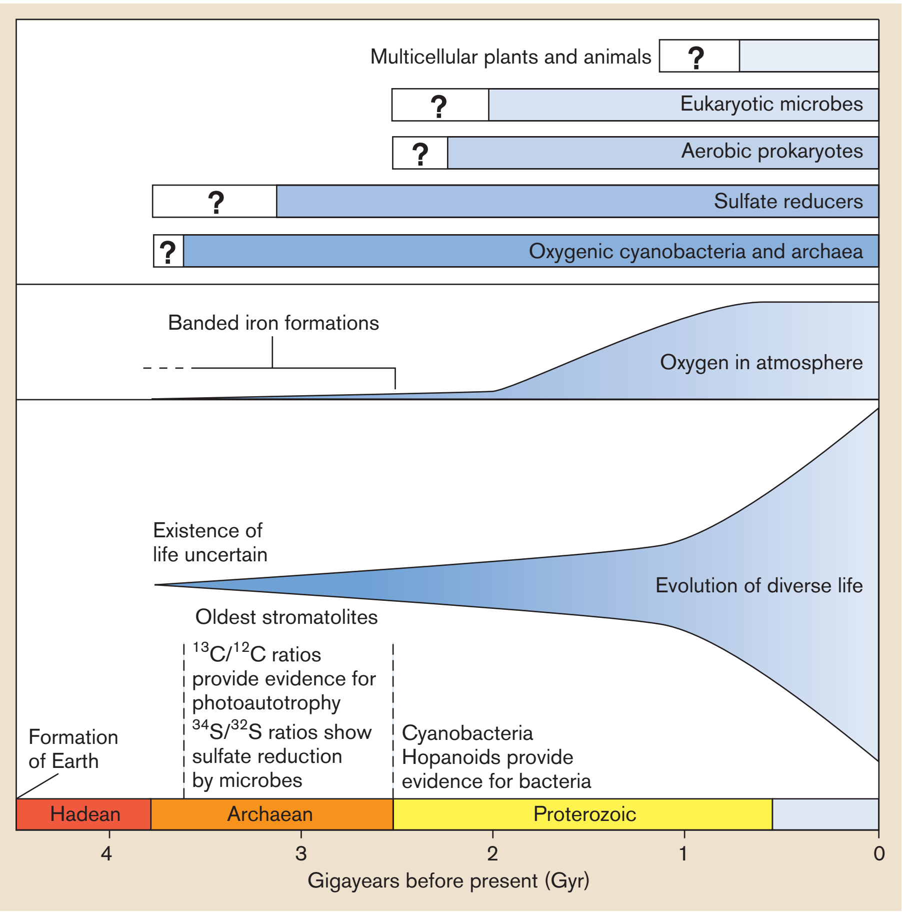

Figure 17.13 **Proposed timeline for the origin and evolution of life.** The planet Earth formed during the Hadean eon (about 4.5 Gyr ago). The environment was largely reducing until cyanobacteria pumped O_2 into the atmosphere. When the O_2 level reached sufficient levels (about 0.6 Gyr ago), multicellular animals and plants evolved. Question marks designate periods when evidence for given life-forms is uncertain.

TO SUMMARIZE:

- **Elements of life** were formed through nuclear reactions within stars that exploded into supernovae before the birth of our own sun.
- **Reduced molecules** compose Earth's interior. Oxidized minerals are found only near the surface. Early Earth had no molecular oxygen (O_2).
- **Archaean rocks show evidence for life** based on fossil stromatolites, isotope ratios, and chemical biosignatures. Fossil stromatolites appear in chert formations formed 3.4 Gyr ago. Isotope ratios for carbon indicate photosynthesis at 3.7 Gyr ago and sulfate reduction at 3.47 Gyr. Cyanobacterial hopanoids appear at 2.5 Gyr ago.
- **Microfossils of filamentous and colonial prokaryotes** date to 2.0 Gyr ago. At 1.2 Gyr, larger fossil cells resemble those of modern eukaryotes.
- **Early metabolism** involved anaerobic oxidation-reduction reactions. Likely forms of early metabolism include sulfate respiration, light-driven ion pumps, iron phototrophy, and methanogenesis.

- **Banded iron formations** reflect the cyclic increase and decrease of oxygen produced by cyanobacteria and consumed through reaction with reduced iron. After all the ocean's iron was oxidized, oxygen increased gradually in the atmosphere.

17.2 Models for Early Life

Various models have been proposed to explain how the first life-forms originated from nonliving materials and how they replicated and evolved. Models for early life attempt to address the following questions: In what kind of environment did the first cells form? What kind of metabolism did the first cells use to generate energy? What was their hereditary material?

Models for Origin of the First Cells

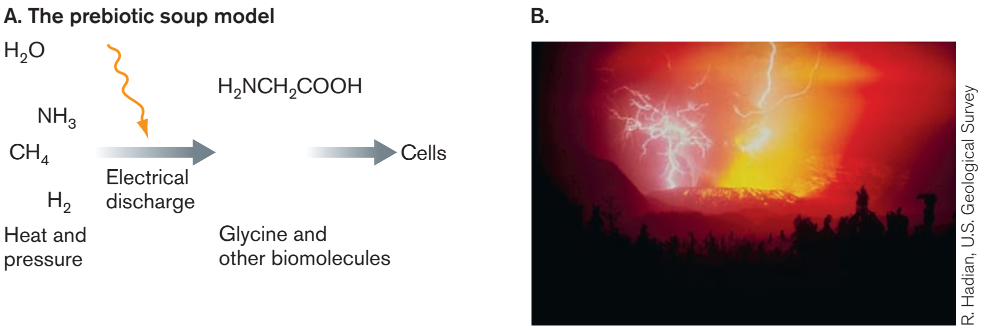
Models for early life include:

- **The prebiotic soup.** Organic building blocks of life could arise **abiotically** (in the absence of life) out of simple reduced chemicals such as ammonia and methane. This "prebiotic soup" could have generated complex macromolecules that eventually acquired the apparatus needed for self-replication and membrane compartmentalization.
- **Metabolist models.** The central components of intermediary metabolism, including the TCA cycle to generate amino acids, arose from self-sustaining chemical reactions based on inorganic chemicals. These abiotic reactions then acquired self-replicating macromolecules and membranes.
- **The RNA world.** Proposed by Francis Crick in the 1960s, the **RNA world** is a model of early life in which RNA performed all the informational and catalytic roles of today's DNA and proteins. The concept of an RNA world derives support from the emerging sequences of genomes, which reveal thousands of catalytic and structural RNAs.

The prebiotic soup. In the mid-twentieth century, biochemists Aleksandr Oparin, at Moscow University, and Stanley Miller and Harold Urey, at the University of Chicago, showed that organic building blocks of life could arise abiotically out of a mixture of water and reduced chemicals, including CH_4, NH_3, and H_2 (**Fig. 17.14**). The mixture was subjected to an electrical discharge, similar to the lightning discharges that arise from volcanic eruptions, which would have been common in the late Hadean or early Archaean eons. The chemical reaction produced fundamental amino acids such as glycine and alanine. Similar experiments by Juan Oró, at the University of Houston, showed the formation of adenine by condensation of ammonia and methane. The same amino acids and nucleic bases are found in meteorites, which are believed to retain the chemistry of the early solar system "frozen" in time.

The original model conditions for the prebiotic soup assumed that molecules in the early Archaean ocean were largely reduced, with little or no oxygen present in the atmosphere. More recent geochemical evidence suggests that the early ocean actually included oxidized forms of nitrogen, sulfur, and iron that arose through reactions driven by ultraviolet radiation, which penetrated the atmosphere in the absence of the ozone layer. These oxidized minerals could have reacted with the reduced crustal minerals, releasing energy to drive production of more complex biomolecules.

Forming the first cell, or "proto-cell," must have required enclosing the first biochemical reactants within a membrane-like compartment. Such compartments can arise spontaneously from fatty acid derivatives such as fatty acid glycerol esters. The fatty acid derivatives are "amphipathic," that is, they posses both hydrophobic portions that associate together as well as hydrophilic portions that associate with water. In water, the fatty acid derivatives collect in "micelles," small round aggregates in which the hydrophobic portions associate in the interior and the hydrophilic portions associate with water. Under certain conditions, micelles can aggregate to form hollow spheres of membrane. The membrane spheres can



R. Hadian, U.S. Geological Survey

Figure 17.14 The prebiotic soup model for the origin of life. **A.** In the prebiotic soup, inorganic molecules could have reacted to form complex macromolecules that eventually acquired the apparatus for self-replication and membrane compartmentalization. **B.** Lightning accompanies eruption of the Galunggung volcano in West Java, Indonesia, 1982. The first biomolecules may have formed as a result of lightning triggered by volcanic eruption.

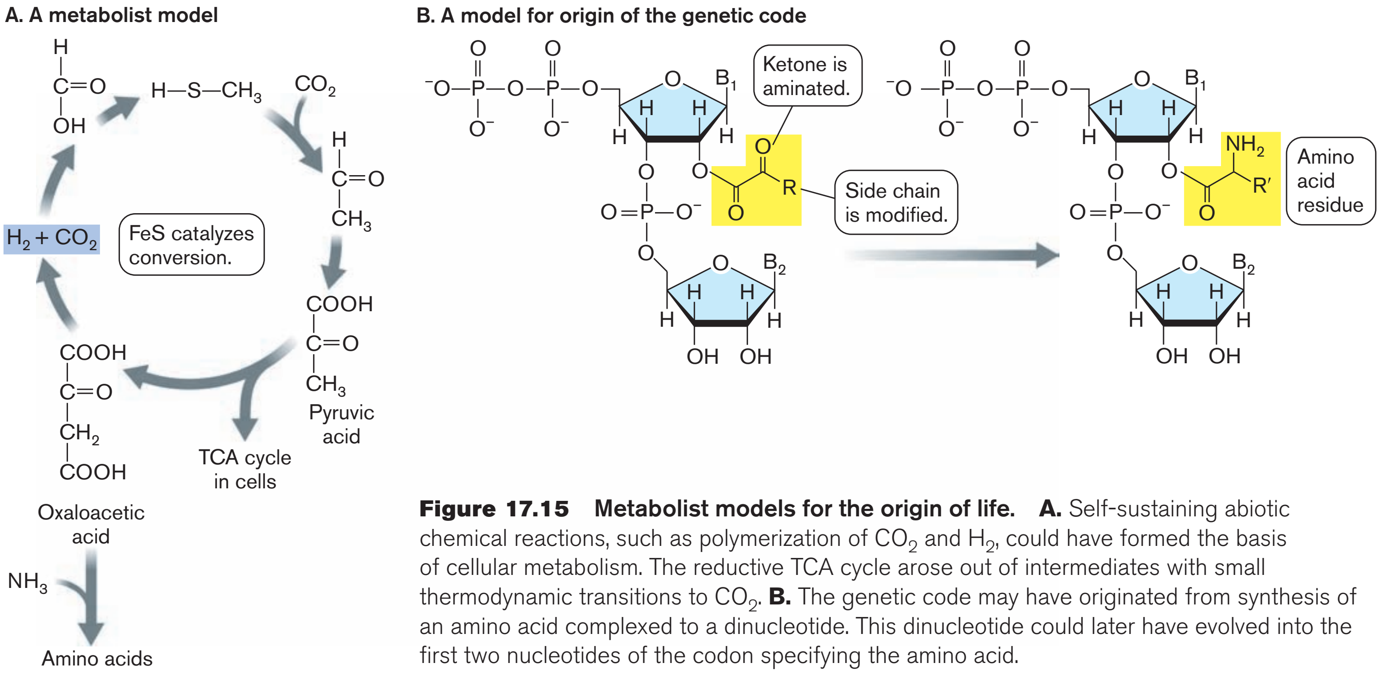
be made to enclose molecules such as RNA, suggesting a primitive cell-like form. These spontaneous processes of membrane formation suggest models for how the first living cells may have arisen.

Metabolist model. Other models attempt to explain the origin of biosynthesis based on CO_2 fixation, the fundamental metabolism of all life today. Proponents of a **metabolist model**, including Harold Morowitz and Günter Wächterhäuser, at George Mason University, propose that CO_2-based metabolism originated through self-sustaining reactions (**Fig. 17.15A**). Simulation experiments suggest that such premetabolic reactions could have been catalyzed by metal sulfides prevalent in the early ocean. For example, abiotic polymerization of CO_2 into TCA cycle intermediates may be catalyzed by FeS.

How did simple inorganic reactions lead to biochemical cycles involving more complex biopolymers such as nucleic acids and proteins? A major challenge is to explain the genetic code by which nucleic acid codons are assigned to unique amino acids. The genetic code may have arisen from an earlier pretranslational mechanism of amino acid biosynthesis (**Fig. 17.15B**). In this mechanism, proposed by Morowitz and colleagues, amino acids were originally synthesized from TCA cycle acids complexed to a dinucleotide. The dinucleotide later evolved into the first two nucleotides of the codon specifying the amino acid. The proposed dinucleotide association explains certain features of the genetic code, such as the fact that most amino acids specified by a codon starting with the same nucleotide are synthesized from the same TCA cycle acid (discussed in Chapter 15).

The RNA world. Neither the prebiotic soup model nor the metabolist models account for the evolution of macromolecules that encode complex information, such as nucleic acids and proteins. A candidate for life's first "informational molecule" is RNA. RNA is a relatively simple biomolecule, with only 4 different "letters," compared to the 20 standard amino acids of proteins. Its purine bases, especially adenine, have been shown to arise spontaneously from ammonia and carbon dioxide under conditions believed to resemble those of the Archaean eon. Its ribose sugar is a fundamental building block of living cells, with key roles in numerous biochemical pathways, including the Calvin-Benson cycle and the synthesis of deoxyribose for DNA. Compared to DNA, RNA is easier to form and degrade, and its pyrimidine base uracil is formed early by biochemical pathways; only later is it transformed to the thymine used by DNA.

Most importantly, RNA molecules have been shown to possess catalytic properties analogous to those of proteins. Catalytic RNA molecules are called **ribozymes**. The first ribozyme, discovered by Nobel laureate Tom Cech in the protist *Tetrahymena*, can splice introns in mRNA. Other ribozymes actually catalyze synthesis of complementary strands of RNA, suggesting a model for early replication of RNA chromosomes. The most elaborate example of catalytic RNA is found in the ribosome. In the ribosome, X-ray crystallography reveals that the



A. A metabolist model

B. A model for origin of the genetic code

Figure 17.15 Metabolist models for the origin of life. A. Self-sustaining abiotic chemical reactions, such as polymerization of CO_2 and H_2, could have formed the basis of cellular metabolism. The reductive TCA cycle arose out of intermediates with small thermodynamic transitions to CO_2. **B.** The genetic code may have originated from synthesis of an amino acid complexed to a dinucleotide. This dinucleotide could later have evolved into the first two nucleotides of the codon specifying the amino acid.

key steps of protein synthesis, such as peptide bond formation, are actually catalyzed by the RNA components, not proteins (discussed in Chapter 8). The ribosomal proteins possess relatively little catalytic function; their main role seems to be protection and structural support of the RNA.

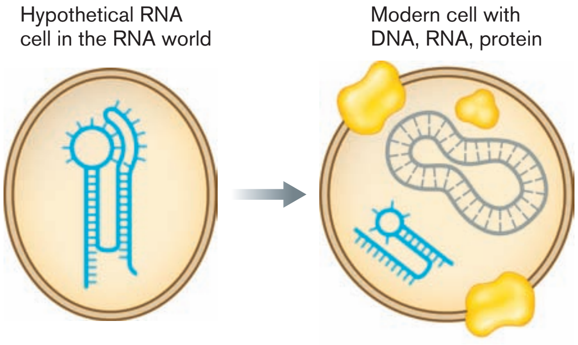
Thus, in the earliest cells, RNA might have fulfilled all the functions today filled by DNA and proteins, including information storage, replication, and catalysis (**Fig. 17.16**). This model is known as the "RNA world." The prominent function of RNA in the ribosome, one of life's most ancient and conserved molecular machines, leads to a model for the transition from an RNA world to the modern cell, with unexpected relevance for modern medicine (**Special Topic 17.1**).

The RNA world model explains the central role of RNA throughout the history of living cells. Yet the role of RNA offers little clue as to the origins of cell compartmentalization and metabolism. No one model of life's origin yet addresses all the requirements for a living cell—metabolism, membrane compartmentalization, and hereditary material. Each model does, however, offer important insights into the evolutionary history and mechanisms of life today.

THOUGHT QUESTION 17.2 Outline the strengths and limitations of each model of the origin of living cells. Which aspects of living cells does each model explain?

Unresolved Questions about Early Life

Overall, geology and biochemistry provide compelling evidence that organisms resembling today's cyanobacteria lived on Earth at least 2.5 Gyr ago, possibly 3.7 Gyr ago, and that bacteria with anaerobic metabolism evolved as early or earlier. Many intriguing questions remain. We outline here three unresolved questions regarding the temperature of early Earth, the role of methane in the early atmosphere, and the actual source of Earth's first cells.



Hypothetical RNA cell in the RNA world
Modern cell with DNA, RNA, protein

Figure 17.16 The RNA world model for the origin of life. In the RNA world, RNA molecules performed all the structural and catalytic functions performed today by proteins and DNA.

Thermophile or psychrophile? The apparent existence of life so soon after Earth cooled suggests a thermophilic origin. Thermophily is supported by the fact that in the domains Bacteria and Archaea, the deepest-branching species (that is, species that diverged the earliest from others in the domain) are thermophiles. Such organisms could have thrived at hydrothermal vents, which offer a continual supply of H_2S and carbonates.

On the other hand, after meteoric bombardment abated, early Earth should have become glacially cold. In the Archaean, solar radiation was 20–30% less intense than it is today, and the thin CO_2 atmosphere was insufficient to increase the temperature by a greenhouse effect. A colder habitat would support psychrophiles. Psychrophiles might have had an advantage in an "RNA world," given the thermal instability of RNA compared to DNA and proteins.

A world of methane? Among Earth's earliest life-forms were methanogens (methane producers). Methanogens are one of the most widely divergent groups of organisms and persist today in environments ranging from anaerobic sediment to the human intestine. Methanogenesis requires only carbon dioxide and hydrogen gas, which would have been plentiful in early anoxic sediment. The production of methane, an extremely potent greenhouse gas, could have greatly increased Earth's temperature during the Archaean. Thus, methanogenesis could explain how Earth escaped the permanent freeze of Mars. Overheating would have been halted when the oxygen gas produced by cyanobacteria enabled growth of methanotrophs, bacteria that oxidize methane. The decline of methane and the rise of CO_2 then brought about relative thermal stability.

The debate over temperature and climate of early Earth has interesting implications for Earth today when we again face the prospect of massive global climate change. Human agriculture favors explosive growth of methanogens, which threaten to accelerate global warming faster than the biosphere can moderate it. Understanding the climate of early Earth may help us better understand and manage our own climate, as discussed in Chapter 22.

Origin on Earth or elsewhere? Twenty years ago, the accepted picture of life's origin was still one of anaerobic early metabolism that gave rise much later to oxygenic and aerobic metabolism. But emerging evidence from fossils and geochemistry has inexorably pushed back the earliest known dates for several kinds of metabolism closer to 3.7 Gyr. This implies that as soon as Earth cooled to a temperature suitable for life, all the fundamental components of cells evolved almost immediately. How could

Special Topic 17.1 The RNA World: Clues for Modern Medicine

An intriguing question is how the cells of the hypothetical RNA world evolved to use proteins. Tom Cech, Sidney Altman, and colleagues propose that the earliest RNA components of cells acquired peptide components to enhance stability, decreasing the tendency of RNA to hydrolyze (**Fig. 1**). As the peptide components increased through natural selection, the RNA component may have shrunk by reductive evolution (the loss of a trait in the absence of selection pressure) until all that remained was one or two nucleotides. Dinucleotide cofactors such as NADH persist in enzymes today, perhaps representing vestigial remnants of the RNA world.

Furthermore, the persistence of ribonucleotides in molecular mechanisms of gene regulation argues for an early central role of RNA in cell function. Bacterial operons for ribosomal components and for purine and pyrimidine biosynthesis are regulated not by DNA-binding proteins but by RNA molecules known as riboswitches, that interact with the DNA promoters (discussed in Chapter 15). Finally, many viruses have RNA genomes and ribozymes that interact with host cells in unique ways, as discussed in Chapters 6 and 11.

If cells acquired proteins through evolution, how did they acquire DNA? A controversial proposal by Patrick Forterre, at the University of Paris-Sud in Orsay, France, is that DNA was acquired through viruses. As discussed in Chapters 6 and 11, many kinds of viruses are capable of inserting their genomes into a host cell for replication along with host chromosomes. Viruses could have evolved DNA as a modified form of chromosome that avoided cleavage by protective enzymes of the RNA-genomic host. A viral DNA molecule within a host cell could eventually acquire genes from the host RNA chromosome by recombination or reverse transcription. Host genes converted to DNA would tend to outlast their RNA counterparts because of DNA's greater stability. Eventually, according to Forterre's model, the entire host cell genome would be converted to DNA.

The study of life's origin some billions of years ago may seem distant from modern human concerns. Yet investigation of early-life phenomena such as ribozymes has led to important developments in medical research. Jennifer Doudna and colleagues discovered the function of an unusual RNA component of hepatitis C virus (**Fig. 2**). The hepatitis viral mRNA possesses a specialized stem loop structure called an internal ribosome entry site (IRES). The IRES binds to a host ribosome and shuts down host protein synthesis while facilitating translation of the viral mRNA. The IRES site then catalyzes cleavage of the RNA to complete the formation of viral genomes by rolling circle replication.

Figure 1 Transition from the RNA world to modern cells. A. Nobel laureate Tom Cech (left) proposed a model for the RNA world transition to protein-based cells. He is shown here discussing a student's poster at an international workshop on ribozymes in Dundee, Scotland; 2001. **B.** Earliest cells may have been composed of RNA enzymes (ribozymes). As the RNA cells evolved, the ribozymes acquired protein subunits that eventually assumed most of the catalytic functions. Remnants of the original RNA may persist as nucleotide cofactors such as NADH. **C.** Nobel laureate Sidney Altman (right) studies a genomic sequence with a student at Yale University. *Source*: B. *Yale Bulletin* 2002–2003 Vol. 2, Number 1.

Doudna published the first structure of an IRES bound to a ribosome initiation site (**Fig. 2B**). The IRES binds specifically to the ribosome at the mRNA recognition groove, so as to facilitate transcription of viral templates while excluding those of the host. Its tertiary structure positions a cytosine just right so as to catalyze hydrolysis of the RNA backbone (**Fig. 2C**).

The study of viral ribosomes has led to design of artificial ribozymes for chemotherapy. One goal is to design a ribozyme to cleave a gene transcript essential in cancer cells. The potential applications of artificial ribozymes have led to the start-up of several ribozyme companies; for example, Ribozyme Pharmaceuticals, Inc. (RPI) conducts clinical trials on ribozymes to treat cancer.

life, with all its diverse kinds of metabolism, have arisen so quickly?

The mystery deepens as we combine geochemistry with **phylogeny**, the measurement of genetic relatedness (discussed in the next section). Australian geochemist Roger Buick and colleagues at the University of Washington discovered early evidence of sulfate respiration based on isotope ratios of sulfur (**Fig. 17.17A**). Sulfate reducers use sulfate (SO_4^{2-}) as an electron acceptor to catabolize organic compounds in the absence of O_2 (as discussed in Chapter 14). The sulfate reductase enzyme preferentially acts on ^{32}S, generating sulfide depleted for ^{34}S. Buick discovered ^{34}S-depleted sulfides trapped in rock crystals of formations in western Australia dated to 3.47 Gyr.

The early date was surprising because sulfate respiration is performed by a class of bacteria that evolved relatively late, based on DNA sequence analysis (**Fig. 17.17B**). Sequence similarity data show that sulfate respirers diverged from other bacteria well after bacteria diverged from archaea and eukaryotes. So if the sulfate respirers had already diverged by 3.47 Gyr ago, when did bacteria diverge from archaea?

DNA sequence analysis shows that the common ancestor of bacteria, eukaryotes, and archaea already possessed most of the complexity of the organisms that diverged from it. Furthermore, data from Buick's laboratory in 2006 indicates biosignatures of eukaryotes as early as 2.4 Gyr ago, far earlier than was thought possible.

If the rate of evolution were constant, the three major domains would have diverged before the formation of Earth. In other words, life would have evolved elsewhere, and then come to Earth.

The idea that life-forms originated elsewhere and "seeded" life on Earth is called **panspermia**. Theories of panspermia remain highly speculative. One hypothesis is that microbial life originated on Mars and was then carried to Earth on meteorites. As the solar system formed, Mars would have cooled sooner than Earth, and as a smaller planet, its weaker gravity would have generated less bombardment by meteorites. Martian rocks ejected into space by meteor impact have reached the Earth, and calculations based on simulated space habitats show that microbes could survive such a journey. A Martian origin, however, only gains us about half a billion years; it does not really explain the origin of life's complexity and diversity. Did life-forms come from still farther away, perhaps borne on interstellar dust from some other solar system?

An alternative possibility is that early evolution on Earth occurred much faster than later evolution. Simpler reproductive entities such as viruses mutate and evolve much faster than modern cells. If early cells mutated as fast as viruses, they would have evolved faster than indicated by molecular clock molecules such as small-subunit ribosomal RNA (a method discussed in Section 17.3). Thus, for example, the common ancestor of Buick's sulfate reducers and cyanobacteria may have arisen on Earth but evolved much faster than later bacteria. The answers are unknown.

THOUGHT QUESTION 17.3 Suppose living organisms were to be found on Mars. How might such a find shed light on the origin and evolution of life on Earth?

Figure 17.17 Chemical biosignatures calibrate microbial divergence. A. Roger Buick, Australian geochemist, explores isotope ratios and fossil evidence for early microbial life. Besides science, he likes "listening to punk bands, reading interminable Russian novels and arguing politics ferociously." **B.** The divergence of major life-forms is based on comparing sequences of small-subunit rRNA. Discovery of ^{34}S-depleted rock formations 3.5 Gyr old suggests that sulfate respirers evolved by that time. Other biosignatures calibrate the divergence of eukaryotes at 2.70 Gyr. *Source*: B. Based on Shen, et al. 2001. *Nature* 410:77–81.

TO SUMMARIZE:

- **Prebiotic soup models** propose that the fundamental biochemicals of life arose spontaneously through condensation of reduced inorganic molecules.
- **Metabolist models** propose that components of intermediary metabolism arose from self-sustaining chemical reactions that connected nucleotides with amino acids, forming the basis of the genetic code.
- **The RNA world model** proposes that in the first cells, RNA performed all the informational and catalytic roles of today's DNA and proteins.
- **Thermophile or psychrophile?** Classic models of early life assume thermophily, but Earth may actually have been cold when the first cells originated.
- **A world of methane?** If the first cells were methanogens, methane production could have led to the first greenhouse effect, warming the Earth and enabling evolution of other kinds of life.
- **Origin on Earth or elsewhere?** Isotope ratios suggest the presence of complex metabolism by 3.7 Gyr ago, shortly after Earth cooled (3.9 Gyr ago). Simpler cells existing before 3.9 Gyr ago may have evolved much faster than life today, or they may have come to Earth from another location, where life evolved earlier. These hypotheses are highly speculative.

17.3 Microbial Taxonomy

Once living cells arose, they evolved and diverged, generating all the many diverse forms of modern life, an ongoing process that continues as populations become extinct while new groups emerge. The description of distinct life-forms and their organization into different categories (**taxa**, singular **taxon**) is called **taxonomy**. Taxonomy includes **classification**, the recognition of different classes of life; **nomenclature**, the naming of different classes; and **identification**, the recognition of the class of a given microbe isolated in pure culture. In this section, we consider how different kinds of microbes are classified and identified, based on DNA sequence as well as phenotypic traits. DNA sequences often bring surprises, upsetting traditional assumptions about life's family tree.

Classification and Nomenclature

Classification generates a hierarchy of taxa (groups of related organisms) based on successively narrow criteria. The fundamental basis of modern taxonomy is DNA sequence similarity; but the use of DNA arises within a long historical tradition of phenotypic description that shapes the views and practice of microbial taxonomy. Historically, taxa have been defined and named based on a combination of genetic and phenotypic traits. The nomenclature of microbes remains surprisingly fluid; as new traits are identified and the genetic sequence of a microbe is established, species are all too frequently renamed. Current information on microbial names is available through online databases such as List of Prokaryotic Names with Standing in Nomenclature.

WWW | List of Prokaryotic Names with Standing in Nomenclature

Traditional classification designates levels of taxonomic hierarchy, or **rank**, such as phylum, class, order, and family. Some levels of rank are designated by certain suffixes: for example, -*ales* (order) and -*aceae* (family). The ultimate designation of a type of organism is that of **species**, which includes the capitalized **genus name** (group of closely related species) followed by the uncapitalized **species name**, for example, *Streptomyces coelicolor.*

The conventions of nomenclature and levels of rank vary widely across different taxa, as seen in **Table 17.2**. Species with a long history of study tend to show many levels of rank in the literature, whereas species discovered recently show relatively few, regardless of genetic diversity. *Streptomyces coelicolor* is a well-studied member of the actinomycetes, filamentous Gram-positive bacteria that produce many complex natural products, including antibiotics. The actinomycetes are subdivided into classes, orders, and families, as well as sublevels of the traditional ranks. Compare the actinomycetes with a species of a more recently described class, the hyperthermophilic methanogen *Methanocaldococcus jannaschii* (formerly *Methanococcus jannaschii*). *M. jannaschii* is defined only by the minimal levels of rank, without subclasses or suborders.

Still more recent, a group of mostly unculturable marine species, the SAR11 cluster, was found to comprise approximately 25% of all marine microbial cells. SAR11 was originally defined based on its small-subunit rRNA sequence of uncultured environmental samples. Surprisingly, the rRNA sequence places these marine oligotrophs in the order Rickettsiales, most of whose known members are obligate intracellular parasites, such as *Rickettsia*, the cause of Rocky Mountain spotted fever. The SAR11 cluster has not been classified below the rank of order, except for one species cultured in 2002, *Pelagibacter ubique.*

NOTE: Taxonomic categories generally have two forms, formal and informal. The formal term is capitalized, with a latinized suffix: Actinomycetales, *Pseudomonas*, *Micrococcus*. The informal term is lowercase, in some cases with an anglicized ending; and informal references to genera are not italicized: actinomycete, pseudomonad, micrococci.

Table 17.2 Taxonomic hierarchy of classification.

Taxon rank	A long-studied taxon	A less-studied taxon	An uncultivated environmental sample
Domain	**Bacteria**	**Archaea**	**Bacteria**
Division (phylum)	**Actinobacteria** Filamentous gram-positive	**Euryarchaeota** Methanogens and halophiles	**Proteobacteria** Purple bacteria and relatives; gram-negative
Class	**Actinobacteria** High GC gram-positive	**Methanococci** Methanogens	**Alpha Proteobacteria** Gram-negative bacteria
Subclass	**Actinobacteridae**		
Order	**Actinomycetales** Filamentous; acid-fast stain	**Methanococcales** Methanogenic cocci	**Rickettsiales** Includes intracellular bacteria
Suborder	**Streptomycineae**		
Family	**Streptomycetaceae** Filamentous; hyphae produce spores	**Methanocaldococcaceae** Thermophilic methanogens	**SAR11 cluster** Nonculturable planktonic marine bacteria
Genus	***Streptomyces***	***Methanocaldococcus***	***Pelagibacter***
Species (date first described)	***S. coelicolor*** (1908)	***M. jannaschii*** (1984)	***P. ubique*** (2002)

Nongenetic Categories for Medicine and Ecology

Genetic relatedness is the standard for classifying and naming organisms in all fields of biology. At the same time, several nongenetic systems of categorization serve a practical purpose in certain fields. These systems include:

- **Phenotypic categories for identification.** Categories such as pigmentation or cell shape (rod or coccus) may have minor genetic significance but are useful for practical identification of organisms isolated from field or clinical sources.
- **Ecological categories.** In ecology, the niche filled by an organism may be more important than its phylogeny. For example, cyanobacteria and sequoia trees both fill the role of photosynthetic producer of biomass. Both are primary producers, a trophic category of organisms that feed other organisms in the food web. Ecological categories are discussed further in Chapter 21.
- **Disease categories.** In medical microbiology, microorganisms are categorized according to the type of disease they cause or the host organ system they inhabit. For example, *Mycoplasma pneumoniae* and influenza virus are both pulmonary pathogens, whereas *Escherichia coli* and *Bacteroides thetaiotaomicron* are both normal gut flora. Disease categories are discussed further in Chapters 25 and 26.

Defining a Species

What is a species? Among eukaryotes, a species is defined by the principle that members of different species do not normally interbreed with each other. Thus, the failure to interbreed is the traditional property defining species. Microbes, however, and especially prokaryotes, reproduce asexually, so interbreeding is not a basis for classification. At the same time, microbes show much evidence of **horizontal transfer** of genetic material (also known as **lateral transfer**), that is, gene flow between distantly related species. Horizontal transfer is particularly problematic in natural communities where distantly related organisms interact. In the laboratory, on the other hand, one population may give rise to many different isolated strains that acquire different mutations during laboratory cultivation, such as resistance to an antibiotic. Even populations frozen away in laboratory stocks may show selective survival of genetic variants.

Microbial species are defined based on DNA relatedness. Members of a common species are generally defined as a value of 70% or greater genomic sequence similarity based on DNA-DNA hybridization, and 97% ribosomal small subunit sequence similarity. However, definitions of a species are debated. For example, the genus *Salmonella* historically was subdivided into hundreds of species and subspecies. In 1987, a study based on DNA analysis proposed renaming all *Salmonella* bacteria as members of a single species, *Salmonella enterica*, subdivided by subspecies and serovars (strains expressing envelope proteins with different antigenicity). Clinicians objected, however, insisting on retaining species designation for certain strains that cause distinctive diseases, such as *Salmonella typhi*, which causes typhoid fever.

A commonly accepted set of names for species and higher taxa is essential for research and communication.

The official rules for naming species and taxa are determined by the International Committee on Systematics of Prokaryotes (ICSP). ICSP establishes minimal criteria for designating species, genera, classes, and other taxa of bacteria and archaea. To establish a new species, a new form of microbe must be isolated and grown in pure culture, known as an **isolate.** The isolate's unique genetic and phenotypic traits are published, with a proposed species name designated "*Candidatus*" for **candidate species**. An example of a candidate species is *Candidatus* "*Nitrosopumilus maritimus,*" a marine archaeon that oxidizes ammonia, first isolated in 2005. The candidate species becomes accepted as an official species upon publication in the *International Journal of Systematic and Evolutionary Microbiology*, the official journal of record for novel prokaryotic taxa.

All accepted taxonomic categories and species descriptions are compiled in *Bergey's Manual of Determinative Bacteriology*, a multivolume reference work of prokaryotic taxonomy. Up-to-date taxonomy of prokaryotes as well as eukaryotes is maintained in the interactive online database National Center for Biotechnology Information (NCBI) under the Taxonomy Browser, supported by the U.S. government.

We will revisit the question of defining bacterial species at the end of Section 17.5, after considering the molecular basis of phylogeny and gene sequence relatedness.

Identification

Once a species has been described and classified, we need a way to identify future members of the species isolated from natural environments. Identification poses special difficulties for microbes, which by definition are invisible to the unaided eye. Even under the electron microscope, thousands of divergent species may possess similar shape and form.

Because the definition of species is based on its genetic sequence, the most consistent and straightforward way to identify an isolate is to sequence part or all of its genome or to attempt hybridization of its DNA with a labeled sequence probe (see Chapter 7). In clinical practice, such DNA-based methods are used increasingly. Nevertheless, even in the clinical lab—as well as in field and environmental microbiology—it is convenient to narrow down the possibilities using various easily determined traits, such as cell shape, staining properties, and metabolic reactions. Thus, practical identification is based on a combination of phylogeny (relatedness based on DNA sequence divergence) and phenetic or phenotypic traits.

A common strategy of practical identification is the **dichotomous key**, in which a series of yes/no decisions successively narrows down the possible categories of species. **Figure 17.18** shows an example of a dichotomous key used to identify filamentous bacteria found during wastewater treatment. Filamentous bacteria are important in wastewater because their entangled filaments interfere with the settling of bacteria out of the treated water. Note that in the key shown, most of the traits are phenotypic, such as cell size and motility. Most of the branch decisions have two choices, although one juncture (cell motility and shape) has four. The key identifies some organisms down to the species level (*Sphaerotilus natans*), others to the genus level (*Flexibacter*), and others only to numbered samples whose characterization remains incomplete (0914, 021N).

THOUGHT QUESTION 17.4 Based on **Figure 17.18**, what would be the identification of a straight nonsheathed gram-negative bacterium that has sulfur granules, is motile, and is 1.0 μm wide? What would happen if you happened to assign the bacterium a width of 0.9 μm?

A disadvantage of the dichotomous key is that it requires a series of steps, each of which takes time. In the clinical setting, time is critical in identifying a potential pathogen and prescribing appropriate treatment. An alternative means of identification in the clinical setting is the probabilistic indicator. A **probabilistic indicator** is a battery of biochemical tests performed simultaneously on an isolated strain (**Fig. 17.19**). The indicator requires a predefined database of known bacteria from a well-studied habitat, such as Gram-negative bacteria from the human intestinal tract. To build such a database, numerous strains of each species must be isolated in pure culture and tested for all the traits in the database. The fraction of isolates that test positive for each trait, for each species, is noted in the database as the probability of obtaining a positive result. The probability of a negative result would be 1 minus the probability of a positive result. For example, if 97 out of 100 strains of *Salmonella enterica* test positive for ornithine decarboxylase, the probability of a positive result is 0.97, and the probability of a negative result is 0.03.

The database can be used to identify a newly isolated specimen from a patient. When the test results are obtained, the probabilities for all results, negative or positive, for a given species are then multiplied to generate a probability score for the species. For each species in the database, a score is computed, and the scores are sorted. The top-scoring species is then taken as the most probable identification.

A simplified example of indicator results appears in **Figure 17.19B**. Most of the tests generate pH-dependent color changes from products of bacterial catabolism, such as fermentation of sugars to acid or decarboxylation of

amino acids to generate alkaline amines. For each species in the database, the probabilities of all the test results are multiplied; for example, for *Salmonella enterica*:

$$\begin{aligned}\text{Score} &= (0.99)(0.98)(0.97)(0.95)(1-0.01)\\&\quad(1-0.01)(0.95)(1-0.96)\\&= 3.3 \times 10^{-2}\end{aligned}$$

The advantage of the probabilistic indicator is its inherent redundancy; if an isolate gives one atypical result for its species, it may still show the highest probability score in the database.

THOUGHT QUESTION 17.5 In **Figure 17.19B**, were any test results atypical for *Salmonella enterica*? What would happen if another atypical result had been obtained? What would happen if the actual isolate had not been one of those in the database?

Note that both the dichotomous key and the probabilistic indicator assume a known set of organisms. To explore and characterize a completely unknown organism requires phylogenetic analysis—when possible, the sequencing of the organism's entire genome.

TO SUMMARIZE:

- **Taxonomy** is the description and organization of life-forms into classes (taxa). Taxonomy includes classification, nomenclature, and identification.
- **Classification** is traditionally based on a hierarchy of ranks. Groups of organisms long studied tend to have many ranks, whereas recent isolates have few.
- **DNA sequence relatedness** defines microbial taxa. Below genus level, however, the definition of bacterial species can be problematic.
- **Practical identification** is based on phenotypic and genetic traits. Methods of identification include the dichotomous key and the probabilistic test battery. Both methods assume a predefined set of organisms.
- **Nongenetic categories** based on ecological niche or host organ infected are useful in ecology or medicine, respectively.

17.4 Microbial Divergence and Phylogeny

The unifying assumption of modern biology is genetic relatedness, or molecular phylogeny. Phylogeny generates a series of branching groups of related organisms called **clades**. Each clade is a **monophyletic group**—that is, a group of species that share a common ancestor not shared by any species outside the clade. Each monophyletic group then branches into smaller monophyletic groups and ultimately species. The full description of branching divergence of a species is called its phylogeny.

Divergence through Mutation and Natural Selection

Populations of organisms diverge from each other through several fundamental mechanisms of evolution. These include:

- **Random mutation.** DNA sequence changes through rare mistakes (in prokaryotes, typically one out of a million base pairs) as the chromosome replicates. Replication errors result in mutation. Most mutations are neutral; that is, they have no effect on gene function.
- **Natural selection.** In a given environment, natural selection favors organisms that produce greater numbers of offspring in that environment. Genes encoding traits under selection pressure may show mutation frequencies much higher or lower than the random mutation rate. Genes under selection pressure do not serve as molecular clocks.
- **Reductive evolution (degenerative evolution).** In the absence of selection for a trait, the genes encoding the trait accumulate mutations without affecting the organism's reproductive success. Because mutations that decrease function are more common than mutations that improve function, accumulating mutations without selection pressure leads to decline and ultimately loss of the trait. The loss or mutation of DNA encoding unselected traits is called **reductive evolution** (or degenerative evolution).

Random mutations with neutral effects that are not subject to selection tend to accumulate at a steady rate over generations because the error rate of the DNA replication machinery stays about the same. The resulting "genetic drift" causes sequences in separate populations to diverge over time. The constancy of mutation rate (within limits) provides a tool for us to measure the time of divergence of species based on their DNA sequences.

THOUGHT QUESTION 17.6 What kind of DNA sequence changes have no effect on gene function?

Molecular Clocks Are Based on Mutation Rate

An important conceptual advance of the twentieth century was that information contained in a macromolecule such as protein or DNA could measure the history of a species. The temporal information contained in a macromolecular sequence is called a **molecular clock**. Molecular clocks have revolutionized our understanding of the emergence of all living organisms, including human beings. The first molecular clocks, based on protein sequencing and DNA hybridization, were developed in the 1960s. Subsequently, the sequences of ribosomal RNA (rRNA) were used by Carl Woese to reveal the divergence of three domains of life. The rRNA sequence is particularly useful because ribosome structure and function are highly similar across all organisms. Genomic sequences now offer many other genes to measure divergence at different levels of classification.

A molecular clock is based on the acquisition of new random mutations in each round of DNA replication. In **Figure 17.20**, each offspring in generation 2 acquires two new mutations; their sequences now differ by 25%. In the next generation, each individual propagates the earlier mutant sequences while acquiring two more random mutations. Strain 3A now differs by 50% from strains 3B

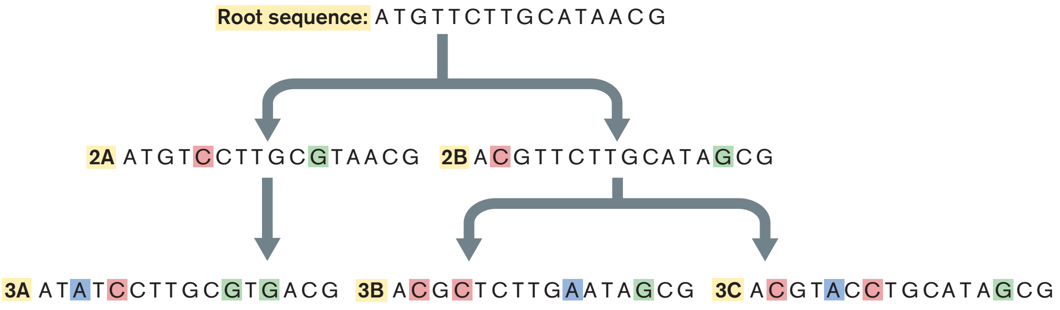

Figure 17.20 The molecular clock. As genetic molecules reproduce, the number of mutations accumulated at random is proportional to the number of generations and thus the time since divergence. Sequence label numbers indicate generations; letters identify individual organisms.

and 3C, which differ by 25% from each other. (Actual mutation frequencies, of course, are much lower, about one base per million per generation.) The key assumption is that the chromosomes of offspring acquire a consistent number of random mutations from their parents, and therefore the number of sequence differences between two species should be proportional to the time of divergence between them.

In practice, the molecular clock works best for a particular gene sequence with the following features:

- The gene has the same function across all species compared. That is, all versions are orthologous; they have not evolved to serve different functions. Functional difference may lead to different rates of change.
- The generation time is the same for all species compared. Shorter generation times (more frequent reproductive cycles) lead to overestimates of the overall time of divergence because of the increased opportunity for DNA mutation.
- The average mutation rate remains constant among species and across generations. If different species mutate at different rates, species with more rapid rates of mutation will appear to have diverged over a longer time than is actually the case.

Genes that show the most consistent measures of evolutionary time encode components of the transcription and translation apparatus, such as ribosomal RNA and proteins, tRNA, and RNA polymerase. The most widely used molecular clock is the gene encoding the **small-subunit rRNA** (**Fig. 17.21**). The small-subunit rRNA is also known by its sedimentation coefficient: 16S rRNA (bacteria) or 18S rRNA (eukaryotes). (Sedimentation coefficients are discussed in Chapter 3.)

The use of a molecular clock requires the alignment of homologous sequences in divergent species or strains (**Fig. 17.22**). Alignment refers to the correlation of portions of two gene sequences that diverged from a common ancestral sequence. In practice, correct alignment requires difficult decisions based on rule-of-thumb assumptions about mutation rates. These assumptions include:

- **Minimum number of changes.** The best alignment between two sequences is that which assumes the smallest number of mutational changes.
- **Loop positions change more frequently than stems.** Bases found in single-stranded loops of RNA, and the lengths of these loops, are more likely to change than bases found in double-stranded stems. This is because a base change in one strand of a loop necessitates a second mutation in the opposite strand to maintain base pairing in the stem. Intramolecular base pairing is required for RNA structure in solution.
- **Functional sequences change more slowly.** Functional sequences change more slowly than portions of the molecule without essential catalytic function. Within small-subunit rRNA, sequences essential to the function of translation remain remarkably consistent across all three domains of life. These regions can be used to devise primer pairs for PCR amplification of rDNA from unknown organisms.
- **Key positions in the sequence are conserved.** Key positions in the sequence are conserved within a particular class of organisms, but differ between classes.

THOUGHT QUESTION 17.7 Solve the three alignment problems shown in **Figure 17.22.** How could errors or ambiguities in alignment lead to mistakes in interpreting the molecular clock?

Phylogenetic Trees

Once homologous sequences are aligned, the frequency of differences between them can be used to generate a **phylogenetic tree** that estimates the relative amounts of evolutionary divergence between them. All phylogenetic trees depend on complex mathematical analysis to measure degrees of divergence and determine the most probable tree that connects present sequences with their common ancestor. Two common approaches are:

- **Maximum parsimony.** Evolutionary distances are computed for all pairs of taxa based on numbers of nucleotide or amino acid substitution between them. A proposed common ancestor, or "ancestral state," is reconstructed. All possible trees comparing relative time of divergence from the common ancestor are computed. The "best fit" tree is defined as that which requires the smallest number of changes to fit the data (that is, the most "parsimonious"). A limitation of parsimony reconstruction is that more than one tree may produce results consistent with the data.
- **Maximum likelihood.** For each possible tree, one calculates the likelihood (probability) that such a tree would have produced the observed divergence data. The probability of given substitution events is based on complex statistical calculations. Maximum likelihood methods require large amounts of computation but obtain the most information from the data, usually generating one tree or a small set of probable trees.

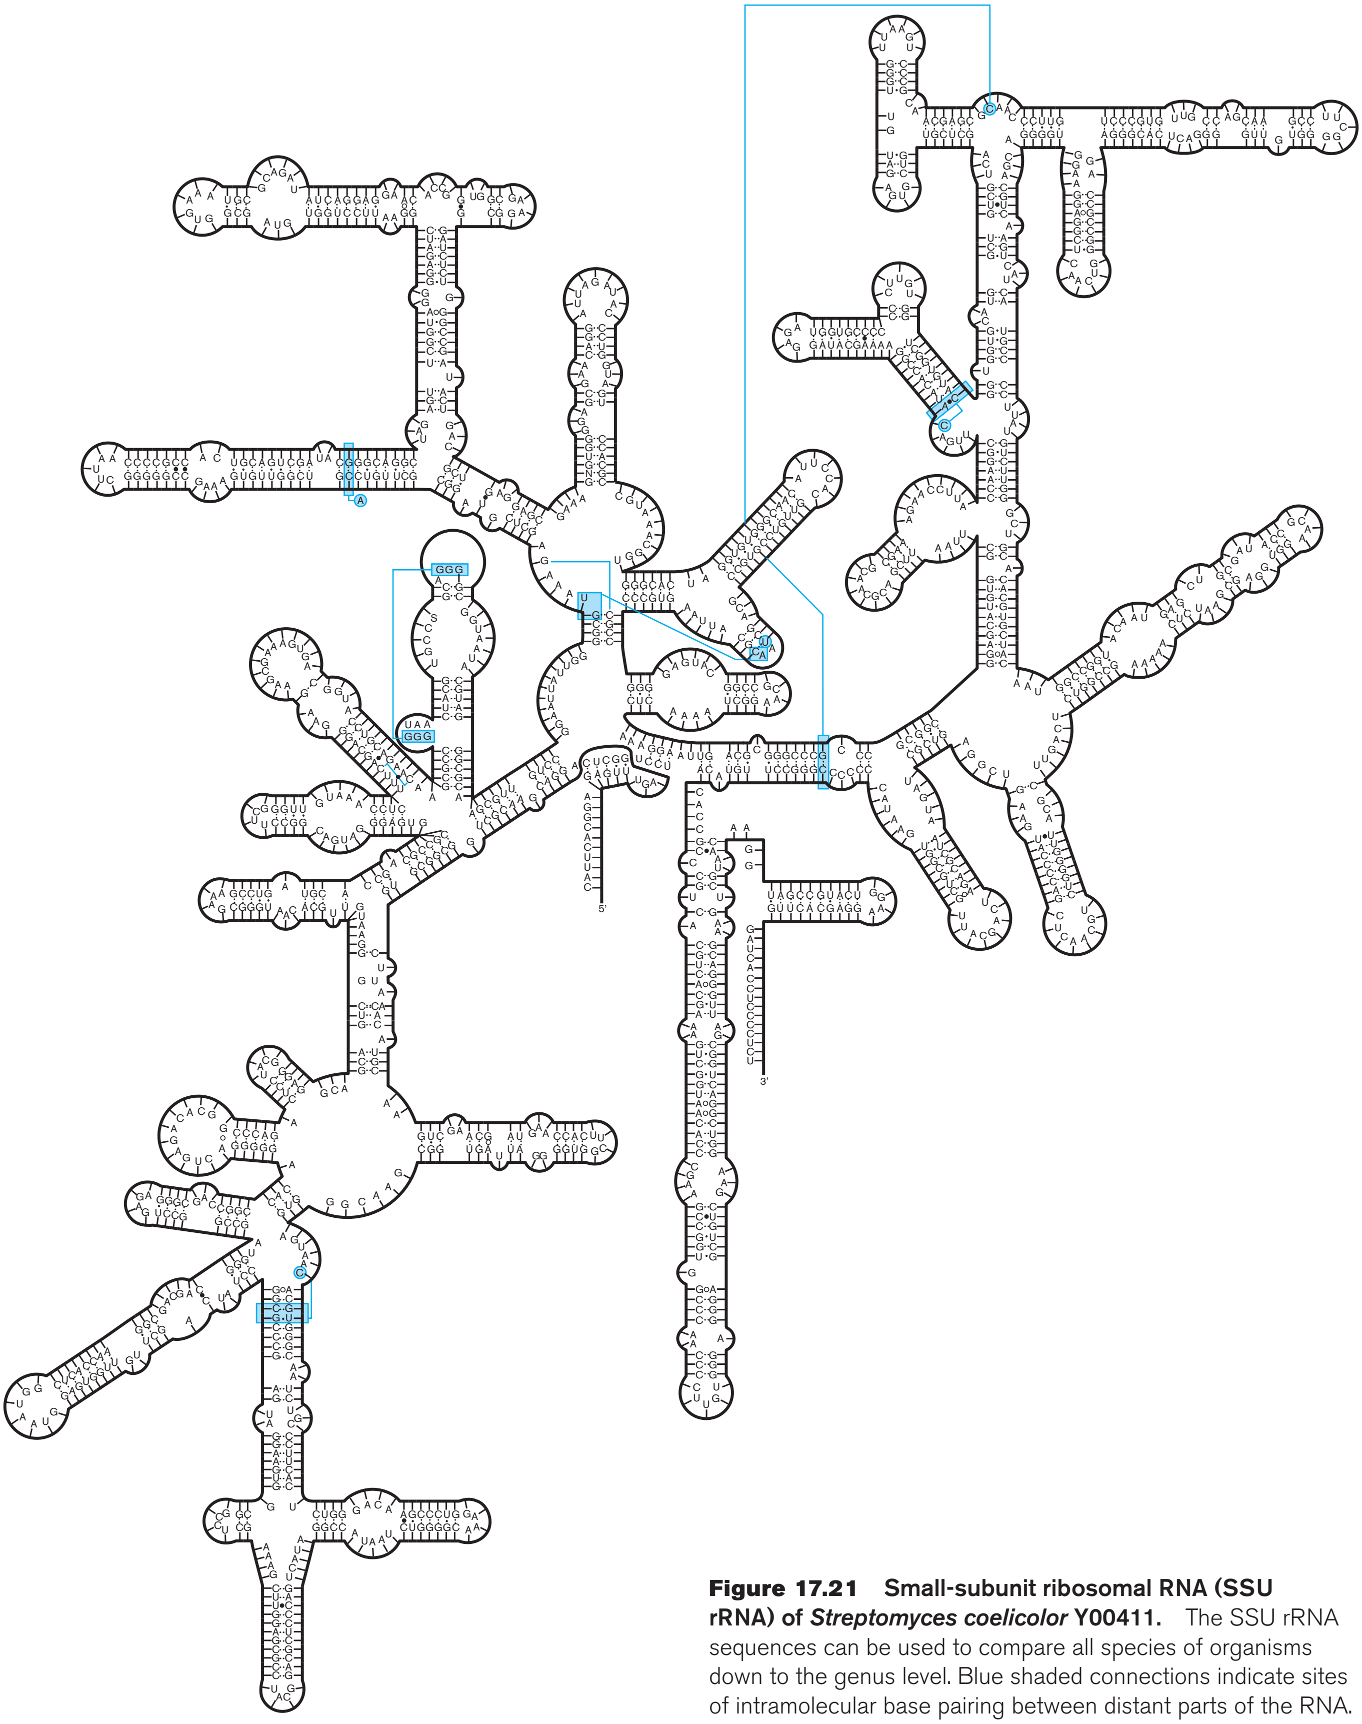

Figure 17.21 Small-subunit ribosomal RNA (SSU rRNA) of *Streptomyces coelicolor* Y00411. The SSU rRNA sequences can be used to compare all species of organisms down to the genus level. Blue shaded connections indicate sites of intramolecular base pairing between distant parts of the RNA.

Figure 17.22 **RNA sequence comparison by phylogeny exercises.** **A.** Homologous RNA sequences from different species can be aligned at regions of similarity. The best alignment is that which minimizes mismatches. **B.** Knowledge of the secondary structure can help predict alignments. Inset: James W. Brown, author of these phylogeny exercises, samples diverse thermophiles from Obsidian Pool, Yellowstone National Park. **C.** A new archaeal isolate can be assigned to a division based on key positions in the sequence. B. Make an alignment of these RNAs:

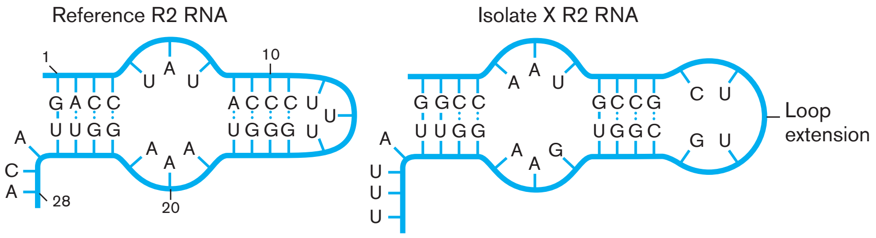
C. Based on its rRNA sequence, to which archaeal group does isolate X most likely belong?



Position number	Crenarchaea	Euryarchaea	Korarchaea
4	C or U	C	U
5	U	U	A
8	A	G	C
11	C	G	G
15	A or G	C	U
18	U	U	C
19	A	G	C or U
20	A	A	U
21	A	A	C or U
22	G	G	A

A portion of a computed phylogenetic tree is shown in **Figure 17.23**. The sequence data were obtained from PCR-amplified sequences of small-subunit rRNA from isolates in Obsidian Pool, a thermal spring at Yellowstone. The sequences were analyzed by Susan Barns and colleagues at Indiana University in the laboratory of Norman Pace, a pioneering investigator of extreme habitats. Note that some of the Obsidian Pool samples are known species, such as the thermophile *Pyrodictium occultum,* whereas others are uncharacterized organisms given alphanumeric designations, their existence known only by the rRNA sequences reported here. In fact, any microbial habitat surveyed by PCR, including a "soap scum" biofilm on a shower curtain, will yield previously unknown species (**Special Topic 17.2**).

The Obsidian Pool rRNA sequences were aligned based on the principles shown in **Figure 17.22**, and divergence distances were analyzed by maximum likelihood. In each tree, the total distance (in terms of base substitution frequency) between any two sequences is approximated by the distance from each sequence and its branch point. The tree at left (**Fig. 17.23B**) is an **unrooted tree**; it shows only the relative distances between different sequences, without indicating which of these diverged earliest from the common ancestor. To root the tree (at right), the researchers identified a sequence well outside the selected cluster of isolates (portion of tree not shown). The root is the position from which the most different sequence first diverged from the rest.

The Obsidian Pool example reveals an important limitation of phylogenetic trees: Not all the branches add up to the same total length. In other words, some lineages accumulate mutations faster than others. The difference in rate arises from differences in mutation rate and from differences in generation time between organisms whose sequences are compared. Without calibration data outside the tree, approximations need to be made to estimate the actual divergence times. Thus, our molecular clocks are inevitably distorted, especially for distantly diverged organisms with disparate mutation rates. The distortion is reminiscent of the famous painting by Salvador Dali, *Persistence of Memory* (**Fig. 17.24**), in which warped watch dials represent the biological nature of memory.

Figure 17.23 **Phylogenetic trees: rooted and unrooted.** **A.** Norman R. Pace was the first to characterize the sequence phylogeny of thermophiles from high-temperature environments. **B.** Comparison of rRNA sequences was used to generate a phylogenetic tree for thermophiles isolated from Obsidian Pool in Yellowstone National Park. A phylogenetic tree shows the degrees of relatedness among taxa based on the number of molecular substitutions on each branch (see scale bar). An unrooted tree does not indicate the position of a common ancestor for all taxa. A rooted tree indicates the position of a common ancestor. *Source*: B. Susan M. Barns, et al. 1996. *PNAS* 93:9188.

A second problem is the need to calibrate the tree, that is, to relate mutation frequency to units of time. To indicate actual time since divergence, an external measure of time is required. A tree can be calibrated if some kind of fossil evidence or geological record exists to confirm at least one branch point of the tree. An example of a calibrated tree appears in **Figure 17.17**, in which a chemical biosignature (the sulfur isotope ratio) was used to set a minimum time since the divergence of the sulfate-reducing clade from other lineages of bacteria. Another method of calibration is to correlate the divergence of microbial species growing only within particular host species with the divergences of their hosts, based on the host fossil record.

THOUGHT QUESTION 17.8 What are the major sources of error in constructing phylogenetic trees?

Salvador Dali, Gala-Salvador Dali Foundation/Artists Rights Society (ARS)/New York/Bettmann/Corbis

Figure 17.24 **A distorted measure of time.** *Persistence of Memory*, by Salvador Dali, suggests that all organisms measure time through clocks that are distorted. In fact, the molecular clocks of DNA are distorted by differences in mutation rate and generation time.

Divergence of Three Domains of Life

Carl Woese first used small-subunit rRNA phylogeny to reveal the existence of a third domain of life, Archaea, roughly as distant from prokaryotes as from eukaryotes (**Fig. 17.25**). How was an entire domain of life missed in the past? Many archaea grow in habitats previously thought inhospitable for life; for example, *Thermoplasma* species grow at 60°C at pH 2 (**Fig. 17.26**). Others, such as methanogens and halophiles, were long known to microbial ecologists, but without tools for genetic analysis they were simply classified among bacteria.

Rooting the tree of life. Where is the root of the tree, the position of the last universal common ancestor of all life-forms? Which of the three domains (bacteria, archaea, eukaryotes) first diverged from the other two? The question has profound importance for biology, as the research community defines "model systems" for study based on their commonalities with organisms of importance to humans. For example, investigators of intron splicing in archaea argue that archaea represent a model system for related processes in complex eukaryotes such as humans.

The root, however, can only be found by measuring divergence relative to an outside group of organisms. Because no "outgroup" exists for the tree of all life, how is the tree rooted? One approach is to compare a pair of homologous genes within one organism, homologs that diverged from a common ancestral gene and acquired distinct functions (paralogs). The pair of paralogs chosen for analysis must have diverged within the common

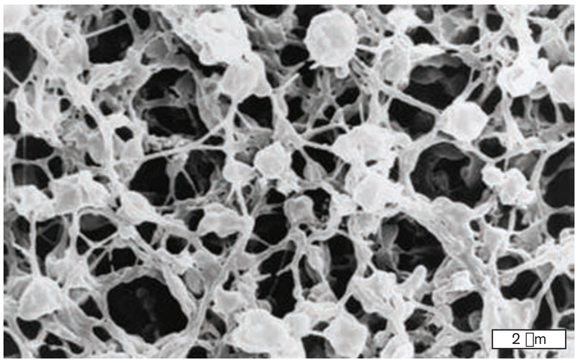
Figure 17.25 **Three domains of life.** Carl Woese (inset) used SSU rRNA sequencing to reveal three equally distinct domains of life: Bacteria, Eukarya (eukaryotes), and Archaea. The tree is “unrooted,” since it does not show which of the three domains diverged first from the common ancestor.



M. Yasuda, et al. 1995. *Appl. Environ. Microbiol.* 61:3482

Figure 17.26 ***Thermoplasma.*** This archaeon lives at 60°C at pH 2—with no cell wall, only a cell membrane.

ancestral cell *before* the divergence of the three domains of life. The early divergence is determined by comparing the pair’s sequence similarity in many different organisms and constructing a tree of gene phylogeny. A limitation of this approach is that genes with divergent function have been subjected to natural selection in addition to random variation.

As of this writing, there is no general agreement as to which of the three domains diverged first from the other two. While the position of the root remains controversial, the three major divisions of life based on rRNA phylogeny have been confirmed by sequence data from the hundred-plus genomes published to date. Furthermore, structural and physiological comparison of the three domains largely confirms the rRNA tree (**Table 17.3**). Note first that all living cells on Earth share profound similarities. All cells consist of membrane-bound compartments that shelter the same fundamental apparatus of cell production, the DNA-RNA-protein machine. The fundamental components of this machine appear to have evolved before the three domains diverged from their last universal common ancestor. From a molecular standpoint, all cells on Earth appear more similar than they are different.

Nonetheless, important differences emerge between each pair of domains; indeed, each domain shows distinctive traits absent or scarce in the other two. We summarize here the major features common to most members of each domain. Specific classes and species within each domain are explored in Chapters 18–20, and on the Microbial Biorealm website.

Archaea, bacteria, and eukaryotes. Of the three domains, the eukaryotes stand out as having a nucleus and other complex membranous organelles (**Table 17.3**). Eukaryotic organelles include mitochondria and chloroplasts, which evolved from internalized bacteria. Bacteria and archaea are prokaryotes; they possess no nucleus and have relatively simple intracellular membranes. Their size is limited by diffusion across the cell membrane, with occasional exceptions, such as the “giant bacterium” *Epulopiscium fishelsoni.* The larger size and complexity of eukaryotic cells generally requires the most high-powered sources of energy, such as aerobic respiration and oxygenic photosynthesis, although some protists conduct fermentation. By contrast, the prokaryotes (bacteria and archaea) employ a wider range of metabolic alternatives, including lithotrophy and anaerobic respiration. Finally, eukaryotic plants and animals have attained a degree of multicellular complexity unknown in the prokaryotic domains.

On the other hand, eukaryotes share key traits with archaea that distinguish both from bacteria. The core information machinery of eukaryotes more closely resembles that of archaea. The two domains share closely

Special Topic 17.2 Phylogeny of a Shower Curtain Biofilm

The deep sea and the tropical forest receive much attention as habitats to discover new exotic life-forms. But novel microorganisms can be discovered closer to home—in the soil, on the roots of grass, within our own digestive tract. Even within our own homes lurk microbial communities that include potentially dangerous pathogens. Such organisms were discovered by Norman Pace and colleagues at San Diego State University and at the University of Colorado, taking a break from their submarine studies to explore a domestic aquatic habitat: the "soap scum" biofilm on a shower curtain (**Fig. 1**).

Domestic water sources are well known as a source of pathogens such as *Legionella pneumophila*, the cause of Legionellosis, a deadly form of pneumonia. Pathogens persist in biofilms growing within plumbing and air-conditioning lines. Lesser known reservoirs for microbes are the biofilms that collect on household surfaces such as shower curtains, which are often neglected during cleaning. Viable cells of the shower curtain biofilm are revealed by fluorescence microscopy using the DAPI stain for DNA (**Fig. 1B**).

Pace's students Scott Kelley and Ulrike Thiesen obtained biofilm from a shower curtain and used it to extract DNA. The biofilm DNA was amplified for sequences transcribed to rRNA using the PCR technique. The PCR amplification was conducted with a pair of sequence primers based on portions of the small-subunit rRNA sequence that are extremely conserved across all known species of bacteria. The region between the primers, however, is known to vary among species; thus, the DNA amplified should show distinguishing features that identify the source organism.

The shower curtain biofilm revealed a wide range of species, including 117 unique sequences for small-subunit rRNA. The most abundant groups of species include two genera of Alpha-Proteobacteria, *Sphingomonas* and *Methylobacterium*. *Sphingomonas* is named for its outer membrane content of sphingolipids, lipids containing an amide link to fatty acid. The phylogeny of the shower curtain sphingomonads is shown in **Figure 2**. *Sphingomonas* species are known to grow in a wide range of soil and water habitats and are occasionally isolated as yellow colonies from natural water supplies. They catabolize complex carbon sources such as dibenzofuran and hexachlorocyclohexane and thus are of interest for bioremediation of environmental pollutants. Some species, however, particularly *S. paucimobilis*, cause opportunistic infections in immune-compromised individuals, including bacteremia, peritonitis, and abscesses.

Species of the next-most abundant genus, *Methylobacterium*, are versatile heterotrophs known for their ability to metabolize single-carbon sources such as methanol and methylamine. Species grow in soil and water as well as within plant tissues; they are also isolated from automobile air-conditioning systems, printing paper machines, and dental unit water lines. Their pink color may be responsible for the pink color commonly observed in shower biofilms. Some species, such as *M. extorquens* and *M. zatmanii,* cause illness in immune-compromised individuals, including pneumonia, skin ulcers, and bacteremia.

Growing numbers of immune-compromised individuals care for themselves at home, where they need to control their own microbiological exposure. Thus, it is of concern to discover opportunistic pathogens in a home setting. The authors conclude with a reminder that "exposure can be minimized by regular cleaning or by changing shower curtains."

Table 17.3 Three domains of life.

Characteristic	Traits of living organisms		
	All cells on Earth resemble each other		
Chromosomal material	Double-stranded DNA		
RNA transcription	Common ancestral RNA polymerase		
Translation	Common ancestral rRNAs and elongation factors		
Protein	Common ancestral functional domains		
Cell structure	Aqueous cell compartment bounded by a membrane		
	Comparison of domains		
	Bacteria	**Archaea**	**Eukaryotes**
	Archaea resemble bacteria		
Cell volume	1–100 µm^3 (usually)		1–10^6 µm^3
DNA chromosome	Circular (usually)		Linear
DNA organization	Nucleoid		Nucleus with membrane
Gene organization	Multigene operons		Single genes
Metabolism	Denitrification, N_2 fixation, lithotrophy, respiration, and fermentation		Respiration and fermentation
Multicellularity	Simple		Simple or complex
		Archaea resemble eukaryotes	
Intron splicing	Introns are rare	Introns are common	
RNA polymerase	Bacterial	Eukaryotic form	
Transcription factors	Bacterial	Eukaryotic form	
Ribosome sensitivity to chloramphenicol, kanamycin, and streptomycin	Sensitive	Resistant	
Translation initiator	Formylmethionine	Methionine (except mitochondria use formylmethionine)	
Cell wall	Peptidoglycan	Pseudopeptidoglycan or other polymer; or protein S-layer	
	Bacteria resemble eukaryotes and differ from archaea		
Methanogenesis	No	Yes	No
Thermophilic growth	Up to 90°C	Up to 120°C	Up to 70°C
Photosynthesis	Many species; bacteriochlorophyll Proteorhodopsin derived from archea	Haloarchaea only; bacteriorhodopsin	Many species; chlorophyll (bacterial origin)
Chlorophyll light absorption	Red and blue	Green (central range of solar spectrum)	Red and blue (chloroplasts of bacterial origin)
Membrane lipids (major)	Ester-linked fatty acids	Ether-linked isoprenoid	Ester-linked fatty acids
Pathogens infecting animals or plants	Many pathogens	No pathogens	Many pathogens

related components of the central DNA-RNA-protein machine: RNA polymerase, ribosomes, and transcription factors. Even such hallmarks of Eukarya as intragenic introns and the splicing machinery and the "RNA interference" regulatory complexes are found in archaea. This explains why rRNA trees place archaea closer to eukaryotes than to bacteria.

At the same time, eukaryotes share fundamental structures with bacteria that differ from those in archaea. Archaea possess unique cell membrane components, such as their ether-linked lipids. Outside the archaea, ether-linked membrane lipids are found in only a few deep-branching bacterial species that share habitat (and exchange genes) with hyperthermophilic archaea. Only the domain Archaea includes species capable of growth in the most “extreme” environments of temperature (above 110°C or below –20°C) and pH (below pH 1), although other archaeal species grow well at mesophilic temperatures in soil or water. Perhaps the most striking distinction of archaea is the complete absence of known pathogens of animals or plants. Even the many methanogens that live within animal digestive tracts have never been shown to cause disease.

Overall, the three-domain phylogeny divides life usefully into three distinctive groups. Yet the tree also shows signs of gene flow unaccounted for by monophyletic descent. The eukaryotes contain mitochondria derived from entire assimilated prokaryotes, whose genomes persist within the organelle. And pathogenic bacteria such as *Agrobacterium* species transfer DNA into the genomes of plants. Moreover, sequenced genomes reveal evidence of gene transfer between bacteria and archaea sharing high-temperature habitats. What if the tree of life is not strictly monophyletic?

TO SUMMARIZE:

- **Phylogeny is the divergence of related organisms.** Organisms diverge through random mutation, natural selection, and reductive evolution.
- **Molecular clocks are based on mutation rate.** Given a constant mutation rate and generation time, the degree of difference between two DNA sequences correlates with the time since the two sequences diverged from a common ancestor.
- **Different sequences diverge at different rates.** Under selection pressure, the actual divergence rates of sequences depend on structure and function of the RNA or protein products.
- **Phylogenetic trees are calculated based on sequence analysis.** The more different the two sequences are, the longer the branch representing time since divergence from the common ancestor. Rooting a tree requires comparison with an outgroup.
- **The tree of life diverges to three domains: Bacteria, Archaea, and Eukarya.** Eukaryotes are distinguished by the nucleus, lacking in prokaryotes (archaea and bacteria). Archaea possess ether-linked isoprenoid lipids rare or absent in bacteria and eukaryotes, and they are never pathogens. The machinery of archaeal gene expression resembles that of eukaryotes.

17.5 Horizontal Gene Transfer

In retrospect, the very first demonstration of hereditary material, the transformation of avirulent *Pneumococcus* to virulence in 1928, involved horizontal transfer. Horizontal transfer is the acquisition of a piece of DNA from another cell, as distinguished from **vertical transfer**, the transmission of an entire genome from parent to offspring. Among bacteria, DNA is transferred horizontally by plasmids, transposable elements, and bacteriophages, as well as through the process of transformation, as discussed in Chapter 9. For example, drug resistance genes are transferred from harmless flora to pathogens of distantly related species. Another example is the transfer of genes encoding light-driven proton pumps (bacteriorhodopsin) from halophilic archaea into marine bacteria. Such transfer events are relatively rare, occurring perhaps once in a million generations. But over time, the number of such “rare” events can accumulate.

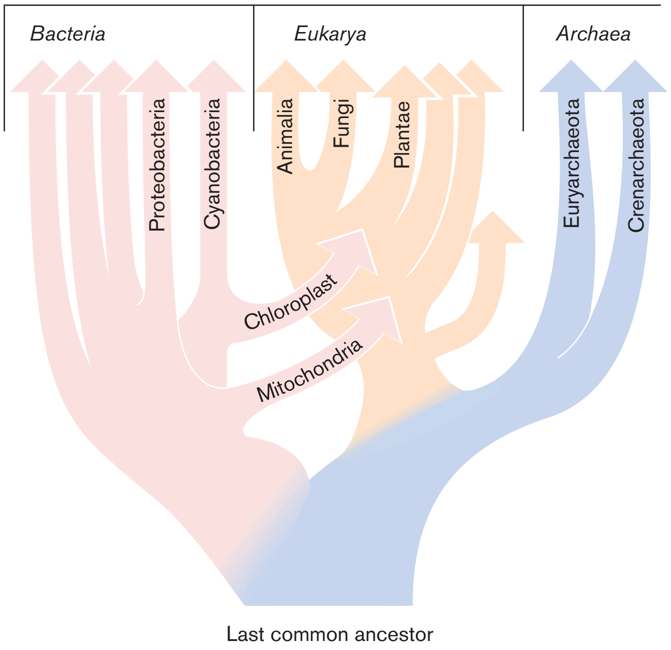
Genomic Evidence for Gene Transfer

A strong sign of horizontal transfer is a DNA sequence whose **GC/AT ratio** (proportion of GC and AT base pairs) differs from the rest of the genome. A surprising proportion of genomic DNA can show “spikes” of GC contact indicating origin elsewhere, even from species of a different kingdom. For example, *Archaeoglobus fulgidus*, a sulfur-oxidizing archaeon that grows in petroleum deposits, possesses numerous genes for lipid catabolism closely related to counterparts in bacteria. The presence of such genes in an archaeon fits no phylogenetic tree unless horizontal transfer is assumed. In other archaea, particularly hyperthermophiles *Pyrococcus* and *Aeropyrum,* 10–20% of the genes appear to be of bacterial origin. On the other hand, the thermophilic bacterium *Thermotoga maritima* shows a number of genes transferred from archaea.

Between more closely related taxa, transfer occurs even faster. For example, the *Escherichia coli* genome has acquired about 18% of its genes from other species after its relatively recent divergence from the close relative *Salmonella enterica*. Some medically important genera, such as *Neisseria* (causing gonorrhea and meningitis), are particularly “recombinogenic.” Rapid gene exchange enables pathogens to avoid the host immune system by expressing novel proteins not recognized by host antibodies (discussed in Chapter 23).

Eukaryotic genomes include many genes acquired from bacteria, most of them from the endosymbiotic ancestors of their mitochondria and chloroplasts. And the content of their noncoding intergenic sequences and introns derives largely from ancient viruses and retroposons (discussed in Chapter 11). In 1999, Ford Doolittle, at Dalhousie University, redrew the standard tree of life with a bewildering array of cross-cutting lineages (**Fig. 17.27**). Perhaps the “last common ancestor” was actually a “last common community” of diverse life-forms that contributed different parts of our genetic legacy.

A. Monophyletic tree: Limited lateral transfer



B. Lateral transfer obscures phylogeny

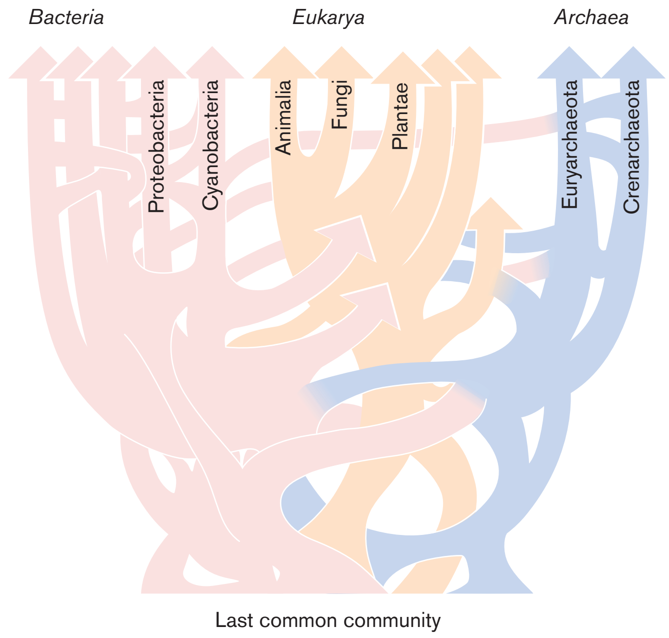


Figure 17.27 Vertical and horizontal gene transfer. **A.** The traditional view of phylogeny holds that the vast majority of gene transfer is vertical and that most lineages are monophyletic. Only occasional transfers occur, such as that of mitochondria and chloroplasts from bacteria into eukaryotes. **B.** An alternative view argues that lateral (or horizontal) gene transfer is so prevalent among microbes that it obscures monophyletic distinctions between taxa. *Source*: W. Ford Doolittle. 1999. *Science* 284:2126.

THOUGHT QUESTION 17.9 What are the limits of evidence for horizontal gene transfer in ancestral genomes? What alternative interpretation might be offered?

Reconciling Vertical and Horizontal Transfer

A promising model to sort out vertical and horizontal gene transfer was proposed by James Lake and colleagues at the University of California Los Angeles and developed further by Doolittle. Lake argues that the genome contains two kinds of genes that evolve differently. **Informational genes** specify products essential for transcription and translation of information-rich macromolecules. Such products include RNA polymerase as well as ribosomal RNAs and elongation factors. Informational genes need to interact directly in complex ways with large numbers of cellular components; thus, their capacity for horizontal transfer is limited. On the other hand, **operational genes** are those whose products govern metabolism, stress response, and pathogenicity. Operational genes function with relative independence from other cell components and consequently undergo horizontal transfer more easily than informational genes. Operational gene products also tend to meet conditional needs, dependent on the availability of nutrients and other environmental conditions, whereas informational gene products have functions essential to cell growth under every condition.

The concept of differentially transferable genes does much to clarify genome-based phylogeny. New phylogenetic trees are drawn based on sets of informational genes. These multiple-gene trees largely confirm the results of the small-subunit rRNA tree of life. At the same time, we increasingly find that significant traits of species arise from horizontal transfer. In particular, pathogens show extensive horizontal transfer of virulence genes and genes encoding resistance to host defenses and antibiotics. Groups of such genes are often transferred together on plasmids or on **genomic islands**, regions of DNA of foreign origin that confer special properties such as virulence or nitrogen fixation (discussed in Chapter 9). Examples of a virulence plasmid and a genomic island are found in the deadly pathogen *E. coli* O157:H7 (**Special Topic 17.3**).

A balanced view of vertical and horizontal transfer is shown in **Figure 17.28**. The row of arrows designates vertical transfer of the bulk of the genome as two species diverge. Black lines represent core informational genes, such as ribosomal RNA, whereas gray indicates genes with more flexible function. At various levels, colored lines indicate where genes enter each lineage. Gray lines

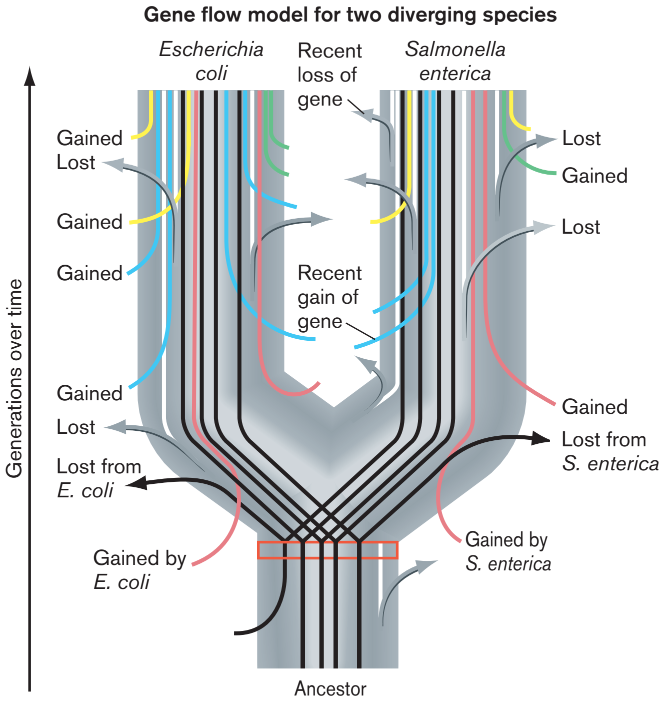

Figure 17.28 Genes enter and leave genomes. Both rRNA trees and whole-genome trees consistently reflect monophyletic descent (black lineages) down to the genus level. Below the genus level, monophyletic descent may be obscured by high rates of horizontal transfer (colored lines entering, gray lines departing). White spaces indicate genes lost by reductive evolution.

peel out, indicating loss of a gene. Overall, the vertical lineage persists for most of the core informational genes (black lines), while horizontally acquired genes enter and leave.

Species: A Molecular Definition

Our changing view of molecular phylogeny requires us to revisit the concept of species. As genome sequence data became available, scientists hoped that quantitative measures of divergence could provide a consistent basis for defining species of asexually reproducing microbes. But in some organisms, such as *Helicobacter pylori*, the genomes of different strains that cause the same disease (gastritis) differ by as much as 7%. On the other hand, strains of *Bacillus* with nearly identical genomes cause completely different diseases, such as anthrax (*B. anthracis*) and caterpillar infection (the biological pesticide *B. thuringiensis*).

A working definition of microbial species includes two perspectives: phylogeny (based on DNA relatedness) and ecology (based on shared traits and ecological niche).

Phylogenetic relatedness. A species is a group of individuals that share relatedness of a key set of "housekeeping genes," typically informational genes such as ribosomal and transcriptional components. Ideally, these genes should all be orthologs (genes with a common origin and function), not paralogs (which diverged from a common ancestor but now differ in function). Within a genus, species that cannot be distinguished based on small-subunit rRNA alone may be defined by analysis of multiple genes. For example, analysis of multiple gene loci effectively distinguishes *Neisseria meningitidis* (the cause of meningitis) from *N. lactamica*, a harmless resident of the nasopharynx. The multigene approach has proved successful even in the case of highly "recombinogenic" organisms known to acquire and rearrange genes readily.

Ecological niche. Besides a high degree of genomic relatedness, a species should include individuals that share common traits and an ecological niche. Shared traits should include cell shape and nutritional requirements, and there should be a common habitat and life history (for example, causing the same disease). By this criterion, highly divergent strains of *H. pylori* causing gastritis make up one species, whereas *B. anthracis* (anthrax) and *B. thuringiensis* (caterpillar infection) are different species despite their high degree of genetic similarity. In 2005, Dirk Gevers and colleagues from several countries proposed a three-part basis for classifying microbial species: rRNA sequence analysis identifies the family or genus; multiple-sequence analysis or whole-genome analysis distinguishes putative species; and the species distinction is confirmed based on ecological niche or disease involvement.

TO SUMMARIZE:

- **Horizontal transfer of genes occurs between different species.** Horizontal transfer is most frequent between closely related species or between distantly related species that share a common habitat.
- **Genomes include informational genes and operational genes.** Informational genes involve central processes of gene expression; they tend to be transferred vertically. Operational genes involve metabolic processes that function independently of other components. They are more likely to be transferred horizontally.
- **Horizontal transfer is important for adaptation to new environments and for pathogenesis.** Gene transfer among pathogenic and nonpathogenic strains leads to emergence of new pathogens.
- **The definition of microbial species requires complex criteria.** A microbial species may be defined based on rRNA sequence, multilocus sequence analysis, and ecological niche or pathogenesis.

Special Topic 17.3 Horizontal Transfer in *E. coli* O157:H7

Microbial evolution is essential to pathogenesis (discussed in Chapter 25). Evolution provides clues to the source of emerging pathogens that cause new diseases, such as *E. coli* O157:H7, the "hamburger *E. coli.*" The original appearance of *E. coli* O157:H7 in foods came as a surprise, especially given how fast the strain caused death in healthy children (**Fig. 1A**). The strain commonly contaminates grain-fed beef and the surfaces of vegetables grown near pastured cattle or manure.

Despite its genetic similarities to harmless enteric *E. coli,* the O157:H7 strain clearly possesses several new genes that contribute to virulence. Some of the virulence genes specific to strain O156:H7 (for example, genes *bfp* and *per*) are carried in a distinctive plasmid. Other virulence genes (such as the LEE genes) are found in the core genome. Both kinds of virulence genes contribute to the invasion cycle (**Fig. 1B**). First, the bacteria attach to the intestinal mucosa via special pili encoded by the "bundle-forming pilus" gene *bfp*. The attached bacteria then express proteins causing irritation and effacement (removal) of projecting villi. This "attaching and effacing" behavior is mediated by a genetic region called the locus of enterocyte effacement (LEE). The LEE region includes genes encoding the attachment protein intimin (*eae*) in the outer membrane and the intimin attachment protein Tir (*tir*), which the *E. coli* actually makes and inserts in the host cell membrane (discussed in Chapter 25). Then each bacterium induces the intestinal cell to form a "pedestal" stiffened by host actin filaments (**Figs. 1B** and **C**). Each stage of colonization requires specific virulence factors, such as the LEE proteins.

But where did the LEE genes come from, and how did they make the *E. coli* pathogen so different from its close relatives in the normal human flora? Completion of the genome sequences of O157:H7 and of *E. coli* K-12 revealed an astonishing 25% more genes in the pathogen. These novel genes are not scattered at random around the chromosome; instead, they appear in genomic islands, large chunks transferred together (red segments in **Fig. 2**). Other genomic islands (yellow) are present at the same location in both strains, but differ in sequence.

The chunks of contiguous transferred genes show GC content and tRNA codon usage substantially different from that of the genomic sequences shared with *E. coli* K-12. Thus, they appear to represent horizontal transfer from distantly related species. This horizontal transfer brings an entire system of gene products conferring a mechanism of pathogenesis, such as the LEE system for intestinal villus effacement. Such a transferred set of virulence genes is known as a "pathogenicity island" (discussed in Chapter 9). Pathogenicity islands undergo horizontal transfer among different organisms, generating new pathogenic strains.

17.6 Symbiosis and the Origin of Mitochondria and Chloroplasts

So far, we have largely considered evolution of a species in isolation. In fact, however, all organisms evolve in the presence of others, with whom they share interactions, both positive and negative. A major engine of evolution is **symbiosis**, the intimate association of two unrelated species (discussed fully in Chapter 21). The word *symbiosis* is popularly understood to mean **mutualism**, a relationship in which both partners benefit and may absolutely require each other. Biologists, however, recognize **parasitism**, in which one partner is harmed, as a relationship equally as intimate as mutualism; both are forms of symbiosis. Intimate relationships between species, either negative or positive, lead to **coevolution**, the evolution of two species in response to one another, showing parallel phylogeny. Coevolution commonly involves reductive evolution, where one partner species loses traits provided by the other partner. For example, the intracellular bacterium *Wolbachia*, found within nematodes that cause river blindness, has lost the ability to produce many nutrients, while retaining the ability to make purines and pyrimidines required by their host cell.

Microbial Interactions Lead to Coevolution

Interactions of microbial populations with different organisms include a range of positive through negative relationships (discussed in Chapter 21). A famous example of mutualism is that of bacterial nitrogen fixation, in which rhizobia form intracellular "bacteroids" within legume tissues. Both rhizobia and their plant hosts are highly evolved to respond to each other chemically and develop the nitrogen-fixing system. The plants provide protection and nutrients from photosynthesis while receiving fixed nitrogen from the bacteria. Another case of mutualism is that of lichens, multicellular systems composed of fungi and algae. These two cases and other forms of mutualism are discussed from the perspective of ecology in Chapter 21.

The distinction between mutualist and parasite is often subtle. Lichens consist of a mutualistic association between fungi and algae; but environmental change can convert the fungus to a parasite. On the other hand, parasitic microbes may coevolve with a host to the point that each depends on the other for optimal health. For example, the incidence of certain allergies and immune disorders, such as multiple sclerosis, appears to correlate with lack of exposure to pathogens and parasites.

In natural habitats, microbial symbiosis may involve multiple partners, both positive and negative. A classic example is that of the leaf-cutter ants, which cultivate fungal partners (**Fig. 17.29A**). Leaf-cutter ants arrange cut leaves in underground burrows for growth of a fungus that the ant is adapted to consume. Each ant species associates with one species of fungus. A third "partner," however, is a parasitic fungus of the genus *Escovopsis,* which feeds on the cultivated fungus and harms the ant colony. Each ant-fungus pair is parasitized by an *Escovopsis* species unique to that pair. To counteract the parasite, however, the ant supports growth of a fourth partner, *Streptomyces* bacteria that produce potent antifungal antibiotics. The bacteria grow on a specific structure on the ant cuticle, evolved for the specific function of hosting the bacteria (**Fig. 17.29B**).

Three of the four partners of the leaf-cutter system show extensive evidence of coevolution (**Fig. 17.29C**). The molecular phylogeny of both cultivated and parasitic fungal species tracks the divergence of the ant species. For example, the fungus strains from *Atta* and *Acromyrmex* host species are highly diverged from the fungi of *Trachymyrmex* hosts. The bacterial phylogeny is as yet unknown, but it is likely that the *Streptomyces* species as well has coevolved with its three partners.

Endosymbiosis Leads to Reductive Evolution and Obligate Association

The most intimate kind of symbiosis is **endosymbiosis**, in which one partner population grows within the body of another organism. Endosymbiosis includes communities of microbes within the digestive tract of animals, such as the human intestinal flora (discussed in Chapter 21). The internalized **endosymbiont** can also be intracellular, as in the case of rhizobial bacteroids within legume tissues. Rhizobia retain the genetic capacity for independence, growing readily in soil. Other intracellular endosymbionts, however, become wholly dependent on their host cells. Such endosymbionts undergo drastic reductive evolution, evolving ever deeper interdependence with their host cells. A surprising number of human invertebrate parasites, such as filarial nematodes and *Anopheles* mosquitoes, have been discovered to carry bacterial endosymbionts required for host growth. This discovery has exciting implications for treatment.

Microbial endosymbionts. A simple example of intracellular endosymbiosis is that of the alga *Chlorella* growing within *Paramecium bursaria* (**Fig. 17.30**). The algae conduct photosynthesis and provide nutrients to the paramecium, which in turn shelters the algae from predators and viruses. The relationship is highly specific in that only certain species of algae and paramecia participate, and it is highly controlled in that the algal growth is limited to a population that avoids harming the host. This relation-

ship may give clues to how the bacterial ancestor of chloroplasts began its intracellular existence.

The algal symbiosis, however, is reversible in that *Chlorella* retains its ability to multiply outside the paramecium. Moreover, under conditions of starvation in the absence of light, the paramecium may start to digest its endosymbionts as prey. Thus, the nature of the symbiosis (mutualistic or predatory) depends on the environment.

Bacterial endosymbionts of invertebrates. Many invertebrate animals, often themselves parasites of animals or plants, possess obligate bacterial endosymbionts. In some cases the endosymbiont is a parasite, such as the bacterium *Wolbachia pipientis* that grows within cells of the fruit fly *Drosophila*. *Wolbachia* bacteria are related to the rickettsias, obligate intracellular pathogens carried by arthropods and transmitted to humans. The *Wolbachia* strains that infect *Drosophila* cells are transmitted only through

egg cells; they cannot exist outside the insect. The bacteria have evolved ways to manipulate *Drosophila* reproduction so as to enhance their own transmission; for example, they feminize infected males so as to produce eggs, which carry *Wolbachia* into the next generation of flies.

Other invertebrate endosymbionts are mutualists. In fact, 15% of insect species depend on intracellular bacteria to produce essential nutrients, such as certain amino acids or vitamins. In these mutualisms, both partners have lost essential traits by reductive evolution, and each now requires the partner species to provide the lost function. The degree of genome reduction is most extreme in the intracellular partner, which can be seen as heading in the same evolutionary direction that led to mitochondria and chloroplasts.

The discovery of intracellular bacteria in invertebrates has exciting medical implications for treatment of parasitic diseases. Invertebrate parasites such as filarial worms invade human lymph nodes, causing forms of disease (filariasis) that are notoriously difficult to treat. A form of filariasis is elephantiasis, in which a limb expands with huge numbers of worms (**Fig. 17.31**). Filariasis afflicts more than 120 million people worldwide, largely in the Indian subcontinent and in Africa.

The filarial worms are nematodes that harbor *Wolbachia* endosymbionts (**Figs. 17.32A** and **B**). These *Wolbachia* strains differ from those that parasitize insects. *Wolbachia* may have entered the nematode originally as a pathogen or parasite, then persisted based on its metabolic contributions to the host. The nematode endosymbiont strains are mutualists; their presence is required for the nematode's embryonic development. The bacteria are found within tissue layers beneath the nematodes' skin and within the uterine tubes of females, where they enter the developing offspring (**Fig. 17.32B**). When human patients infected by the nematodes are treated with antibiotics such as tetracycline, the bacteria disappear from worm tissues. The worm burden gradually decreases, and no offspring are produced. Antibacterial antibiotics eliminate the worms sooner and more completely than treatment with anti-nematode agents.

The genome of a *Wolbachia* strain from the filarial nematode *Brugia malayi* reveals extensive reductive evolution (**Fig. 17.33**). With barely a million base pairs, the

Figure 17.33 Metabolic pathways retained in the *Wolbachia* genome. Reductive evolution has eliminated much of the *Wolbachia* genome, but it retains metabolic pathways to make purines, pyrimidines, and vitamins such as riboflavin for its nematode host.

Wolbachia genome has lost many metabolic pathways, barely retaining glycolysis and the TCA cycle. It has lost the pathways for biosynthesis of all amino acids and most vitamins. It nonetheless retains pathways to make purines, pyrimidines, and the coenzymes riboflavin and FAD—essential pathways lost by its host nematode. Overall, *Wolbachia* appears to be evolving into an organelle of its host, like the ancestors of mitochondria and chloroplasts.

Mitochondria and Choroplasts

As Lynn Margulis and colleagues have shown, the assimilation of endosymbionts as mitochondria and chloroplasts played a central role in the evolution of eukaryotes (**Fig. 17.34**). Many similar endosymbioses are known today, such as the free-living algae *Chlorella* acquired by the protist predator *Paramecium bursaria* (see **Fig. 17.30**). Mitochondria, like *Wolbachia*, evolved from a bacterium related to the rickettsias. The mitochondrial ancestor must have entered the eukaryotic lineage as, or shortly after, the eukaryotes diverged from archaea, since all known eukaryotes retain mitochondria or vestigial remnants of mitochondrial genomes. Mitochondria provide the cell with the essential functions of electron transport and respiration. The electron transport system (ETS) is found in the mitochondrial inner membrane, believed to derive from the cell membrane of the ancestral bacterium. The outer membrane may derive from the invaginating membrane of the host cell that originally engulfed the endosymbiont.

Chloroplasts arose from cyanobacteria at some point before the divergence of red and green algae (discussed in Chapter 20). A model for cyanobacterial uptake can be seen in the protist *Glaucocystophyta*, which independently (and much later) took up cyanobacterial endosymbionts. The endosymbionts of *Glaucocystophyta* retain cell walls and some metabolism. Like mitochondria, chloroplasts possess inner and outer membranes, believed to derive from the ancestral endosymbiont and host, respectively. Photosynthetic complexes are located in the thylakoid membranes, similar to those of modern cyanobacteria.

The genomes of mitochondria and chloroplasts both show extreme reduction, even more extreme than that of any known endosymbiotic bacteria (**Fig. 17.35**). The few genes that remain include remnants of the central transcription-translation apparatus, such as rRNA and tRNAs, as well as a handful of genes whose products are essential for survival of the host cell: for respiration (mitochondria) or photosynthesis (chloroplast). In human mitochondria, the essential products form the respiratory chain, including subunits of NADH dehydrogenase, cytochrome oxidase, and ATP synthase. Mutations in these key genes

lead to serious diseases; for example, damage to mitochondrial genes of respiration is associated with motor neuron disease, parkinsonism, and forms of ataxia.

But thousands of genes encoding ETS subunits, as well as other essential parts of mitochondria, have migrated from the mitrochondrion to the nucleus. Some of these genes show tissue-specific expression, resulting in different mitochondrial types associated with different tissues. Thus, some mitochondrial defects are actually inherited through the nuclear genome. The mitochondria have evolved as integral parts of the host cell.

In chloroplasts, the organellar genome encodes essential products for photosynthesis, including photosystems I and II and the ATP synthase. The chloroplast genome shown in **Fig. 17.35B** retains the large subunit of rubisco, whereas the gene encoding the small subunit has migrated to the nucleus.

Remarkably, the process of **symbiogenesis**, the generation of new symbiotic associations, continues in a number of protist species. Protist-algae called cryptomonads result from symbiogenesis in which an alga (containing a chloroplast) was engulfed by an ancestral protist. The cryptomonad cell contains the degenerate remains of the algal endosymbiont (**Fig. 17.36**). The algal mitochondrion was lost through reductive evolution, and the nucleus shrank to a **nucleomorph**, the vestigial remains of a nucleus containing a small amount of the chromosomal DNA of the original algal nucleus. But the algal chloroplast

was maintained, "enslaved" by its new host. The result is a new cryptomonad species, *Guillardia theta*. The cryptomonad chloroplast has a double membrane derived from the original cyanobacterial ancestor of the chloroplast and from the algal ancestor, surrounded by another double membrane derived from the cell membranes of alga and a secondary host. In other species, tertiary symbiosis has been documented, in which a cryptomonad has been swallowed in turn by another protist.

THOUGHT QUESTION 17.10 Besides mitochondria and chloroplasts, what other kinds of entities within cells might have evolved from endosymbionts?

TO SUMMARIZE:

- **Symbiosis is the intimate association of two unrelated species.** A symbiosis in which both partners benefit is called mutualism. If one partner benefits while harming the other, this is called **parasitism**.
- **Symbiotic partners undergo coevolution**, the evolution of two species in response to one another. Coevolution involves reductive (degenerative) evolution, in which each partner species loses some functions that the other partner provides.
- **An endosymbiont lives inside a much larger host species.** Many microbial cells harbor endosymbiotic bacteria whose metabolism yields energy for their hosts.
- **Many invertebrates harbor endosymbiotic bacteria.** The bacteria are required for host survival and in some cases for pathology caused by a parasitic invertebrate.
- **Mitochondria evolved from endosymbionts.** The ancestor of mitochondria was an alphaproteobacterium related to rickettsias.
- **Chloroplasts evolved from endosymbionts.** The chloroplast ancestor was a cyanobacterium.

Concluding Thoughts

Over 3.85 Gyr ago, microbial communities had evolved, their strata building rock layers that persist today. From these or other microbes, all subsequent life evolved. It is hard to say which is more astonishing: the overall commonalities of all living cells, including membrane-bounded support systems for genomes of 3.85 billion years of shared ancestry, or the subsequent evolution of organisms with vastly different adaptations to exploit every possible niche of our planet. The next three chapters explore these diverse adaptations: Chapter 18, bacterial diversity; Chapter 19, archaeal diversity, and Chapter 20, diversity among microbial eukaryotes including fungi, algae, and protists.

CHAPTER REVIEW

Review Questions

1. What was the composition of Earth's early crust and atmosphere? What processes changed their composition to that found today?
2. What kinds of evidence support the presence of life in the Archaean eon? What are the advantages and limitations of each kind of evidence?
3. What kinds of metabolism are believed to have existed in Archaean life? What kinds of evidence support their existence?
4. Compare and contrast three models for the origin of the first cells. What features of life does each model explain, and which features are unexplained?
5. Explain the roles of classification, nomenclature, and identification for microbial taxonomy.
6. Why is the definition of species in prokaryotes more problematic than for eukaryotes? What is generally considered the present basis for defining prokaryotic species?
7. Discuss the roles of mutation, natural selection, and reductive evolution in the divergence of microbial species. Cite specific examples.
8. Explain the basis of a "molecular clock" for measuring microbial evolution. What fundamental properties must be met by a gene to function as a microbial clock? What are the limitations of a molecular clock?
9. Explain the basis of a phylogenetic tree. Why is the fundamental tree at the divergence of bacteria, archaea, and eukaryotes unrooted?
10. How does horizontal gene transfer determine genomic content? What kinds of genes are likely to undergo horizontal transfer?
11. Explain how endosymbiosis can lead to obligate association. Explain how reductive evolution and gene transfer lead to the evolution of organelles that are inseparable from host cells.

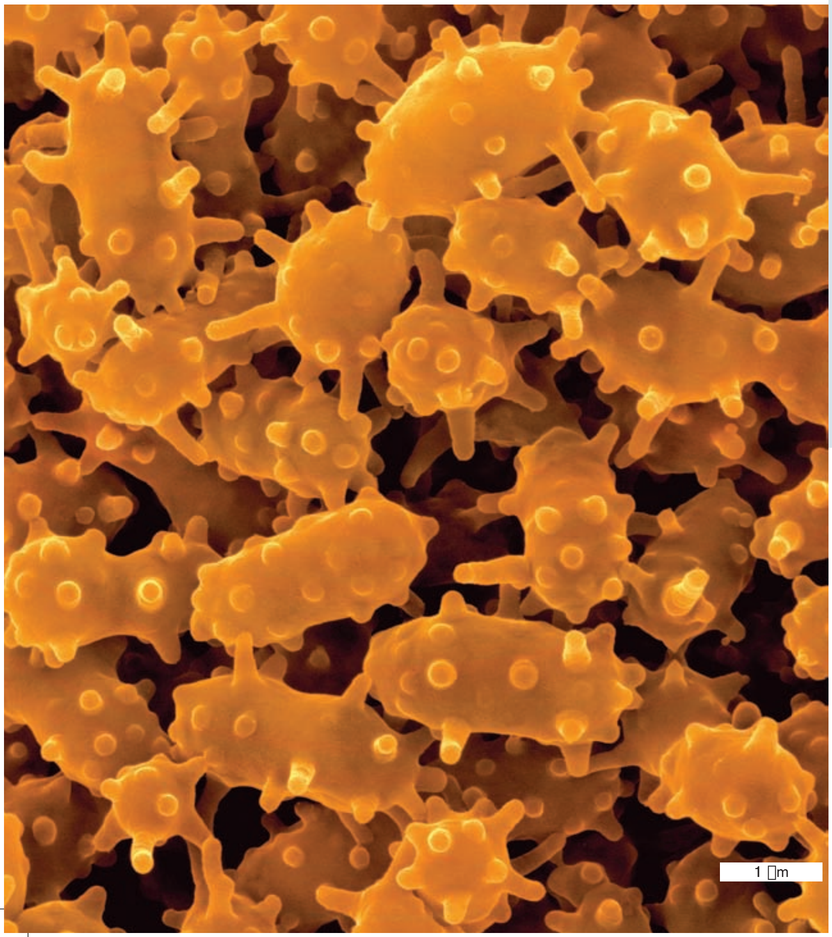
Chapter 18

Bacterial Diversity

18.1 Bacterial Diversity at a Glance
18.2 Deep-Branching Thermophiles
18.3 Cyanobacteria: Oxygenic Phototrophs
18.4 Gram-Positive Firmicutes and Actinobacteria
18.5 Gram-Negative Proteobacteria and Nitrospirae
18.6 Bacteroidetes and Chlorobi
18.7 Spirochetes: Sheathed Spiral Cells with Internalized Flagella
18.8 Chlamydiae, Planctomycetes, and Verrucomicrobia: Irregular Cells

Bacteria vary tremendously in their cell structure and metabolism. They include heterotrophs, phototrophs, and lithotrophs, with some species that could be classified as all three. There are obligate aerobes, anaerobes, and microaerophiles. Their cell shapes include rods, cocci, spirals, and budding forms. Ecologically, bacteria include mutualists, pathogens, and organisms that cannot be cultured in our laboratories. New species, even entire new phyla of bacteria, are continually discovered in soil and water, in our homes, and even within our own bodies.

How do we begin to make sense of the thousands of different kinds of bacteria? This chapter introduces the major categories of bacteria about which we know most. These include the gram-positive rods and cocci, the gram-negative proteobacteria, anaerobes, phototrophs, and spirochetes. There are cell wall-less chlamydiae and planctomycetes and deep-branching thermophiles. Even now, all the species we know represent but a tiny fraction of the diverse bacterial species growing in nature.



Verrucomicrobium spinosum, isolated by Heinz Schlesner at Christian Albrechts University. Verrucomicrobia, or "bumpy bacteria," metabolize sugars in soil and water and in the human digestive tract. These bacteria were barely known until recently, but DNA analysis shows they may account for 5% of all bacteria. The sequencing of their genomes is supported by the U.S. Department of Energy Joint Genome Institute, in collaboration with German and Australian scientists (2006). Figure 18.1 Bacterial succession in the digestive tract of a newborn baby. A. A nursing infant shows a unique combination of bacterial species. Comparative sequence analysis reveals the closest relative of each species isolated. **B.** From a newborn baby over time, fecal samples were tested. PCR-amplified sequences of 16S (SSU) rRNA genes were separated by denaturing gradient gel electrophoresis (DGGE). The patterns of bands change as species disappear and new ones appear, with the greatest changes occurring at weaning from breast milk to solid food. Band numbers refer to isolates for which 16S rRNA was sequenced (list at left). *Source*: B. Christine Favier, et al. *Applied and Environmental Microbiology* 68:219.

Bacteria have evolved a bewildering array of life-forms that colonize every habitat on Earth, from the dunes of the Sahara desert to the ice-buried Lake Vostok of Antarctica. Every day we discover new species never before recorded, not just from exotic environments, but from habitats closer to home. Consider, for example, the digestive tract of a newborn infant (**Fig. 18.1**). Dutch researcher Antoon Akkermans and colleagues identified bacterial species from the feces of an infant during the first year of life. The bacterial species were identified using polymerase chain reaction (PCR) to amplify small-subunit rRNA gene sequences directly, without culturing, as discussed in Chapter 17. The rRNA sequences from the infant's fecal sample were separated by denaturing gradient gel electrophoresis (DGGE), a technique in which the cloned DNA products denature and form secondary structures that influence their banding patterns in the gel. As each infant grows, the DGGE bands change as bacterial species disappear and new ones appear. The species distribution changes the most during months 4–6 as the infant is weaned from breast milk onto foods containing very different carbon sources. Some of the DNA samples show close sequence homology with well-characterized anaerobic genera such as *Bifidobacterium*, a gram-positive rod that ferments without gas production. The lack of gas production by *Bifidobacterium* helps prevent colic (gas pains). Other gram-positive rods were identified as clostridia, gram-positive spore formers that include harmless species as well as pathogens causing tetanus and botulism. But more than half of the fecal isolates showed rRNA with less than 97% similarity to any known sequence, a criterion for distinct species. Thus, even a human infant constitutes a microbial frontier full of unknown kinds of bacteria.

Characterizing bacteria is a formidable task, as even in familiar habitats the vast majority of species remain unknown and new phyla are discovered daily. At the same time, new fields of genomics, microscopy, and culture techniques clarify our view of major groups of bacteria with physiological, ecological, and medical significance. Chapter 18 presents these taxa in a format that emphasizes phylogeny (evolutionary relatedness) as well as key traits such as the gram-positive cell wall of Firmicutes and the oxygenic photosynthesis of cyanobacteria. For each taxon, a few key species are introduced to represent the spectrum of diversity that spans even a group of close relatives. For more information on particular species, consult the following public online resources:

- **The National Center for Biotechnology Information (NCBI) Taxonomy Database**, funded by the U.S. government, lists the full taxonomy of biological species reported in the literature and an ever-growing database of sequenced genomes.

WWW National Center for Biotechnology Information (NCBI)

- **The Microbial Biorealm** at Kenyon College is a student-edited online encyclopedia of microbial genera. Entries briefly summarize the taxonomy, genome structure, physiology, and societal relevance of each species.

WWW Microbial Biorealm

NOTE: Bacteria are also known as eubacteria or "true bacteria," to distinguish them from archaea, many of which were originally described as bacteria. Current literature equates bacteria with eubacteria. Archaea are discussed in Chapter 19.

18.1 Bacterial Diversity at a Glance

To survey bacterial diversity in one chapter is like touring all the countries of a continent in a single day. Like countries, bacterial taxa have complex traits and histories and often contested borders. At the same time, bacteria as a whole share major commonalities that offer an important perspective from which to appreciate their differences.

Common Traits of Bacteria

Chapter 17 summarized the differences and similarities between the three major domains—Bacteria, Archaea, and Eukarya (see **Table 17.3**). A profound commonality of bacteria is their central apparatus of gene expression, particularly their RNA polymerase and their ribosomal RNAs and translation factors. The bacterial gene expression complexes differ more from those of Archaea or Eukarya than those of Archaea or Eukarya differ from each other. This subtle point of molecular biology has a profound consequence for human medicine and agriculture: It underlies the selective activity of a wide array of antibiotics, such as streptomycin, that attack only bacterial pathogens, without harming the animal or plant host.

Another fundamental trait of bacteria with useful consequences in controlling pathogens is that most bacterial cells possess a cell wall of peptidoglycan comprising a single covalent molecule (**Fig. 18.2**; discussed in Chapter 3). Peptidoglycan is composed of disaccharide-peptide chains that can cross-link in three dimensions; key enzymes that build the peptide links are blocked by antibiotics such as penicillin and vancomycin. Variant forms of peptidoglycan distinguish different species. For instance, the gram-positive pathogen *Staphylococcus aureus* has cell wall peptides cross-linked by pentaglycine (a chain of five glycine residues). Some species such as mycoplasmas lack peptidoglycan altogether, but they arose by reductive evolution from bacteria that possess it.

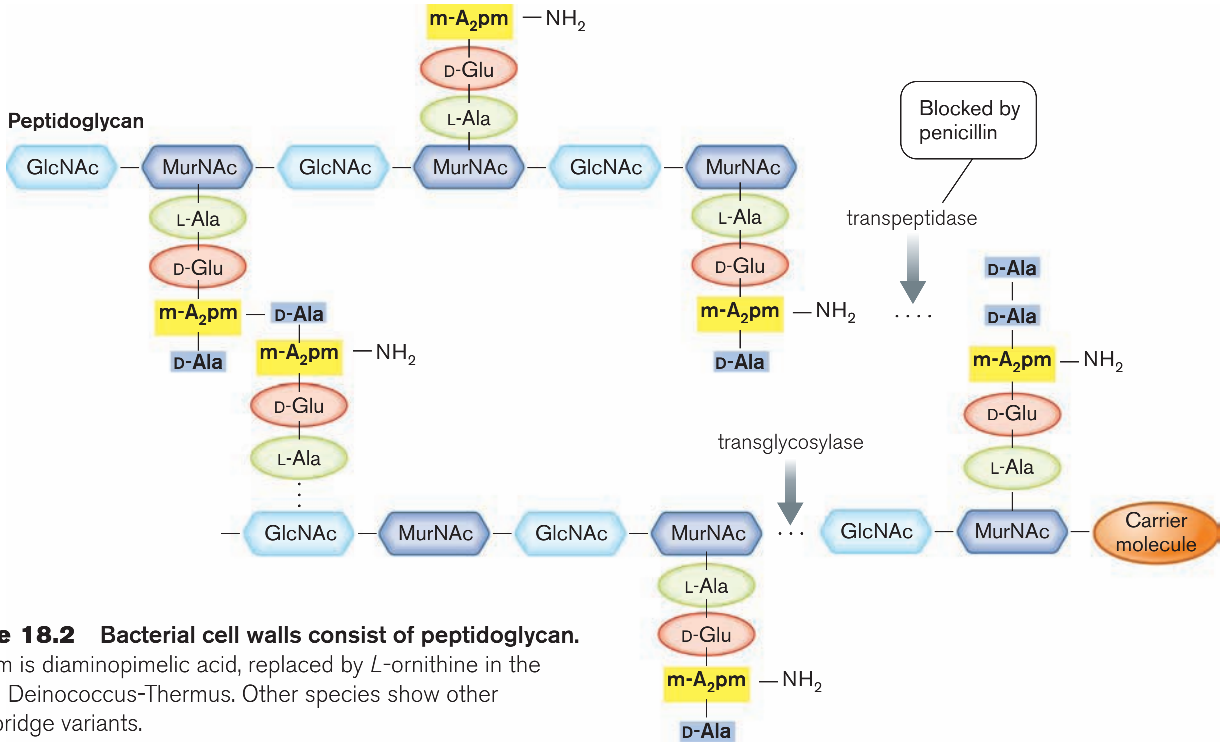

Figure 18.2 Bacterial cell walls consist of peptidoglycan. m-A$_2$pm is diaminopimelic acid, replaced by *L*-ornithine in the phylum Deinococcus-Thermus. Other species show other cross-bridge variants.

By contrast, most archaea lack cell walls, although methanogens have independently evolved an analogous sugar-peptide structure called pseudopeptidoglycan (discussed in Chapter 19). Eukaryotes such as fungi and plants have cell walls of polysaccharides such as cellulose.

The Bacterial Tree

The phylogeny of known bacteria is presented in **Figure 18.3**. The names of well-studied phyla are lettered blue. A **phylum** is defined as a group of organisms sharing a common ancestor that diverged early from other bacteria based on rRNA sequence (discussed in Chapter 17). Phyla and other major divisions are also defined on the basis of historical convention and consensus of the research community.

A bacterial phylum generally comprises species that share key traits as well as ancestry. While sharing key traits, the member species often show remarkable diversity in other ways. Some phyla, such as Cyanobacteria, share a unique form of metabolism (oxygenic photosynthesis), yet have evolved many diverse cell shapes and grow in diverse habitats. Other phyla, such as Spirochetes, share a unique cell structure while diverging in habitat and metabolism.

Table 18.1 introduces the bacterial species that are most frequently encountered in the literature. Bear in mind, however, that more than 50 other bacterial phyla are known to date and that deep-branching clades continue to be discovered.

Deep-branching thermophiles. The most deeply branching bacterial phyla (that is, those that appear to have diverged earliest) include hyperthermophiles that share physiology and habitat with archaea. For example, *Aquifex* grows at 95°C and possesses traits typical of archaea, such as ether-linked membrane lipids. Some "archaeal" traits of bacteria arose from a common ancestor of bacteria and archaea, whereas others arose through lateral transfer of genes from archaea to bacteria sharing the high-temperature habitat. In other aspects of structure and physiology, the deep-branching phyla diverge from each other. Order Aquificales consists of gram-negative rods that oxidize hydrogen, whereas order Thermotogales is made up of sheathed gram-negative rods that are obligate anaerobic heterotrophs. Deinococcus-Thermus includes moderately thermophilic gram-negative heterotrophs, often filamentous. *Thermus aquaticus* was the first source of heat-resistant DNA polymerase for PCR.

Figure 18.3 Bacterial phylogeny. A phylogenetic tree of representative Bacteria based on 16S rRNA sequence comparison. The tree is rooted with respect to Archaea and Eukarya. Bold labels correspond to major groups in Table 18.1. Phylum names are lettered blue.

Table 18.1 Representative groups of bacteria.

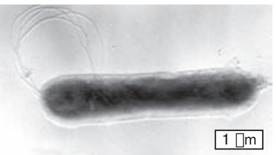
Note: Each trait applies to *most* members of the taxon described, but exceptions have evolved.

Blue-lettered terms indicate phyla.

- **Bulleted terms are representative orders** within the phylum.

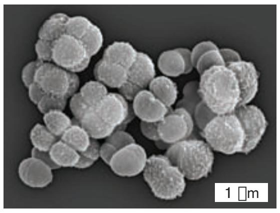
Deep-branching Thermophiles

Thermophilic bacteria that diverged early from the archaea and eukaryotes. Many genes transferred laterally from archaea.



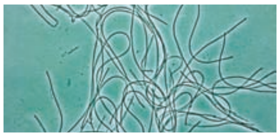
Aquifex

K. O. Stetter & R. Rachel, U. of Regensburg



Deinococcus

Dennis Kunkel/Visuals Unlimited



Chloroflexus aurantiacus

DOE-Herter/Visuals Unlimited

Aquificae. Hyperthermophiles (70–95°C). Oxidize H_2, H_2S, or thiosulfate.

- **Aquificales.** Outer membrane; cells may be single with flagella or grow in filaments. *Aquifex, Thermocrinis.*

Thermotogae. Thermophiles or hyperthermophiles (55–100°C).

- **Thermotogales.** Outer membrane with large periplasm; anaerobic heterotrophs. *Petrotoga, Thermotoga.*

Deinococcus-Thermus. Peptidoglycan contains ornithine. Diverse growth temperatures.

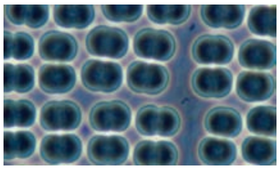
- **Deinococcales.** Thick envelope; stains gram-positive. Not thermophilic, but extremely resistant to ionizing radiation and to desiccation. *Deinococcus.*
- **Thermales.** Species are filamentous clustered cells or single-celled. Grow at 70–75°C. *Thermus aquaticus* is the source of Taq polymerase for PCR.

Chloroflexi. Filamentous green nonsulfur bacteria.

- **Chloroflexales.** Filamentous phototrophs. Most contain photosystem II in chlorosomes. *Chloroflexus aurantiacus* is thermophilic; forms mats in hot springs.

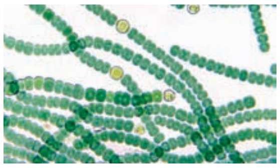
Cyanobacteria

Oxygenic photoautotrophs with thylakoid membranes. Share ancestry with chloroplasts.



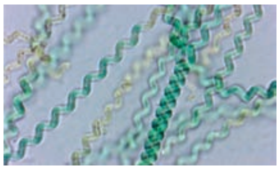
Merismopedia

Michael Abbey/Visuals Unlimited



Anabaena

©Carolina Biological Supply/Visuals Unlimited



Spirulina

Peter Siver/Visuals Unlimited

Cyanobacteria. Oxygenic photoautotrophs with thylakoid membranes. Fix CO_2 using rubisco. Often mutualists. Share ancestry with chloroplasts.

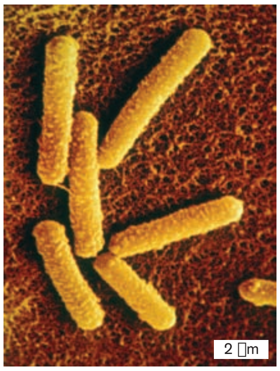
- **Chroococcales.** Square colonies based on two division planes.
  - ***Chroococcus.*** Single, double, or quartet of cells. Grow in pond sediment.
  - ***Merismopedia.*** Platelike colonies of elliptical cells.
  - ***Synechococcus.*** Single or double cells. Marine producer.
- **Nostocales.** Filamentous chains with N_2-fixing heterocysts. Often grow symbiotically with other microbes, corals, or plants.
  - ***Anabaena.*** Aquatic. Grow in association with red water fern (*Azolla*).
  - ***Nostoc.*** Aquatic. Grow independently; or mutualistically with fungi, as lichens; or as endosymbionts of *Gunnera* plant cells.
- **Oscillatoriales.** Filamentous chains with motile hormogonia (short chains).
  - ***Oscillatoria.*** Aquatic or marine. Grow independently; or as sponge endosymbionts.
  - ***Spirulina.*** Aquatic. Farmed as food supplement.
  - ***Trichodesmium.*** Major marine producer. Forms “blooms” of overgrowth.
- **Pleurocapsales.** Globular colonies; reproduce through baeocytes. *Pleurocapsa, Myxosarcina.*
- **Prochlorales.** Tiny single cells, elliptical or spherical.
  - ***Prochlorococcus.*** Most abundant marine producer. One of the smallest cells of a free-living microbe, with a highly reduced genome.
  - ***Prochloron.*** Tropical marine producer; endosymbiont of sea squirt.

(*continued*)

Table 18.1 Representative groups of bacteria (*continued*)

Firmicutes and Actinobacteria (gram-positive)

Gram-positive. Peptidoglycan multiple layers, cross-linked by teichoic acids. Aerobes and facultative anaerobes.



Andrew Syred/Photo Researchers, Inc.

Bacillus subtilis

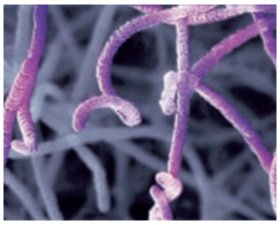
Firmicutes. **Low GC, gram-positive rods and cocci.**

- **Bacillales.** Aerobic or facultative anaerobes.
  - ***Bacillus.*** Endospore-forming rods. Obligate aerobes. Grow in soil. *B. subtilis* is gram-positive model system; *B. anthracis* causes anthrax. Include extremophiles: *B. alkalophilus, B. thermophilus, B. halodurans.*
  - ***Listeria.*** Non-spore-forming rods. *L. monocytogenes* is an enteric intracellular pathogen.
  - ***Staphylococcus.*** Non-spore-forming cocci; hexagonal clusters. *S. aureus* causes toxic shock and lethal flesh infections.
- **Clostridiales.** Anaerobic rods.
  - ***Carboxydothermus.*** Oxidizes carbon monoxide (CO) to CO_2. Forms endospores.
  - ***Clostridium.*** Forms endospores. *C. botulinum* and *C. difficile* are pathogens. *C. acetobytylicum* generates butanol.
  - ***Dehalobacter.*** Non-spore-forming rods. Dechlorinate chloroethenes.
  - ***Epulopiscium.*** Exceptionally large cells. Reproduce by "live birth."
  - ***Heliobacterium, Heliophilum.*** Endospore-forming photoheterotrophs; use a distinctive bacteriochlorophyll *g*.
  - ***Metabacterium.*** Exceptionally large cells; form multiple endospores. *M. polyspora.*
  - ***Ruminococcus.*** Digestive flora of ruminant animals.

Don W. Fawcett/Photo Researchers, Inc.

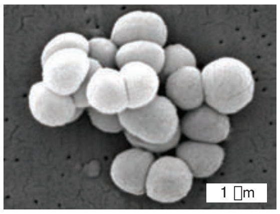
Mycoplasma genitalium

- **Lactobacillales.** Facultative anaerobes. Ferment producing lactic acid.
  - ***Enterococcus.*** Enteric cocci.
  - ***Lactobacillus.*** Non-spore-forming rods. *L. acidophilus* is used for dairy culture.
  - ***Lactococcus.*** Non-spore-forming cocci. Used for dairy culture.
  - ***Streptococcus.*** Non-spore-forming cocci; chains. Human throat flora. Group A streptococci cause "strep throat" and scarlet fever.
- **Mollicutes** (class). Lacks cell wall and S-layer; requires an animal host. *Mycoplasma genitalium* has one of smallest known genomes. *M. pneumoniae* causes pneumonia.



Science VU/Frederick Mertz/Visuals Unlimited

Streptomyces



CDC/Betsy Crane

Micrococcus luteus

Actinobacteria. **High GC, gram-positive bacteria with moderate salt tolerance.**

- **Actinomycetales.**
  - **Actinomycetes.** Filamentous, producing aerial hyphae and spores.
    - ***Streptomyces*** species produce many antibiotics. *S. coelicolor, S. griseus.*
    - ***Frankia*** **species** fix nitrogen for plants.
    - ***Actinomyces.*** *A. israelii* causes actinomycosis.
  - **Corynebacteraceae.** Irregular rods. *Corynebacterium diphtheriae* causes diphtheria.
  - **Mycobacteriaceae.** Exceptionally thick cell envelope holds acid-fast stain.
    - ***Mycobacterium.*** *M. tuberculosis* causes tuberculosis; *M. leprae* causes leprosy.
  - **Micrococcaceae.** Nonfilamentous soil bacteria; mostly obligate aerobes.
    - ***Arthrobacter.*** Rods. Respire on oxygen or on chlorinated aromatics.
    - ***Micrococcus.*** Aerobic cocci such as *M. luteus*. Grow in soil.
- **Bifidobacteriales.** Rods; fermenting without gas production. Commonly found among the enteric flora of breast-fed infants.
- **Propionibacteria.** Facultative anaerobic rods. Propionic acid fermentation. *Propionibacterium acnes* causes acne; *P. freudenreichii* makes Swiss cheese.

Proteobacteria and Nitrospirae (gram-negative)

Gram-negative. Outer membrane contains LPS. Diverse metabolism. Lineage includes mitochondria.

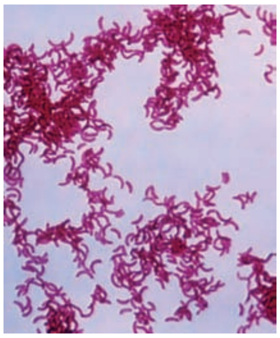
Proteobacteria. **Gram-negative. Diverse cell forms and metabolism.**

Alpha Proteobacteria (class). Heterotrophic rods or spirilla with diverse metabolism.

- **Caulobacterales.** Aquatic oligotrophs. Crescent-shaped cells with stalk; develop flagellar form. *Caulobacter*. Other oligotrophs with variable shape (lineage uncertain): *Hyphomicrobium, Seliberia.*

Table 18.1 Representative groups of bacteria (*continued*)

- **Nitrobacter.** Nitrite-oxidizing lithotrophs. *Nitrobacter winogradskyi.*
- **Rhizobiales.** Plant mutualists and pathogens, methyl oxidizers, and animal pathogens.
  - ***Agrobacterium.*** *A. tumefaciens* causes plant tumors; transgenic plant vector.
  - ***Rhizobium* group.** Related to *Agrobacterium. Rhizobium, Bradyrhizobium, Sinorhizobium* fix nitrogen intracellularly in legumes.
  - ***Brucella.*** Animal pathogens. *B. abortus.*
  - ***Methylobacterium.*** Grow on single-carbon compounds. Opportunistic pathogens found in shower-curtain soap scum.
  - ***Rhodopseudomonas, Rhodomicrobium.*** Soil photoheterotrophs.
- **Rhodobacterales, Rhodospirales.** Photoheterotrophs using sulfides and organic substrates. Unicellular with flagella. *Rhodobacter sphaeroides, Rhodospirillum rubrum, Rhodopseudomonas palustris.* Some non-phototrophs: *Acetobacter* makes vinegar.
- **Rickettsia.** Includes intracellular parasites; lineage includes mitochondria.
  - ***Rickettsia.*** Intracellular parasites. *R. rickettsii* causes Rocky Mountain spotted fever; *R. prowazekii* causes typhus.
  - **SAR11 cluster.** Marine photoheterotrophs use proteorhodopsin. *Pelagibacter.*
- **Sphingomonadales.** Catabolizes complex organics; useful for bioremediation. Some species are opportunistic pathogens. *Sphingomonas.* Also aerobic photoheterotrophs: *Citromicrobium, Erythromicrobium.*

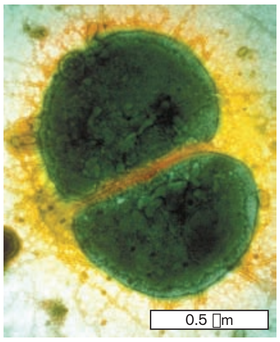


David M. Phillips/Visuals Unlimited

Rhodospirillum rubrum

Beta Proteobacteria (class). Phototrophs, heterotrophs, and lithotrophs.

- **Burkholderiales.** Soil bacteria and opportunistic pathogens. *Burkholderia pseudomallei* causes melioidiosis in humans and farm animals.
- **Hydrogenophilales.** Lithotrophs.
  - ***Thiobacillus.*** *T. ferrooxidans* oxidizes iron and sulfur.
- **Neisseriales.** Mucous membrane normal flora and pathogens. Aerobic or microaerophilic diplococci. *Neisseria gonorrhoeae* causes gonorrhea; *N. meningitidis* causes meningitis.
- **Nitrosomonadales.** Lithotrophs. *Nitrosomonas europea* oxidizes ammonia.
- **Rhodocyclales.** Soil heterotrophs and photoheterotrophs. *Azoarcus evansii* catabolizes complex aromatic molecules. *Rhodocyclus* species are purple photoheterotrophs.



Kwangshin Kim/Photo Researchers, Inc.

Neisseria gonorrhoeae

Gamma Proteobacteria (class). Facultative anaerobes and lithotrophs.

- **Aeromonadales.** Aquatic heterotrophs. *Aeromonas hydrophila* infects fish; causes opportunistic infections in humans.
- **Chromatiales.** Lithotrophs (*Nitrococcus* oxidizes ammonia). Sulfur and iron phototrophs (*Chromatium*). Nitrite phototrophs (*Thiocapsa*).
- **Enterobacterales.** Enterobacteraceae. Facultative anaerobes; colonize the human colon.
  - ***Escherichia coli.*** Strains include normal flora and enteric pathogens.
  - ***Salmonella.*** Pathogens. *S. enterica* causes gastrointestinal infection. *S. typhi* causes typhoid fever.
  - ***Yersinia.*** Pathogens. *Y. pestis* causes bubonic plague.
- **Legionellales.** Waterborne intracellular pathogens. *Legionella pneumophila* causes legionellosis pneumonia.
- **Oceanospirilles.** Marine heterotrophs, including degraders of petroleum. *Alcanivorax.*
- **Pseudomonadales.** Rods, usually aerobic or respire on nitrate; catabolize aromatics. *Pseudomonas aeruginosa* opportunistically infects lungs of cystic fibrosis patients. *P. fluorescens* suppresses plant diseases.
- **Thiotrichales.** Lithotrophs and heterotrophs. *Beggiatoa alba* and *Thiomargarita namibiensis* oxidize sulfur. *Cycloclasticus* catabolizes polycyclic aromatic hydrocarbons in petroleum.
- **Vibrionales.** Marine heterotrophs. *Vibrio cholerae* causes cholera.
- **SAR86 cluster.** Marine photoheterotrophs use proteorhodopsin.

Nitrospira

Delta Proteobacteria (class). Diverse form and metabolism.

- **Bdellovibrionales.** Bacterial intracellular predators. *Bdellovibrio bacteriovorus* parasitizes and consumes *E. coli.*
- **Desulfobacterales.** Reduces sulfate. *Desulfobacter* spp.
- **Desulfuromonadales.** Lithotrophs; reduce or oxidize sulfur or metals.
  - ***Geobacter metallireducens*** reduces iron oxide.
  - ***Desulfuromonas*** reduces elemental sulfur.
- **Myxococcales.** Gliding bacteria that form fruiting bodies. *Myxococcus* spp.

Epsilon Proteobacteria (class).

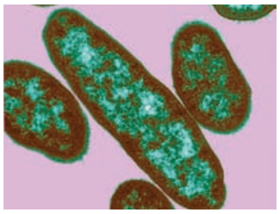
- **Campylobacterales.** Spirillar pathogens.
  - ***Campylobacter.*** *C. jejuni* causes food poisoning.
  - ***Helicobacter.*** *H. pylori* causes gastritis.
  - ***Thiovulum.*** Oxidizes sulfides, producing sulfur granules.

Nitrospirae. **Nitrite oxidizers. Obligate aerobes.**

- **Nitrospirales.** Tight spirillum. In soil and water, oxidizes NO_2^- to NO_3^-. *Nitrospira*; *Leptospirillum.* Includes acidophilic Fe oxidizers.

Bacteroidetes/Chlorobi Group

Gram-negative. Obligate anaerobes and/or green sulfur phototrophs.



Collection CNRI/Phototake

Bacteroides

Bacteroidetes. **Obligate anaerobes. Heterotrophs that feed on diverse carbon sources.**

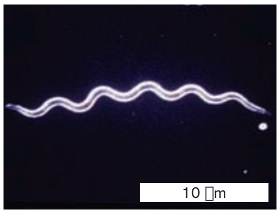
- **Bacteroidales.** Obligate anaerobes, soil or human flora.
  - ***Bacteroides.*** Enteric. *B. thetaiotaomicron* digests complex plant carbohydrates in gut.
    - *Bacteroides* species escaping the colon cause abscesses.
  - ***Porphyromonas.*** Includes gingival pathogens such as *P. gingivalis.*
- **Flavobacteriales.** Heterotrophs in soil and water; opportunistic pathogens. *Flavobacterium psychrophilum* infects freshwater trout fish.

Chlorobi. **Green sulfur-oxidizing phototrophs.**

- **Chlorobiales.** Conducts anaerobic photolysis of H_2S, absorbing primarily red and infrared. *Chlorobium tepidum.*

Spirochetes (Spirochaeta)

Narrow coiled cell encased by sheath, which encloses polar flagella.



Charles Stratton/Visuals Unlimited

Borrelia burgdorferi

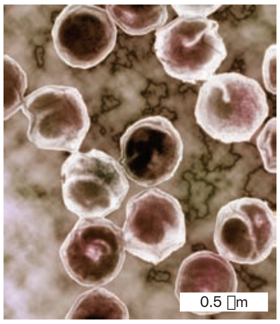
Spirochetes. **Narrow coiled cell with axial filaments, encased by sheath. Polar flagella beneath sheath double back around cell. Often symbiotic or pathogenic.**

- **Spirochaetales.** Aquatic, free-living or pathogenic.
  - ***Borrelia.*** *B. burgdorferi* causes Lyme disease, transmitted by ticks.
  - ***Hollandina.*** Termite gut endosymbionts.
  - ***Leptospira.*** L-shaped animal pathogen; causes leptospirosis.
  - ***Treponema.*** *T. pallidum* causes syphilis.
  - ***Spirochaeta.*** Aquatic, free-living.

Table 18.1 Representative groups of bacteria (*continued*)

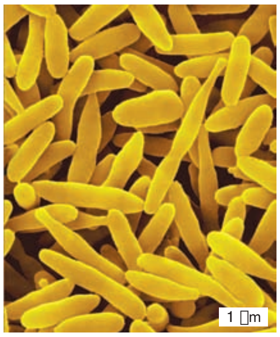
Chlamydiae, Planctomycetes, and Verrucomicrobia

Irregular cells lacking peptidoglycan, with subcellular structures analogous to eukaryotes.



David Phillips/Visuals Unlimited

Chlamydia trachomatis



Dennis Kunkel/Phototake

Prosthecobacter fusiformis

Chlamydiales. Intracellular cell wall-less pathogens of animals or protists.

- **Chlamydiales.** Reticulate bodies form multiple spore-like transfer particles (elementary bodies) that infect the next host.
  - ***Chlamydia.*** *C. trachomatis* causes sexually transmitted disease and trachoma (eye infection).
  - ***Chlamydophila.*** *C. pneumoniae* causes pneumonia; *C. abortus* causes spontaneous abortion in animals; *C. psittaci* causes psittacosis in birds and humans.
  - ***Parachlamdia.*** Chlamydia-like species that infect free-living amebas.

Planctomycetes. Nucleoid has double membrane analogous to eukaryotic nuclear membrane and other intracytoplasmic subcellular membrane compartments.

- **Planctomycetales.** Aquatic or marine. Flexible cell shape.
  - ***Brocadia.*** *B. anammoxidans* anaerobically oxidizes ammonium, using a membrane-bound organelle, the anammoxosome.
  - ***Gemmata.*** Nuclear double membrane, surrounded by additional intracellular membrane.
  - ***Pirellula.*** Only one intracellular membrane. Has fimbriae and single flagellum. Marine habitat.
  - ***Planctomyces.*** One intracellular membrane. Halophile.

Verrucomicrobia. Stalk-like appendages contain actin filaments in addition to peptidoglycan. Aquatic oligotrophs.

- **Verrumicrobiales.**
  - ***Prosthecobacter.*** Each cell has a polar cytoplasmic extension called a prostheca.
  - ***Verrucomicrobium.*** Stellate cells have multiple prosthecae.

By contrast, members of the closely related order Deinococcales grow in the middle range of temperature and stain gram-positive. *Deinooccus radiodurans* shows extreme resistance to ionizing radiation and desiccation (discussed in Chapters 5 and 9). The phylum Chloroflexi consists of thermophilic green phototrophs that often share habitat with thermophilic cyanobacteria.

Cyanobacteria. The **Cyanobacteria** are a deeply branching phylum of profound importance for all ecosystems. Cyanobacteria conduct photosynthesis by splitting water or H_2S and fixing CO_2 (discussed in Chapter 14). Only cyanobacteria and chloroplasts (in eukaryotes) can produce oxygen gas. They have a unique two-photosystem apparatus for oxygenic photosynthesis arranged in lamellar arrays of membranes called thylakoids. Unique to cyanobacteria and chloroplasts are the chlorophylls, most notably chlorophylls *a* and *b*; these are distinct from the "bacteriochlorophylls" used by nonoxygenic bacterial phototrophs. Cyanobacteria share a common metabolism, yet the cell shape and organization of cyanobacterial species show an immense range of different forms, including chains of cells, square arrays, and globular colonies. Many cyanobacteria grow in seawater or fresh water, whereas others grow in mutualism with a eukaryotic host.

Gram-positive bacteria. Two major phyla, **Firmicutes** and **Actinobacteria**, are called "the gram-positive bacteria" because most members stain gram-positive. Some Firmicutes fail to stain gram-positive because they lack cell walls (the mycoplasmas), whereas some Actinomycetes possess a thick waxy coat that excludes the gram stain. Most Firmicutes and Actinobacteria have an exceptionally thick cell wall, with several layers of peptidoglycan generally interpenetrated by supporting molecules such as teichoic acids or mycolic acids. The thick, reinforced cell wall is what retains the Gram stain (discussed in Chapter 2). In addition, most gram-positive species possess a well-developed S-layer of protein with glycan strands. By contrast, in other bacterial phyla the S-layer is either absent or present in diminished form.

Firmicutes and Actinobacteria are distinguished genetically based on their **GC content**, that is, the proportion of their genomes consisting of guanine-cytosine base pairs (as opposed to adenine-thymine). The Firmicutes (low GC) generally grow as well-defined rods or cocci, isolated or in simple filaments consisting of cells that divide but remain attached end to end. Many Firmicutes form **endospores**, inert heat-resistant spores that can remain viable for thousands of years. Endospores are the most durable type of spore formed by bacteria. The

Actinobacteria have a relatively high GC content. Actinobacteria (high GC) include the **actinomycetes** (order Actinomycetales), which undergo complex life cycles forming filamentous hyphae and arthrospores. Other groups closely related to actinomycetes grow as isolated rods and cocci, often with variable shape, such as the corynebacteria. Actinomycete relatives include the well-known causative agents of tuberculosis (*Mycobacterium tuberculosis*) and leprosy (*M. leprae*).

Gram-negative bacteria. **Proteobacteria** and **Nitrospirae** are called "the gram-negative bacteria" because their single layer of peptidoglycan fails to retain the Gram stain. (Note, however, that members of other phyla also stain gram-negative.) Species of Proteobacteria and of Nitrospirae have a complex outer membrane consisting of lipopolysaccharides (LPS) and porins. Some porins in the outer membrane are homologs of firmicute S-layer proteins, which suggests that the gram-negative outer membrane may have evolved from an S-layer. All Proteobacteria have in common the LPS outer membrane, but they show an immense range of shape (rods, cocci, spirals, and filaments) and metabolism (heterotrophy, lithotrophy, and anaerobic phototrophy). Most species are aerobic, facultative, or microaerophilic.

Proteobacteria include five major classes, labeled Alpha, Beta, Gamma, Delta, and Epsilon. (Some sources merge the Greek letter into the name, as in Alphaproteobacteria, Betaproteobacteria, and so on.) Proteobacteria include famous model organisms and pathogens, such as *Escherichia coli*, *Salmonella typhimurium*, and *Yersinia pestis*. Many are human or animal symbionts, either as mutualists or as pathogens—including *Rickettsia*, the genus most closely related to mitochondria. Members of the gram-negative phylum Nitrospirae largely resemble proteobacteria in form, though they diverged earlier. Species of Nitrospirae (such as *Nitrospira* spp.) oxidize nitrite to nitrate, a lithotrophic conversion essential for ecosystems.

Bacteroidetes and Chlorobi. The phyla **Bacteroidetes** and **Chlorobi** stain gram-negative, but nearly all their members are obligate anaerobes. Within Bacteroidetes, *Bacteroides* species ferment complex carbohydrates, serving as the major mutualists of the human gut. Chlorobi species are also obligate anaerobes, but they are "green sulfur" phototrophs that photolyze sulfides or H_2.

Spirochetes. The **Spirochetes** (Spirochaetes) exhibit a unique and complex cellular form of a flexible, extended spiral, resembling a telephone cord. The cytoplasm and cell membrane are contained within an outer membrane called the sheath. Between the sheath and the cell membrane extend flagella, doubled back from each pole. The rotation of these flagella is coordinated so as to twist and flex the helical body, generating motility and chemotaxis. Spirochetes include many free-living forms in aquatic systems, as well as digestive endosymbionts and pathogens.

Irregular shaped bacteria. Three phyla of bacteria display remarkable adaptations suggestive of eukaryotes: **Chlamydiae**, **Verrucomicrobia**, and **Planctomycetes**. Most members of these groups have lost their peptidoglycan cell walls, but they show complex structural adaptations and developmental forms. The Chlamydiae (best-known genus *Chlamydia*) consists of intracellular parasites that lose most of their cell envelope during intracellular growth. The replicating parasites generate multiple spore-like "elementary bodies" that escape to infect the next host. Verrucomicrobia, by contrast, are free-living aquatic bacteria with wart-like protruding structures containing actin. Planctomycetes, also free-living, have stalked cells that reproduce by budding. Each planctomycete cell contains an extra double membrane surrounding its nucleoid, analogous to a eukaryotic nuclear membrane, though it evolved independently.

THOUGHT QUESTION 18.1 Which taxonomic groups in **Table 18.1** stain gram-positive and which gram-negative? Which group contains both gram-positive and gram-negative species? For which groups is the Gram stain undefined, and why?

THOUGHT QUESTION 18.2 Which groups of species share common structure and physiology within the group? Which groups show extreme structural and physiological diversity?

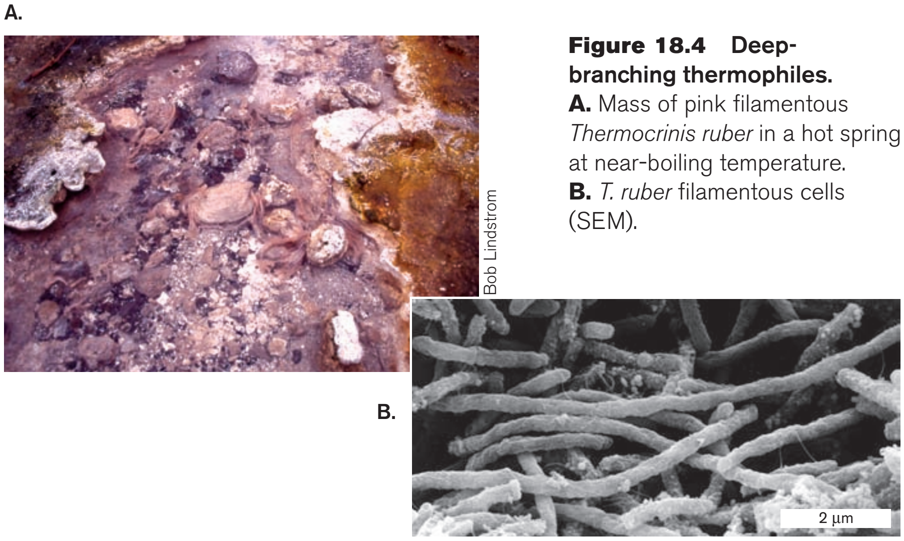
NOTE: Formal names for taxa such as phyla, orders, and genera are capitalized (phylum Cyanobacteria, genus *Streptococcus*. Informal forms are lowercase roman (cyanobacteria, streptococci), as are adjectival forms (cyanobacterial, streptococcal).

New Isolates: Unclassified and Uncultured Bacteria

The seven groups outlined in **Table 18.1** represent those bacteria of greatest historical interest and those best characterized by microbiologists. As new organisms emerge, they may be known initially only by their habitat and their small-subunit rRNA sequence. Such isolates require description of essential cell structure and metabolism before designation as new species. "Incompletely described" samples are designated as follows:

- An **unclassified organism** or **uncultured organism** is assigned to a taxonomic rank based on rRNA sequence but not yet grown in pure culture; for example, an “uncultured actinomycete.”

- An **environmental sample** is designated by its habitat and assigned a rank based on rRNA. Examples of environmentally defined actinomycetes in the NCBI database include “oil-degrading bacterium AOB1” and “glacier bacterium FJS11.”
- A species with some physiological characterization beyond DNA sequence may be published with a provisional status of **candidate species**, designated by the prefatory term *Candidatus*. For example, *Candidatus Nostocoida limicola* was published as “a filamentous bacterium from activated sludge.”



Bob Lindstrom

R. Huber and W. Eber. *Prokaryotes*, Springer

Figure 18.4 Deep-branching thermophiles. **A.** Mass of pink filamentous *Thermocrinis ruber* in a hot spring at near-boiling temperature. **B.** *T. ruber* filamentous cells (SEM).

Following our brief “one-day tour” of the bacterial domain, we now explore some of the diverse species within the major groups. Each section presents species from one of the seven major groups outlined in **Table 18.1**.

> **NOTE:** The primary organizing principle used in Chapters 18–20 is that of phylogeny based on DNA relatedness. Characteristic traits described for each branch apply to the majority of its known species, though exceptions are discovered daily, such as members of Spirochetes that lack spiral form.

18.2 Deep-Branching Thermophiles

Several of the most deeply branching phyla show traits similar to those of archaeal extremophiles and share high-temperature habitats such as hot springs. The precise nature of their relationship with archaea is controversial, however, because these organisms also show the fastest doubling rates of all cells (in some cases less than 10 minutes) and high rates of mutation, which may have “accelerated” their molecular clock. Thus, the deep-branching thermophiles may appear to have diverged from other bacteria earlier than they in fact did.

Aquificales and Thermotogales: The Most Extreme Bacterial Hyperthermophiles

The order Aquificales includes bacteria growing at high temperatures, up to 95°C. Most members of this group are hydrogenotrophs, oxidizing hydrogen gas with molecular oxygen to make water. *Aquifex pyrophilus*, a flagellated rod (see **Table 18.1**), was first discovered by extremophile microbiologist Karl Stetter at Regensburg University in a submarine hydrothermal vent north of Iceland. Stetter named it *Aquifex*, Latin for “water maker,” in reference to its metabolism of oxidizing hydrogen gas with O_2 to form water. *Aquifex* species are obligate autotrophs, fixing CO_2 into biomass using the reverse TCA cycle.

Other genera of Aquificales form filamentous mats in hydrothermal springs. *Thermocrinis ruber* was discovered by Thomas Brock at the University of Wisconsin-Madison as a mat of pink filamentous streamers (“pink filaments”) growing at 82–88°C in the outflow channel of Octopus Spring, in Yellowstone National Park (**Fig. 18.4**). As the filaments grow, they break off flagellated single cells that grow new filaments. *T. ruber* gains energy by oxidizing hydrogen, thiosulfate, and elemental sulfur as well as small organic molecules such as formate.

Another deep-branching order of thermophiles (growing at 50–80°C) is Thermotogales. *Thermotoga maritima* was isolated from a geothermal vent in Volcano, Italy. Their cells have a loosely bound sheath, or “toga,” for which the genus is named. They use anaerobic respiration, reducing elemental sulfur, thiosulfate, and sulfite to hydrogen sulfide.

The genomes of *T. maritima* and of *Aquifex aeolicus* reveal a surprisingly high content of genes transferred horizontally from archaea, well after the bacteria diverged from their common ancestor. Nearly a quarter of the *T. maritima* genome appears to be of archaeal origin, including fundamental enzymes such as glutamate synthase and inositol 1-phosphate synthase.

> **THOUGHT QUESTION 18.3** What taxonomic questions are raised by the apparent high rate of gene transfer between archaea and thermophilic bacteria?

Thermus and *Deinococcus*

The phylum Deinococcus-Thermus shares a unique structural trait, the substitution of *L*-ornithine for diaminopimelic acid in the peptidoglycan cross-bridge. *Thermus* species (growing at 70–75°C) are heterotrophs commonly isolated from hot tap water. *Deinococcus* species, however, are not thermophilic. *D. radiodurans* bacteria resist extremely high doses of ionizing radiation (discussed in Chapters 5 and 9). An otherwise ordinary heterotroph, *D. radiodurans* was originally isolated from cans of meat supposedly sterilized with a dose of several megarads. The natural habitat of *Deinococcus* species is not known, but the genus also resists extreme desiccation; it may have evolved as a soil organism capable of surviving drought. *Deinococcus* species, unlike *Thermus* species, have a thick cell wall that stains gram-positive, as well as an S-layer.

Chloroflexi: Thermophilic Green Photoheterotrophic Bacteria

Chloroflexi bacteria are filamentous photoheterotrophs, absorbing light to split organic molecules. Photosystem II (PS II) generates ATP through cyclic electron flow (discussed in Chapter 14). Chloroflexi species conduct nonphotosynthetic heterotrophy in the presence of oxygen. Most are moderate thermophiles, often found in hot springs in association with thermophilic cyanobacteria. *Chloroflexus aurantiacus* and thermophilic cyanobacteria form massive microbial mats in the hot springs of Yellowstone (**Fig. 18.5A**).

Chloroflexi are informally called "green nonsulfur bacteria" to distinguish them from Chlorobi, a different phylum of green phototrophs that photolyze sulfur compounds. Some chloroflexi appear green because their bacteriochlorophylls (Bchl) absorb primarily blue and red, allowing transmission of green (**Table 18.2**, top row). Other species, however, appear red or yellow owing to accessory pigments. A more inclusive term for this group is filamentous anoxygenic phototrophs, distinguishing them from other photoheterotrophs that mainly grow as single cells.

Chloroflexus species contain their photosynthetic apparatus within membranous organelles called **chlorosomes**. The chlorosome contains Bchl *c* and Bchl *d*, complexed with Bchl *a* at the plasma membrane. Other species of Chloroflexi, however, such as *Roseiflexus* and *Helothrix*, lack chlorosomes. Chloroflexi are the main filamentous phototrophs outside the Cyanobacteria.

Table 18.2 summarizes key features of phototrophy in clades throughout the bacterial domain; we shall return to this table as a guide throughout the chapter. All light-harvesting complexes descend from one of two ancestral sources: the chlorophyll/bacteriochlorophyll with electron transport (PS I, PS II) or the proteorhodopsin proton pump. It is not clear whether one or both ancestral photosystems were present in the ancestor of all bacteria or whether extensive horizontal transfer distributed the photosystems among divergent clades.

B. *C. aurantiacus* filaments often combine with *Synechococcus* (cyanobacteria) to form a microbial mat. Red autofluorescence reveals the cyanobacteria.

NOTE: Distinguish phylum Chloroflexi (filamentous photoheterotrophs) from phylum Chlorobi (sulfur photoautotrophs of the Bacteroidetes/Chlorobi group). Both are phototrophs containing green photopigment complexes arranged in chlorosomes, but they are deeply divergent genetically.

Table 18.2 Phototrophic bacteria.

Taxon	Energy generation	Cell structure and photopigments	Absorption spectrum (whole cell)	Reaction center
Chloroflexi "Green nonsulfur" *Chloroflexus*	$+O_2$ Heterotrophy $-O_2$ Photoheterotrophy	 Chlorosome Bchl *a* Bchl *c/d*		PS II
Cyanobacteria "Blue-greens" *Anabaena*	$+O_2$ Oxygenic phototrophy $-O_2$ Photolithoautotrophy on reduced sulfur	 Thylakoid Chl *a/b*		PS I and PS II
Firmicutes "Sun bacteria" *Heliobacterium*	$+O_2$ $-O_2$ Photoheterotrophy	 Forms endospore Bchl *g*		PS I

TO SUMMARIZE:

- **Deep-branching thermophiles** such as *Aquifex* and *Thermatoga* species share traits and habitats with thermophilic archaea. They show extensive transfer of archaeal genes.
- **Deinococcus-Thermus** bacteria have ornithine in their peptidoglycan cross-bridges. *Deinococcus* bacteria are highly resistant to ionizing radiation, and they can be isolated from irradiated foods. *Thermus* bacteria are moderate thermophiles isolated from hot-water taps.
- **Chloroflexi** bacteria are deep-branching thermophilic photoheterotrophs, occurring as filamentous mats in association with thermophilic cyanobacteria in hot springs.

18.3 Cyanobacteria: Oxygenic Phototrophs

Cyanobacteria (or Cyanophyta) are the only bacteria that produce oxygen gas. The phylum is named for the blue phycocyanin accessory pigments possessed by some genera, giving them a bluish tint. Cyanobacteria commonly appear green due to the predominant blue and red absorption by chlorophylls *a* and *b* (see **Table 18.2**). Essentially the same chlorophylls are found in plant chloroplasts. Some cyanobacteria, however, appear red due to the accessory pigment phycoerythrin. Cyanobacteria are the only prokaryotes that use both photosystems I and II, photolyzing water to produce oxygen (see **Table 18.2**; details of oxygenic photosynthesis are given in Chapter 14). Under anoxic conditions, most cyanobacteria can also photolyze hydrogen, reduced sulfur compounds, and organic compounds.

The success of oxygenic phototrophy is shown by its fundamental similarity across all members of Cyanobacteria, which account for about a quarter of all of Earth's biomass production and vary widely in cell form and behavior as well as genetic diversity. Even two filamentous genera such as *Synechococcus* and *Anabaena* share only 37% of their genes. Various cyanobacteria are found in all habitats, from tropical soils to Antarctica. Cyanobacteria include species edible for humans, in products such as *Spirulina* salad or *Nostoc* soup (discussed in Chapter 16).

Cyanobacterial Cell Structure

The photosynthetic apparatus of cyanobacteria is organized within thylakoids, pockets of membrane resembling flattened spheres packed with photosynthetic apparatus. The thylakoids may be distributed through the cell, as in "traditional" genera such as *Nostoc* (**Fig. 18.6A**), or they may encircle the cell in concentric layers, as in the more recently discovered marine species *Prochlorococcus marinus* (**Fig. 18.6B**). *Prochlorococcus* is one of the smallest and most abundant oxygen producers in the biosphere. In both large cells and small, the thylakoids are completely separate from the plasma membrane, unlike the attached chlorosomes of Chloroflexi and the plasma membrane extensions of "purple" proteobacteria (see **Table 18.2**). Cyanobacterial thylakoids resemble the thylakoids of eukaryotic chloroplasts; they are the most complex and specialized form of photosynthetic apparatus.

Cyanobacteria have several other subcellular structures. **Carboxysomes** (also known as polyhedral bodies) conduct CO_2 fixation. Cyanobacteria store energy-rich compounds in lipid bodies. To maintain height in the water column and consequently access to sunlight, cyanobacteria have **gas vesicles** whose buoyancy enables cells to float. Their external structures include a thick peptidoglycan cell wall, similar to that of gram-positive cells, plus several external layers that vary with different species. Many species move by "gliding," a form of motility poorly understood.

Besides fixing CO_2, most cyanobacteria fix N_2. Because nitrogen fixation requires the absence of oxygen, cyanobacteria have to solve the problem of maintaining anaerobic biochemistry while producing huge quanitities

Figure 18.6 Cyanobacterial cell structure. **A.** Intracellular organelles of *Nostoc*, a typical filamentous cyanobacterium (colorized TEM). **B.** Intracellular organelles of *Prochlorococcus*, a prochlorophyte cyanobacterium, the smallest known phototroph. *Prochlorococcus* accounts for 40–50% of marine phototrophic biomass.

of highly toxic O_2. Different species solve this problem in different ways:

- Formation of specialized nitrogen-fixing cells called **heterocysts**.
- Temporal separation, alternating between photosynthesis during daylight and nitrogen fixation at night.
- Accumulation of large aggregates of cells in which the interior becomes sufficiently anaerobic for nitrogenase to function, while the exterior continues oxygenic photosynthesis.
- Symbiotic association with microbes or plants that consume oxygen or otherwise maintain anoxic conditions.

Filamentous and Colonial Cyanobacteria

Cyanobacteria have evolved several major categories of form. Single-celled forms include *Synechococcus* and *Prochlorococcus*, the most abundant phototrophs in the oceans. Other genera, such as *Oscillatoria*, generate long filaments of hundreds or even thousands of cells, which can associate in thick biofilms (**Fig. 18.7**). *Oscillatoria* cells are stacked like plates, wider than they are long. To disseminate their cells beyond the biofilm, the filaments produce **hormogonia**, short motile chains of three to five cells. Other filamentous genera, such as *Nostoc*, arrange their filaments in balls of mucilage, possibly to protect from grazing (**Fig. 18.8**). Most filamentous species develop heterocysts to fix nitrogen (**Fig. 18.8B**). The function of heterocysts is discussed in Chapter 11.

Under environmental stress, such as light limitation or phosphate starvation, filamentous cyanobacteria such as *Anabaena* form specialized spore cells called **akinetes**. An akinete forms as a long, oval cell adjacent to a heterocyst, where it stores nitrogen and develops a thickened envelope. Like other types of spores, akinetes resist desiccation and remain viable for long periods. **Table 18.3** compares the properties of akinetes with those of other spore types (which are discussed under Firmicutes and other taxa). Akinetes lie dormant but viable until improved conditions permit germination and growth of new vegetative filaments. In lake water, akinete germination may cause toxic blooms of *Anabaena*.

THOUGHT QUESTION 18.4 What are the relative advantages and disadvantages of propagation by hormogonia, as compared with akinetes?

Nonfilamentous species divide to form small groups or larger colonies (**Fig. 18.9**). *Gloeocapsa* and *Chroococcus* form doublets or quartets, encased in a thick protective mucous slime (**Fig. 18.9A**). Still others, such as *Merismopedia*, continue cell division in two planes, extending to form long square sheets of attached cells (**Fig. 18.9B**).

Figure 18.8 Clumped filamentous cyanobacteria. A. *Nostoc* forms filaments that clump together in large balls of mucilage. **B.** *Nostoc* makes heterocysts (round cells approximately 5 μm in diameter).

Colonial genera such as *Myxosarcina* and *Pleurocapsa* reproduce by multiple fission, producing large cell aggregates (**Figs. 18.9C** and **D**). As the aggregate matures, some cells continue to divide and release unicellular structures called **baeocytes**. Each baeocyte reproduces and develops into a new cell aggregate. The aggregate group maintains anoxic conditions at the center for nitrogen fixation. Both filamentous and colonial cyanobacteria fill key roles in diverse habitats (**Special Topic 18.1**).

THOUGHT QUESTION 18.5 What are the relative advantages and disadvantages of the different strategies for maintaining separation of nitrogen fixation and photosynthesis?

Table 18.3 Spore types in bacteria.

Spore type	Bacteria that produce the spore	Initiation of spore formation	Formation of the spore	Properties of the spore
Akinete	Filamentous cyanobacteria	Light limitation Cold temperature Phosphate starvation	Adjacent to a heterocyst, the akinete develops as a large oval cell with a thickened cell wall and multilayered envelope.	Desiccation resistant Cold resistant Viable for decades
Arthrospore	Actinomycetes	Carbon starvation Phosphate starvation	At the tip of an aerial mycelium, cells undergo vegetative division. Cells develop thick coat and pinch off as arthrospores.	Desiccation resistant Heat resistant
Elementary body	Chlamydiae	Completion of intracellular life cycle	Intracellular chlamydia reticular bodies replicate, then develop into elementary bodies whose envelope contains outer membrane proteins cross-linked by disulfide bonds. Elementary bodies survive outside the host cell.	Survives outside host Desiccation resistant
Endospore	Firmicutes	Carbon starvation Nitrogen starvation Phosphate starvation Low pH Inducers: purine nucleosides, peptide antibiotics	Individual cell develops motherspore and forespore. Motherspore contributes DNA and nutrients to the forespore, which develops into an endospore with a spore coat reinforced by keratin and calcium dipicolinate.	Highly desiccation resistant Highly heat resistant Viable for centuries
Myxospore	Myxobacteria	Nutrient starvation Heat shock Inducers: glycerol, dimethyl sulfoxide, or phenethyl alcohol	Myxobacteria aggregate to form a fruiting body in which vegetative cell division forms a mass of myxospores.	Desiccation resistant UV resistant

Special Topic 18.1 Cyanobacterial Communities: From Ocean to Animal

Cyanobacterial communities play key roles in many ecosystems. Their role as primary producers in marine habitats is highlighted when an environmental change triggers a bloom in population. For example, the colonial cyanobacteria *Trichodesmium* forms giant blooms visible from outer space, covering many square kilometers of ocean surface (**Fig. 1**). Such a bloom can be triggered by an influx of iron carried by wind from a dust storm blowing off the Sahara desert. The concentrated *Trichodesmium* converts nitrogen to forms that promote growth of eukaryotic algae, which prove toxic to consumers such as fish and manatees.

Other cyanobacteria grow in biofilms, containing either a single species or multiple species. In salt marshes and sand flats, cyanobacteria participate in multilayered microbial mats, such as the section shown in **Figure 2**, cut from the sand flats of Great Sippewissett Salt Marsh, on Cape Cod, Massachusetts. The high concentration of sulfides in the sediment support growth of high populations of sulfur phototrophs. Typically, cyanobacteria and eukaryotic algae such as diatoms form the upper green layer. Below, the purple layer consists of "purple sulfur" proteobacteria, whose photopigments (primarily Bchl *a*) absorb at longer wavelengths (discussed in Section 18.5). The pale-colored layer below the purple layer consists of proteobacteria with Bchl *b*, which absorbs farther into the infrared.

Cyanobacteria participate in many kinds of mutualism with animals, plants, fungi, and protists. Sponges growing on coral reefs may have endosymbiotic cyanobacteria that provide the sponge with nutrients from photosynthesis. The products of photosynthesis supplement the nutrients obtained by the sponge from its filter feeding, and these extra nutrients greatly augment the sponge growth rate within the competitive coral reef environment. For example, the sponge *Lamellodysidea* (**Fig. 3**) may gain up to 80% of its nutritional needs from photosynthesis by *Oscillatoria* and *Synechocystis* bacteria growing in the channels between sponge epithelial tissues. As sponge species have evolved, their microbial endosymbionts have evolved in parallel and remain specific to each species of sponge. Sponge symbionts may be associated with the production of pharmaceutically active compounds.

TO SUMMARIZE:

- **Cyanobacteria** are the only oxygenic prokaryotes. They conduct photosynthesis in thylakoids, fix CO_2 in carboxysomes, and maintain buoyancy using gas vesicles. They exhibit gliding motility.
- **Single-celled cyanobacteria** such as *Prochlorococcus* are among the smallest and most abundant phototrophic producers in the oceans.
- **Filamentous cyanobacteria** such as *Nostoc* and *Oscillatoria* are common in aquatic systems. Filaments form heterocysts to fix nitrogen, and reproduce by hormogonia or by akinetes.
- **Colonial cyanobacteria** such as *Myxosarcina* produce large cell aggregates with an anaerobic core for nitrogen fixation. The colonies reproduce through baeocytes.
- **Symbiotic associations** of cyanobacteria are formed with animals, fungi, and plants.

18.4 Gram-Positive Firmicutes and Actinobacteria

Gram-positive bacteria were formerly all classified as Firmicutes, the "tough skin" bacteria, and older sources designate Actinobacteria within this phylum. Today, as shown in **Table 18.1**, the phylum Firmicutes is defined to contain "low GC" species, whereas Actinobacteria are the "high GC" species. They form two distinct phylogenetic branches. Species in both groups have thick cell walls that retain the Gram stain and partly exclude antibiotics (**Fig. 18.10**; discussed in Chapter 3).

Many firmicutes, such as *Bacillus* and *Clostridium* species, survive unfavorable environmental conditions by forming durable endospores. Non-spore-formers such as *Lactobacillus* and *Streptococcus* may have evolved from a common Firmicutes ancestor that formed endospores. In many cases, the machinery to form endospores is revealed in the sequenced genomes of organisms believed to be non-spore-formers such as *Carboxydothermus* sp., soil bacteria that oxidize CO (carbon monoxide) to CO_2. On the other hand, actinobacteria of the order Actinomycetales (actinomycetes) such as *Streptomyces* do not form endospores, but they develop filaments dispersing arthrospores (see **Table 18.3**).

Firmicutes Include Endospore-Forming Rods

Endospore-forming bacteria are common in soil and air, as their spore forms resist desiccation and can remain viable in a dormant state for thousands of years. The best-known orders are Bacillales, mainly aerobic respirers, and Clostridiales, obligate anaerobes. Both groups include species of environmental and economic importance, as well as causative agents of well-known diseases.

Bacillales, genus *Bacillus*. *Bacillus* was one of the first bacterial genera to be classified in the nineteenth cen-

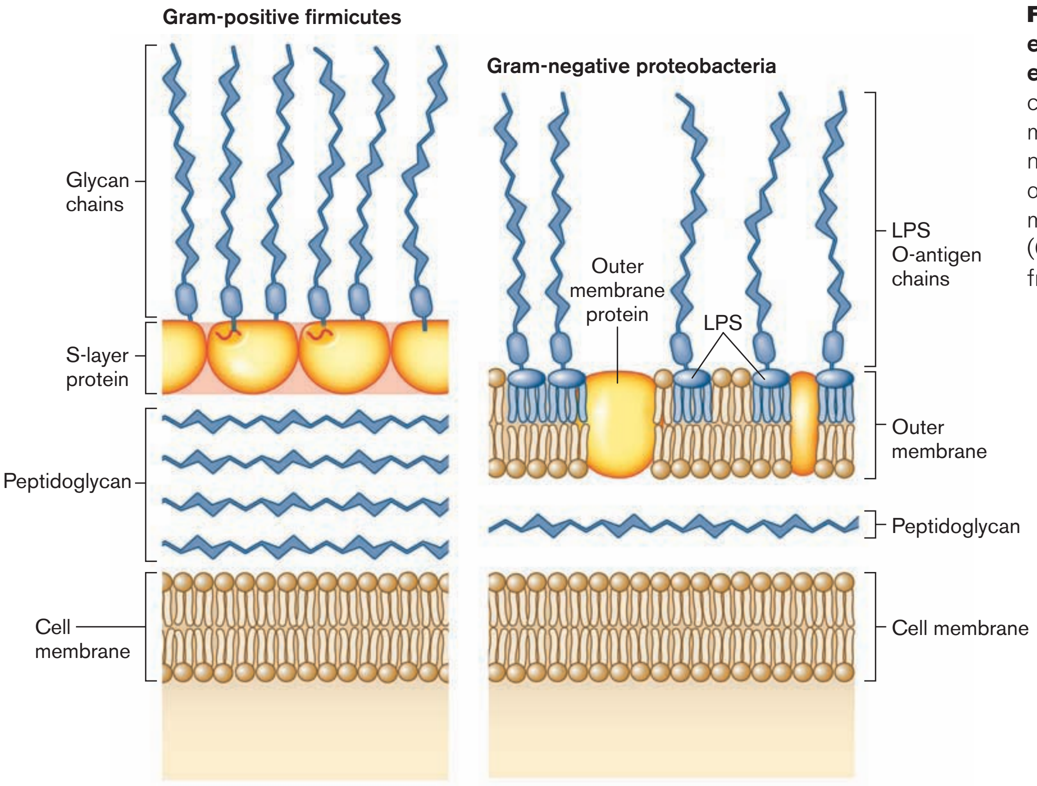

Figure 18.10 Gram-positive envelope and gram-negative envelope. The gram-positive cell has an S-layer and a multiplex cell wall. The gram-negative cell has a single layer of peptidoglycan and an outer membrane containing proteins (OMPs) that may have evolved from ancestral S-layer proteins.

tury. Colonies are readily isolated on a nutrient agar plate exposed to air. *Bacillus* species can be isolated from soil or food by suspending a sample in water and heating at 80°C for half an hour. Vegetative cells (that is, cells undergoing binary fission) and non-spore-formers are killed at that temperature. The remaining endospores will germinate and grow on a beef broth agar plate at 25–30°C. *Bacillus* species isolated in this way include over a thousand characterized strains, all but a few of them harmless to humans.

The large, rod-shaped **vegetative cells** (growing and replicating form) of *Bacillus* species are easily stained and visualized. As the vegetative cells run short of nutrients on an agar plate, they start to produce inert endospores. The resulting pattern of vegetative cells, hollowed out after loss of spores, is highly distinctive in stained specimens (**Fig. 18.11A**). The life cycle of endospore production involves a coordinated developmental plan, in which cell fission directed by FtsZ occurs at the pole instead of at the cell equator (**Figs. 18.11B** and **C**). The polar compartment develops as the **forespore**, directed by unique regulatory proteins such as SpoIIE (**Fig. 18.11B**). The larger compartment, called the **motherspore**, provides DNA and nutrients to the growing forespore and disintegrates after release of the mature endospore. When the released endospore encounters favorable conditions of moisture and nutrients, it germinates and restarts vegetative growth. Further details of sporulation are discussed in Chapter 4.

A species of particular scientific importance is *Bacillus subtilis*, the best-studied gram-positive organism, a "model system" for Firmicutes. The *B. subtilis* genome sequence reveals a large number of transporters for carbon sources and many secretory complexes for industrially important enzymes and drug resistance proteins. It also reveals several integrated prophages (integrated phage genomes). Phage genomes contribute to bacterial evolution by transferring genes between different strains and species, as discussed in Chapter 17. Like *E. coli*, *B. subtilis* is studied as a model system with respect to stress response. Enormous changes in protein expression accompany starvation and general stress conditions, which ultimately cause cells to sporulate.

Figure 18.12 ***Bacillus thuringiensis*: the biological insecticide.** **A.** Sporulating cell of *B. thuringiensis*, showing crystalline inclusion of insecticidal toxin (colorized TEM). **B.** Toxin crystals (colorized blue) embedded in *B. thuringiensis* colony.

A *Bacillus* species of great economic importance is *B. thuringiensis*, the most successful biological control agent yet produced (**Fig. 18.12**). *B. thuringiensis* was originally discovered in 1901 by Japanese bacteriologist Shigetane Ishiwatari as a cause of disease in silkworms. The organism proved easy to culture on agar-based medium, and its spores are now applied as an insecticide against the gypsy moth caterpillar. During sporulation, *B. thuringiensis* generates a diamond-shaped crystal adjacent to its endospore (**Fig. 18.12A**). The crystal contains an insecticidal protein, known as delta-endotoxin. The crystals are ultimately released from the cells (**Fig. 18.12B**). The toxin is activated only at high pH in the digestive tract of insect larvae; thus, it is completely safe for animals with acidic digestive tracts.

Nevertheless, controversy arose when the gene encoding the toxin was introduced transgenically into plants, with the aim of creating insect-resistant crops. The concern is that the *Bt* gene might escape into wild plants and endanger beneficial or harmless species of moths and butterflies.

Many *Bacillus* species are extremophiles, growing at high pH (*B. alkalophilus*), at high temperature (*B. thermophilus*), or in high salt (*B. halodurans*). Some species combine alkaliphily with thermophily, as in the case of the "alkalithermophile" *B. alkalophilus*. Genomic research has focused on the surprisingly subtle differences that distinguish an extremophile from a closely related mesophile. For example, thermostability of proteins can be determined by comparing the protein sequences of a thermophile with those of a related mesophile. The thermophilic sequence shows specific patterns of amino acid residues that confer thermostability. Such amino acid substitutions provide useful information for industrial engineering of enzymes.

Clostridiales, genus *Clostridium*. The anaerobic family of spore formers includes the genus *Clostridium*, species of which cause botulism (*C. botulinum*) and tetanus (*C. tetani*) (**Fig. 18.13A**). The botulism toxin, botulinum, or "botox," is famous for its therapeutic use to relax muscle spasms and to smooth wrinkles in skin (**Fig. 18.13B**; discussed in Chapter 26). Other species, such as *C. acetobutylicum*, have economic importance as producers of industrial solvents such as butanol and acetone (for industrial microbiology, see Chapter 16). The butanol pathway is an example of the wide range of diverse fermentative strategies found among clostridia. Phylogenetically, the genus *Clostridium* is less tightly defined than *Bacillus*, whose members all show highly similar DNA sequence, whereas *Clostridium* species diverge throughout the phylogeny of Firmicutes.

Clostridium cells sporulate in a form distinct from that of *Bacillus* (see **Fig. 18.13A**). The growing endospore swells the end of the cell, forming a "drumstick" appear-

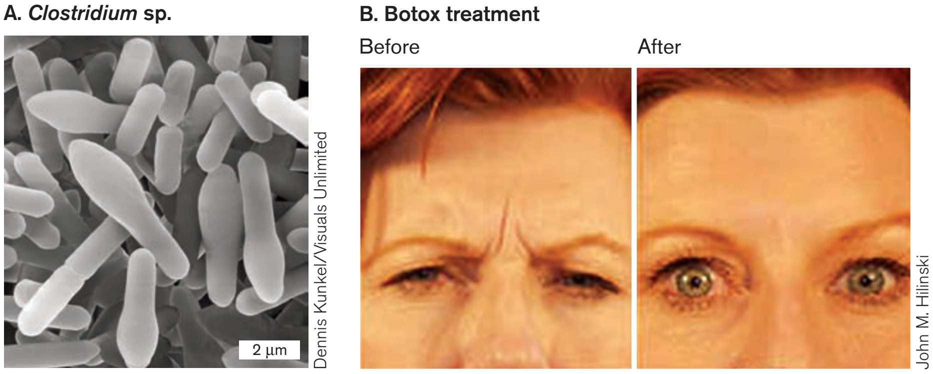

Figure 18.13 ***Clostridium* species: spore-forming anaerobes.** **A.** As *Clostridium* cells sporulate, the endospore swells, forming a characteristic "drumstick" appearance. **B.** The deadly botulinum toxin (botox) from *C. botulinum* is used to relax muscle spasms. This woman was unable to open her eyelids fully (left frame), a condition that was cured by injection of botox (right frame).

ance. Mature clostridial spores are generally less heat resistant than the spores of *Bacillus* and thus more difficult to isolate in pure culture from natural environments. Nevertheless, *Clostridium* spores are found in soil and water, ready to germinate and grow when the environment becomes anoxic. Many harmless species are found in the human colon, particularly in infants (see **Fig. 18.1**). Pathogenic *C. botulinum* can grow within the colon of very young infants, and infant botulism has been implicated in some cases of sudden infant death syndrome. Another species, *C. difficile*, is emerging in hospitals as a life-threatening intestinal pathogen, resistant to most antibiotics. *C. difficile* emerges in patients treated with antibiotics that eliminate normal enteric bacteria, allowing growth of the pathogen.

Related to *Clostridium* are the Heliobacteraceae or "solar bacteria," the only known phototrophs in Firmicutes (see **Table 18.2**, third row). Their name derives from their yellowish color caused by the shift of their red peak absorbance into the infrared, which allows transmission of red light plus green light (perceived as yellow). The heliobacteria are photoheterotrophs, with a PS I reaction center providing a modest boost of energy to supplement heterotrophic metabolism of simple organic compounds. Most heliobacterial cells are elongated rods with peritrichous flagella, and they form endospores—the only known endospore-forming phototrophs.

NOTE: Distinguish *Heliobacterium* from *Helicobacter*, a helical-shaped species of the gammaproteobacteria.

Variant sporulation and "live birth." The order Clostridiales includes species of exceptionally large bacteria that grow only within the digestive tract of specific animal hosts. These species have evolved intriguing variations of the endospore former life cycle, as revealed by Esther Angert and colleagues at Cornell University (**Fig. 18.14A**). *Metabacterium polyspora* (size 15–20 µm) grows throughout the digestive tract of guinea pigs (**Fig. 18.14B**). Endospores ingested from feces germinate in the upper intestine but rarely undergo binary fission. Instead, the growing cell forms forespores at both poles (**Fig. 18.14C**). The forespores actually multiply within the motherspore to form several endospores, which are released in the colon before defecation.

An even larger enteric endosymbiont is *Epulopiscium fishelsoni*, found in the digestive tract of sturgeonfish (**Fig. 18.15**). These bacteria are large enough to be seen by eye, about the size of the period at the end of this sentence. As in *M. polyspora*, Angert showed that *E. fishelsoni* reproduction is synchronized with the digestive cycle of its host, but it has gone even further in transformation of the sporulation cycle. Binary fission is eliminated; the cell must fission at both poles. Each polar fission generates

an intracellular daughter cell that grows to nearly the full length of the mother cell. The two intracellular offspring ultimately emerge in "live birth" from the mother cell, which then disintegrates.

Non-spore-forming Firmicutes

Both Bacillales and Clostridiales, as well as other gram-positive orders, include many non-spore-forming rods and cocci. In these taxa, the endospore-forming system was probably lost by reductive evolution. Non-spore-forming firmicutes include human pathogens such as *Listeria* and *Streptococcus* species, as well as lactic acid bacteria that are important for food production.

Listeria species are facultative anaerobic bacilli, named for the British surgeon Joseph Lister (1827–1912), who first promoted antisepsis during surgery. They include enteric pathogens such as *L. monocytogenes* that contaminate cheese and sauerkraut. Unlike other food-associated organisms, *Listeria* grows at temperatures as low as 4°C. Under preindustrial conditions of food preparation, *L. monocytogenes* was generally outcompeted by other flora, but the era of refrigeration has brought about the emergence of *Listeria* as a serious pathogen. *L. monocytogenes* cells are taken up by macrophages into phagocytic vesicles; but they avoid digestion and escape the vesicles. The bacteria then multiply while traveling through the host cytoplasm, while generating "tails" of actin (**Fig. 18.16**). The actin tails eventually project *Listeria* cells out of the original cell and enable it to penetrate a neighboring host cell.

Lactic acid bacteria. The order Lactobacillales, known as lactic acid bacteria, are aerotolerant (capable of growth in the presence of oxygen), but most are obligate fermenters; that is, they generate ATP by substrate-level phosphorylation but cannot use oxygen to respire. They ferment primarily by converting sugars to lactic acid (a fermentation pathway discussed in Chapter 13). As the acid builds up, the pH decreases until it halts bacterial growth; thus, the carbon source retains much of its food value for human consumption. This is the basis of yogurt and cheese production. *Lactococcus* and *Lactobacillus* species are extremely important for the dairy industry (discussed in Chapter 16). Other common genera of lactic acid bacteria include *Leuconostoc*, often responsible for spoilage of meat, and *Pediococcus*, found in sauerkraut and fermented bean products as well as meat products such as sausage.

The shape of lactate-producing bacteria varies among species, from long, thin rods to curved rods and cocci. Most lactic acid bacteria have fastidious growth requirements and need many amino acids and vitamins. They can be isolated from pasture grasses incubated anaerobically in moderate acid (pH 5). The human intestinal flora include species of lactic acid bacteria. Certain species, particularly *Lactobacillus acidophilus*, are believed to play a positive role in human health by inhibiting the growth of pathogens. For this reason *L. acidophilus* may be ingested as a probiotic therapy.

***Staphylococcus* and *Streptococcus*.** The staphylococci are facultative anaerobic cocci that grow in clusters, often hexagonal in arrangement (**Figs. 18.17A** and **B**). They include common skin flora such as *S. epidermidis*. The staphylococci are generally salt tolerant, and their fermentation generates short-chain fatty acids that inhibit growth of skin pathogens. Certain species, however, are themselves serious pathogens. *Staphylococcus aureus* causes impetigo and toxic shock syndrome, as well as pneumonia, mastitis, osteomyelitis, and other diseases (discussed in Chapter 26). It is a major cause of nosocomial (hospital-acquired) infections, especially contamination of surgical wounds.

The most dangerous strains, now resistant to most known antibiotics, are termed MRSA (methicillin-resistant *S. aureus*).

Streptococcus species generally form chains instead of clusters, as their cells divide in a single plane (**Figs. 18.17C** and **D**). They are aerotolerant (grow in the presence of oxygen) but metabolize by fermentation. Many live on oral or dental surfaces, where they are responsible for caries (tooth decay). Their fermentation of sugars produces such high concentrations of lactic acid that the pH at the tooth surface can fall to pH 4. *Streptococcus* species cause many serious diseases, including pneumonia (*S. pneumoniae*), strep throat, erysipelas, and scarlet fever (*S. pyogenes* or group A strep).

The streptococci are less salt tolerant than *Staphylococcus* species, which tolerate as much as 5–15% NaCl. Another genus whose size and fermentative metabolism resembles that of streptococci is *Enterococcus*. *Enterococcus faecalis* is a common member of the intestinal flora, and related strains are enteric pathogens.

B. Dehalogenation of tetrachloroethene by *Dehalobacter restrictus*

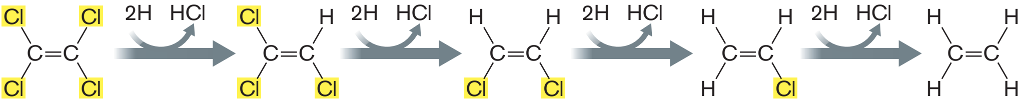

Figure 18.18 ***Dehalobacter restrictus*** **conducts anaerobic respiration by dechlorination.** **A.** *Dehalobacter restrictus*, a flagellated rod related to clostridia. **B.** *D. restrictus* donates electrons to remove chlorine from tetrachloroethene, a major industrial pollutant. The ultimate product, ethene, is much less harmful in the environment.

slowly in the environment. The chlorinated molecules are reduced as alternative electron acceptors. *Dehalobacter restrictus*, a flagellated rod, was isolated as an anaerobe capable of respiring by donating electrons to chlorine atoms in tetrachloroethene (**Fig. 18.18**). Thus, the discovery of *D. restrictus* has promising potential for bioremediation of chlorinated pollutants.

While genetic analysis places *D. restrictus* among the clostridia, the bacterium actually stains gram-negative, perhaps because its peptidoglycan layer is relatively thin. Nevertheless, the species shows no gram-negative outer membrane. It does possess a thick S-layer of hexagonally tiled proteins, typical of gram-positive bacteria.

Mollicutes lack a cell wall. Organisms of the class Mollicutes (named in Latin, "soft skin") have completely lost their cell wall and S-layer through reductive evolution, retaining only their cell membrane. Presumably, the loss of these energy-expensive structures enhanced the reproductive rate of cells in a protected host environment. The Mollicutes comprise many genera of flexible wall-less cells that maintain a shape through some kind of cytoskeleton (**Figs. 18.19A** and **B**). On agar they form colonies of a characteristic "fried-egg" appearance (**Fig. 18.19C**).

The best-known genus of Mollicutes is *Mycoplasma*, although its species now appear to fall in several distantly related branches. Mycoplasmas are found as parasites of every known class of multicellular organism, including vertebrates, insects, and vascular plants; in humans, they cause pneumonia and meningitis. Some *Mycoplasma* species remain adherent to the host cell,

whereas others penetrate and grow intracellularly. Most mycoplasma cells have a rounded cell shape with one or two extended tips. In *Mycoplasma penetrans*, an opportunistic pathogen infecting AIDS patients, the cell's attachment tip is coated with adhesion molecules that enable attachment to a host cell surface (**Fig. 18.19A**). The attachment tip penetrates deep into epithelial tissues. By contrast, the fish pathogen *M. mobile* has no attachment tip, but glides along a surface at a rate of seven cell lengths per second (**Fig. 18.19B**). The basis of mycoplasma motility is not understood, although it may involve gliding or cytoskeletal contraction. In some species, motility involves a specialized cell tip called the "terminal organelle," but species that lack this organelle are equally motile. Species of *Spiroplasma* have a spiral shape and undergo corkscrew motion; the basis for this motion is also unknown.

Mycoplasma genomes are among the smallest known cellular organisms, and they lack biosynthetic pathways for amino acids and phospholipids, which must be acquired from the host. Mycoplasmas have unique nutritional requirements, such as cholesterol, a membrane component typical of eukaryotes but rare for prokaryotes. For these reasons, mycoplasmas are difficult to grow in pure culture, although they readily infect tissue cultures. In fact, mycoplasma contamination of tissue culture is so prevalent that it has compromised major studies of cancer and AIDS.

Actinomycetes Form Multicellular Filaments

The phylum Actinobacteria, the "high GC gram-positives," comprises several orders, including the orders Actinomycetales and Bifidobacteria. Members of the order Actinomycetales are "actinomycetes." Actinomycetes can be identified under the microscope by the **acid-fast stain,** a procedure in which cells are penetrated with a dye that is retained under treatment with acid alcohol (discussed in Chapter 2). The acid-fast property is associated with unusual cell wall lipids, such as mycolic acids. Actinomycetes include filamentous spore formers, such as *Streptomyces* and *Frankia*, as well as short-chain organisms, such as *Mycobacterium*, and irregularly shaped cells, such as *Corynebacterium*.

Streptomyces**: filamentous spore formers.** *Streptomyces* bacteria form multicellular filaments that generate dispersable spores. The streptomycete life cycle is discussed in Chapter 4. Streptomycetes play a major role in the ecosystems of soil (discussed in Chapter 21). Decaying *Streptomyces* cells produce the compound **geosmin**, which causes the characteristic odor of soil and can affect the taste of drinking water. In culture, the best-known species, *S. coelicolor* (Latin, "sky color"), forms strikingly blue colonies (**Fig. 18.20A**). Other species produce filaments that are red, orange, green, or gray, depending on

Source: D. *Prokaryotes*, Springer.

their distinctive products of metabolism, many of which are antibiotics.

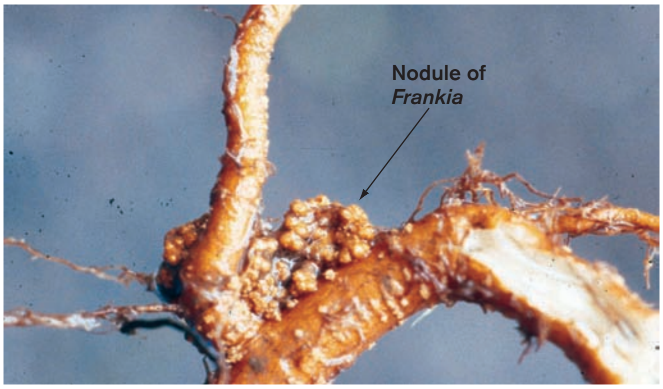
THOUGHT QUESTION 18.6 Why would *Streptomyces* produce antibiotics targeting other bacteria?

Streptomyces species are obligate aerobes, requiring access to air to complete their life cycle. When a *Streptomyces* spore germinates, it forms extended branched filaments into the substrate called **vegetative mycelia**, branched filaments of actively dividing cells. Some of the filaments then grow upward into the air, where they develop into **aerial mycelia**. The aerial mycelia in some species grow in tightly coiled spirals (**Figs. 18.20B** and **C**). As the mycelial colony runs out of nutrients, older cells of the filament age and lyse, releasing nutrients absorbed by the younger cells. The nutrients also attract other scavengers, which may be killed by antibiotics produced by the aging streptomycete cells. The dead scavengers, too, release nutrients that feed the growing tip of the mycelium.

As mycelia mature, they fragment into smaller cells called **arthrospores**. Arthrospores are vegetative cells, not dormant like endospores (**Table 18.3**). The arthrospores separate and are dispersed by the wind, enabling them to colonize a new location. Streptomycete mycelia can be obtained from natural habitats by burying a glass slide in soil, then waiting several days for spores to germinate, covering the slide with mycelia. They are challenging to isolate in pure culture, however, because their coiled filaments trap cells of other bacteria.

The *S. coelicolor* genome contains over 8 million base pairs, one of the largest prokaryotic genomes. Streptomycete chromosomes are linear with special "telomeres," single-stranded end sequences that double back to form hairpin loops (**Fig. 18.20D**). Much of the lengthy genome of a streptomycete encodes catabolism of a rich array of diverse organic components of decaying plant and animal matter, including even lignin. Other genes encode extensive operons for production of diverse secondary products (see Chapter 15), including antibiotics. More than half the antibiotics currently used in medicine derive from *Streptomyces* species.

NOTE: Distinguish the order Actinomycetales from the genus *Actinomyces* within this order. Distinguish *Streptomyces*, filamentous rod-shaped actinomycetes, from nonactinomycete *Streptococcus*, gram-positive cocci that form short unbranched chains.



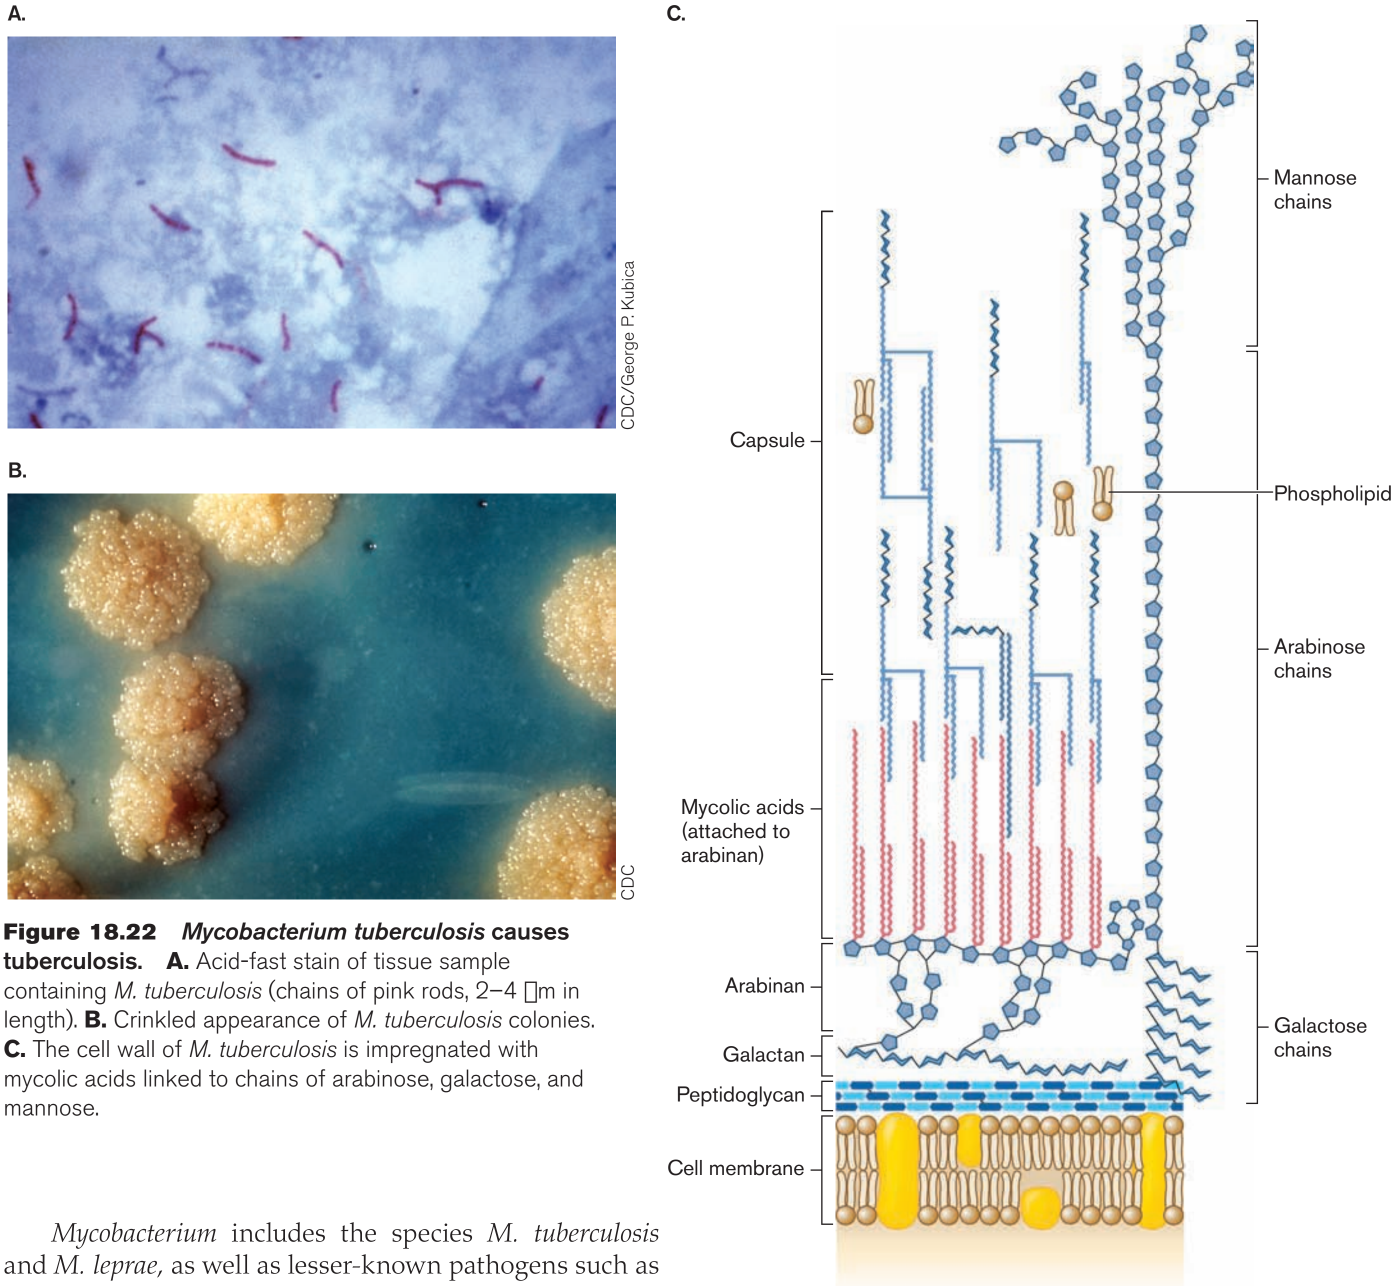
Harwood Silviculture Cooperative, Oregon State Univ.

Figure 18.21 ***Frankia* species associate endophytically with plants.** Root of alder tree (*Alnus glutinosa*) bears the orange-yellow-colored nodules (arrowhead) containing *Frankia*.

Actinomycetes associated with animals and plants. Most actinomycetes, such as *Actinomyces* and *Streptomyces*, have no direct association with animals, either positive or negative, but there are important exceptions. For example, *Actinomyces* species cause **actinomycosis**, a condition of skin abscesses in humans and cattle. A species of *Streptomyces* maintains a mutualism with leaf-cutter ants. The ants culture the bacteria on special organs to produce antibiotics against parasites of their fungal gardens (discussed in Chapter 17).

Actinomycetes have many mutually beneficial associations with plants. For example, *Frankia* associates with the alder tree, which develops orange-yellow colored nodules on its roots to fix nitrogen (**Fig. 18.21**). *Frankia* species live as **endophytes**, endosymbionts of vascular plants. This nitrogen fixation mutualism is analogous to the better-known symbiosis between legumes and rhizobia (see under Alpha Proteobacteria). Other *Frankia* species benefit wheat by conferring resistance to major fungal pathogens, such as "take-all" disease, as well as to certain parasites and insects. A few actinomycetes cause plant diseases. For example, potato scab disease is caused by *Streptomyces scabies*.

Nonmycelial actinomycetes: *Mycobacterium* and *Corynebacterium*. Actinomycetes include a number of species that share the thick acid-fast cell wall of *Streptomyces* but lack the mycelial lifestyle. Two genera associated with dreaded diseases are *Mycobacterium* (**Fig. 18.22**) and *Corynebacterium*. Both genera have thick cell envelopes containing **mycolic acids**, a diverse class of sugar-linked fatty acids (discussed in Chapter 3). The mycolic acids of *M. tuberculosis* are extremely diverse and include some of the longest-chain acids known, up to 90 carbons. The thick, dense layer of mycolic acids forms a waxy coat that impedes the entry of nutrients, which limits growth rate; but it also protects the bacterium from host defenses and antibiotics. For this reason, the cure of tuberculosis requires an exceptionally long course of antibiotic therapy.



CDC/George P. Kubica

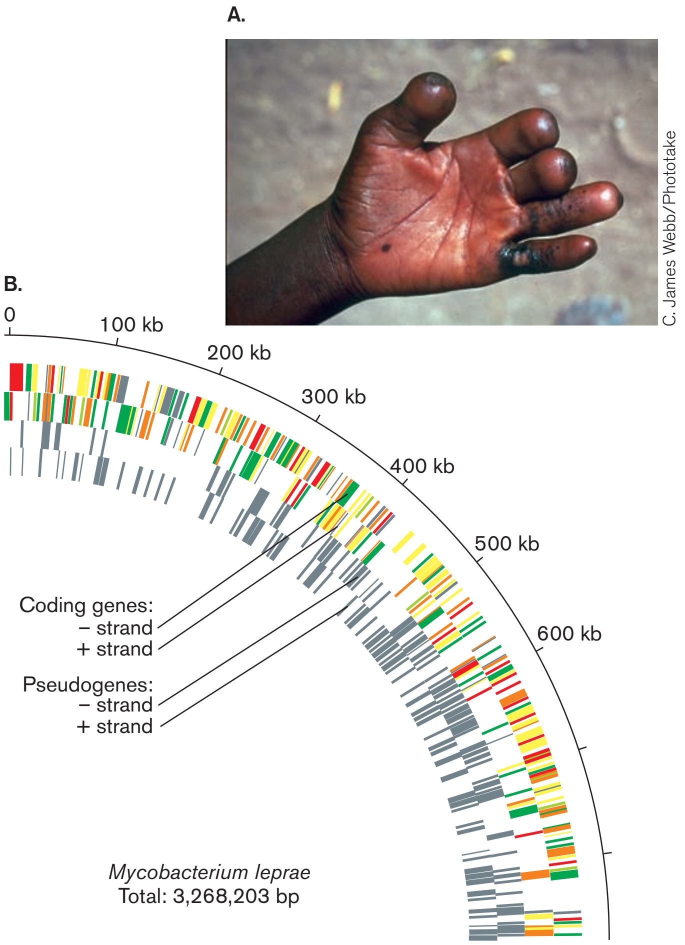
CDC

Figure 18.22 ***Mycobacterium tuberculosis*** **causes tuberculosis.** **A.** Acid-fast stain of tissue sample containing *M. tuberculosis* (chains of pink rods, 2–4 µm in length). **B.** Crinkled appearance of *M. tuberculosis* colonies. **C.** The cell wall of *M. tuberculosis* is impregnated with mycolic acids linked to chains of arabinose, galactose, and mannose.

Mycobacterium includes the species *M. tuberculosis* and *M. leprae*, as well as lesser-known pathogens such as *M. ulcerans*. Cells of *M. tuberculosis* can be detected by the acid-fast stain as tiny rods associated with sloughed cells in sputum (**Fig. 18.22A**). The organism forms crinkled colonies after two weeks of growth on agar-based media (**Fig. 18.22B**).

The closely related species *M. leprae* causes the disfiguring disease leprosy (**Fig. 18.23A**). The species has one of the longest known doubling times of any pathogen (about 14 days), and it can take a year to grow enough cells in the laboratory for observation. Lower temperature is preferred; for this reason, leprosy attacks the extremities. Culture on artificial media is impossible; the bacteria can only be grown within low-temperature animals, such as armadillos, or within genetically immune-deficient mice.

The genomes have been sequenced both for *M. tuberculosis* and *M. leprae*. *M. tuberculosis* has surprisingly few recognizable pathogenicity genes but a large number of environmental stress components, including 16 environmental sigma factors as well as 250 genes for its complex lipid metabolism. Over half the *M. leprae* genome consists of pseudogenes, homologs of *M. tuberculosis* genes undergoing reductive evolution (**Fig. 18.23B**). Thus, *M. leprae* appears to be an evolving pathogen "caught in the act" of losing many genes no longer needed in its sheltered host environment. How it lost the need for so many genes preserved in *M. tuberculosis* remains a mystery.



C. James Webb/Phototake

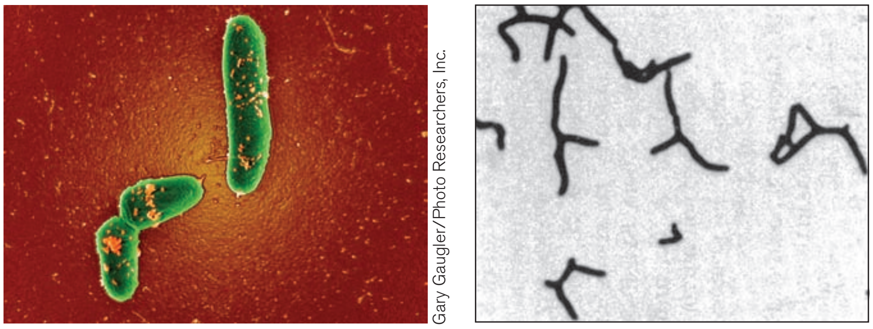
Figure 18.23 ***Mycobacterium leprae*** **causes leprosy.** **A.** Hand disfigured by leprosy. **B.** The genome of *M. leprae* shows a high content of decaying pseudogenes (gray bars), most of which correspond to functional genes in the genome of *M. tuberculosis*.

Mycobacteria also include a much larger number of harmless commensals, such as *M. smegmatis*, isolated from human skin. Species of mycobacteria can be isolated from soil and water, as well as from various animal sources. Their culture is difficult because of their slow growth rates, but isolation can be enhanced by treatment with a base (NaOH or KOH) at concentrations that kill most other bacteria.

NOTE: Distinguish *Mycobacterium*, rods whose cell walls contain mycolic acids, from *Mycoplasma*, cell wall-less firmicutes related to *Bacillus* and *Clostridium*.

Irregularly shaped actinomycetes. Several nonmycelial actinomycetes show unusual cell shapes. Members of the genus *Corynebacterium* include soil bacteria as well as pathogens such as *C. diphtheriae*, the cause of the lung disease diphtheria. *Corynebacterium* species grow as irregularly shaped rods, which may divide by a "half-snapping" mechanism in which one side of the cell remains attached like a hinge (**Fig. 18.24A**). Related soil bacteria include the genera *Nocardia* and *Rhodococcus*.

Soil bacteria of the genus *Arthrobacter* exhibit an unusual cell cycle in which coccoid stationary-phase cells sprout into rods, which eventually run out of nutrients and revert to the coccoid form. The growing rods form irregular branched filaments (**Fig. 18.24B**). An *Arthrobacter* species was discovered conducting anaerobic respiration by reduction of hexavalent chromium (Cr^{6+}), a toxic metal pollutant, to a less toxic oxidation state. Now *Arthrobacter* shows potential as an agent of bioremediation of hexavalent chromium.



A. ***Corynebacterium diphtheriae***

B. ***Arthrobacter globiformis***

Gary Gaugler/Photo Researchers, Inc.

Figure 18.24 **Irregularly shaped actinomycetes: *Corynebacterium* and *Arthrobacter*.** **A.** *Corynebacterium diphtheriae* (cells 1–2 μm in length) divide by snapping off one side while remaining attached at the other; the result is a typical V-shape or "Chinese letter" arrangement (colorized SEM). **B.** *Arthrobacter globiformis* cultures form coccoid cells in stationary phase. With added nutrients, the coccoid cells grow out as rods.

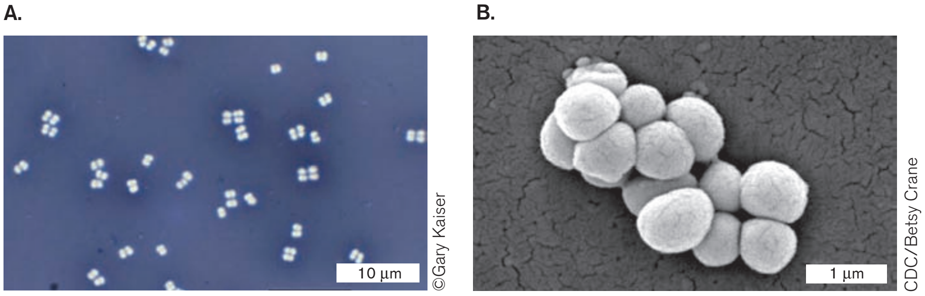

Figure 18.25 *Micrococcus* **species grow in tetrads or sarcinae. A.** *M. luteus* growing in tetrads (negative or indirect stain with nigrosin). **B.** *M. luteus* bacteria grow in clumps when cultured on a solid substrate (SEM).

Micrococcaceae. Relatives of *Arthrobacter* are nonfilamentous cocci such as *Micrococcus*. *Micrococcus luteus* is one of the most ubiquitous of soil bacteria, appearing readily as yellow colonies on agar plates exposed to air. Historically the genus *Micrococcus* in the family Micrococcaceae was classified with *Staphylococcus*, but its DNA sequence data now place *Micrococcus* and most of the Micrococcaceae within the actinomycetes.

Micrococci are aerobic heterotrophs, commonly isolated from air and dust, although their habitat of choice is the human skin. Micrococci grow in square or cuboid formations, dividing in two or three planes (**Fig. 18.25**); cuboid clusters are known as **sarcinae**. *M. luteus* is harmless to humans and grows well at room temperature, so it makes an excellent laboratory organism for observation by students.

TO SUMMARIZE:

- **Firmicutes**, the low GC gram-positive bacteria, include endospore-forming genera such as *Bacillus* and *Clostridium*. The cycle of endospore formation was probably present in the common ancestor of this phylum.
- **Nonsporulating firmicutes** include pathogenic rods such as *Listeria* as well as food-producing bacteria such as *Lactobacillus* and *Lactococcus*.
- ***Staphylococcus* and *Streptococcus*** are gram-positive cocci that include normal human flora as well as serious pathogens causing toxic shock syndrome, pneumonia, and scarlet fever.
- **Mycoplasmas** belong phylogenetically to Firmicutes but lack the cell wall and S-layer. They have flexible cytoskeletons and show ameboid motility. Species cause diseases such as meningitis and pneumonia.
- **Actinomycetes** (order Actinomycetales) include mycelial spore-forming soil bacteria, such as *Streptomyces*. Other actinomycetes have irregularly shaped cells, such as *Clostridium* species that cause tetanus and botulism. Actinomycetes stain acid-fast.
- **Mycobacteria** are actinomycete rods whose cell envelope contains a diverse assemblage of complex mycolic acids. Mycobacterial species cause tuberculosis and leprosy. They stain acid-fast.

18.5 Gram-Negative Proteobacteria and Nitrospirae

The Proteobacteria, with all their diversity of form and metabolism, share a common structure—their triple-layered, gram-negative cell envelope, which consists of outer membrane, peptidoglycan cell wall permeated by the periplasm, and inner membrane (plasma membrane) (see **Fig. 18.10**). The outer membrane is packed with receptor proteins and porins, comprising two-thirds the mass of the membrane. The outer membrane lipids contain long sugar polymer extensions (LPS). In pathogens, LPS repels phagocytosis and has toxic effects when released by dying cells.

The Protean Metabolism of Proteobacteria

Proteobacteria, the "protean" or "many-formed" bacteria, comprise at least five classes, labeled Alpha through Epsilon (see **Table 18.1**). Even within each closely related group, we see nearly as wide a range of cell shape and metabolic strategies as we see in Proteobacteria as a whole.

A closer look at proteobacterial metabolism shows that processes that seem very different on the surface actually connect through linked modules (**Fig. 18.26**; metabolism is discussed in detail in Chapter 14). Many proteobacteria are "photoheterolithotrophs" capable of nearly all the fundamental classes of metabolism, depending on environmental conditions, such as availability of light, oxygen, and nutrients. An example is *Rhodopseudomonas palustris*, the species of Alpha Proteobacteria characterized and sequenced by Caroline Harwood at the University of Washington. In such a "protean" organism, the core of all proteobacterial energy acquisition is a respiratory chain of electron donors and acceptors. Electrons may enter the chain from a photoexcited chlorophyll, from organic electron donors such as sugars or benzoates, or from a mineral electron donor such as reduced sulfur or iron (lithotrophy). In facultative anaerobes, the electron acceptor may be oxygen, or it may be a mineral such as nitrate or sulfate (anaerobic respiration).

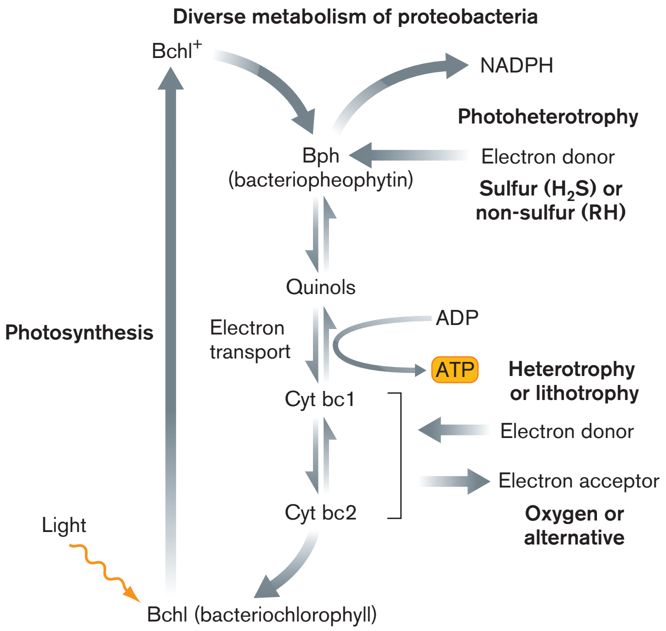

Figure 18.26 The protean metabolism of Proteobacteria. In many gram-negative species, metabolic diversity arises through minor "add-ons" of biochemical modules such as light absorption by bacteriochlorophyll; use of sulfide or organic electron donors; and use of oxygen or alternative (anaerobic) electron acceptors.

Photoheterotrophy. Light-supplemented heterotrophy occurs in Alpha, Beta, and Gamma Proteobacteria (see **Table 18.2**). This ubiquity suggests that the common ancestor of the phylum was a photoheterotroph. At the same time, evidence supports horizontal transfer of photosystems among proteobacterial branches. The evidence is particularly strong in the case of **proteorhodopsin**, a homolog of the retinal protein light-driven proton pump first characterized in halophilic archaea (discussed in Chapter 19). In any case, **Table 18.2** shows the remarkable diversity of light absorption niches that have evolved. The proteorhodopsin light pump in *Pelagibacter* spp. absorbs green and yellow (wavelength 500–600 nm), the mid-range of solar radiation reaching Earth's surface. The various bacteriochlorophylls of Proteobacteria generally peak in two ranges, in the blue and in the red or infrared. Bacteriochlorophyll *b*, in *Blastochloris* spp., peaks well beyond 1,000 nm. Species with different photopigments often grow together in stratified layers of sediment or wetland, the infrared absorbers below, where they capture the longer wavelengths "left over" from the shorter-wavelength absorbers above.

In the literature, proteobacterial phototrophs are historically called "purple bacteria." The actual colors of all the phototrophs range from purple-red through yellow and brown. "Purple sulfur bacteria" are species that photolyze reduced forms of sulfur, such as H_2S, HS^-, S^0, or S_2O_3 (thiosulfate), whereas "purple nonsulfur bacteria" are species that photolyze small organic molecules such as short-chain acids. However, it turns out that many "purple bacteria" photolyze both sulfur and organic molecules. Most proteobacterial phototrophs conduct photosynthesis only in the absence of oxygen, reverting to aerobic heterotrophy when oxygen is present. Some, however, are obligate anaerobes. Still others, found in marine environments, surprisingly photolyze sulfide or organic compounds only in the presence of oxygen. Making sense of this extraordinary diversity is the job of marine and aquatic microbiologists, particularly those calculating global cycles of carbon and oxygen (discussed in Chapters 21 and 22).

THOUGHT QUESTION 18.7 Why might genes for the proteorhodopsin retinal photopump be more likely to transfer horizontally than the bacteriochlorophyll-based photosystems PS I and PS II?

Lithotrophy. The use of inorganic electron donors recurs throughout the phylogeny of bacteria, with notable diversity among Proteobacteria (**Table 18.4**). Many lithotrophic reactions generate acid, which conveniently breaks down rock containing additional reduced minerals. Bacterial and archaeal lithotrophy has tremendous significance for global cycling of elements in the biosphere (discussed in Chapter 22). Some lithotrophs are autotrophs, fixing carbon dioxide into biomolecules by the Calvin-Benson cycle (in carboxysomes) or the reverse TCA cycle. Others have alternative pathways of heterotrophy when organic foods are available. The ability to oxidize or reduce minerals evolved multiple times in different clades as an offshoot of the general electron transport chain.

We now survey species of the major classes of Proteobacteria and the gram-negative phylum Nitrospira.

Alpha Proteobacteria: Photoheterotrophs, Methylotrophs, and Intracellular Endosymbionts

The class Alpha Proteobacteria includes photoheterotrophs and heterotrophs, as well as bacteria metabolizing single-carbon compounds. A remarkable array of intracellular mutualists and pathogens arise in this group.

Photoheterotrophs. The Alpha class photoheterotrophs are generally unicellular. Their cell shapes range from flagellated spirilla to rounded rods (*Rhodobacter sphaeroides*), wide spirals (*Rhodospirillum rubrum*), stalked cells (*Rhodomicrobium*) (**Figs. 18.27A** and **B**). The TEM of *R. sphaeroides* shows how the cell is packed with photomembranes (membranes containing the photosynthetic complex) arranged in folds or tubes invaginated from the cytoplasmic membrane. These intracellular photomem-

Figure 18.27 **Alpha proteobacterial photoheterotrophs.** **A.** *Rhodobacter sphaeroides*, showing intracellular photosynthetic membranes and outer membrane LPS filaments (TEM). **B.** *Rhodomicrobium acidophila* with stalked cells (length 2–7 □m; phase contrast). **C.** *Citromicrobium* species, an aerobic photoheterotroph, forms highly pleomorphic shapes, including the Y shape (TEM).

branes expand the surface area for photon capture; but during growth with oxygen, the photomembranes disappear. The outer surface of the cell shows LPS filaments extending from the outer membrane.

The metabolism of *R. rubrum* has been studied extensively. Anaerobically, *R. rubrum* bacteria grow dark red because they synthesize membrane containing Bchl *a*, which absorbs green and infrared and reflects primarily red. Under aerobic conditions, however, *R. rubrum* fails to synthesize Bchl *a* and the cells grow white as their metabolism switches to straight heterotrophy. A surprising capacity is their ability to oxidize carbon monoxide (CO), a common by-product of photosynthesis. CO oxidation is now thought to occur in a number of proteobacteria.

Alpha photoheterotrophs requiring oxygen for phototrophy (but *not* photolyzing water for O_2) were found unexpectedly in genomic surveys of marine bacteria. Originally thought to be straight heterotrophs, these organisms revealed genes encoding bacteriochlorophyll.

Their aerobic heterotrophy was shown to be driven by light absorption. The source of the oxygen requirement is unclear, as their photosystems do not involve oxygen. Examples of O_2-requiring phototrophs have since been found in most of the proteobacterial clades, and species have been isolated from all major habitats including freshwater, marine, and soil ecosystems. Some show unusual cell morphology, such as the Y shape of *Citromicrobium* (**Fig. 18.27C**).

The aerobic photoheterotroph *Erithromicrobium ramosus* can reduce toxic metal compounds such as tellurite (TeO_3^{2-}). The cells generate tellurium crystals that take up 30% of their cell weight, providing a convenient way to remove tellurite from liquid waste. Other toxic metals reduced by aerobic photoheterotrophs include selenium and arsenic. Thus, these obscure bacteria now have a promising future in remediation of metal-contaminated industrial wastes.

Aquatic and soil oligotrophs. Alpha Proteobacteria also include many nonphototrophic heterotrophs of soil and water. Many aquatic and soil heterotrophs are oligotrophs adapted to extremely low nutrient concentrations; an example is *Caulobacter crescentus*, the stalk-to-flagellum organism discussed in Chapters 3 and 4. Oligotrophic bacteria often have unusual extended shapes enhancing nutrient uptake, such as the starlike cell aggregates of *Seliberia stellata*. In *Seliberia* species, the individual tightly coiled rods generate oval or spherical reproductive cells by a budding process. The budding reproductive cells germinate into rods, which then form new aggregates.

Some heterotrophs common in soil are pathogens. *Brucella* sp. is an intracellular pathogen of animals that can also infect humans. It is classed as a potential bioterrorism agent. The soil bacterium pathogen *Granulobacter bethesdensis* is associated with chronic granulomatous disease, an inherited disorder of the phagocyte oxidase system that leaves patients susceptible to infection.

Methylotrophy and methanotrophy. **Methylotrophy** is the ability of an organism to oxidize single-carbon compounds such as methanol, methylamine, or methane. The Alpha Proteobacteria include several genera of methylotrophs, which are found in all environments, including soil, freshwater, and the ocean. Most methylotrophs can grow on both single-carbon and organic compounds. One such versatile genus, *Methylobacterium*, is equally at home in soil and water, on plant surfaces, and as a contaminant of facial creams and purified water for silicon chip manufacture. Other species are restricted to single-carbon compounds, incapable of metabolizing organic compounds with carbon-carbon bonds. Organisms that grow solely on methane (CH_4) are called **methanotrophs**.

Methane-oxidizing bacteria of both Alpha and Gamma classes contribute to aquatic ecosystems, serving as major food sources for zooplankton. They eliminate much of the methane produced by methanogens before it reaches the atmosphere, where it has a potent greenhouse effect (see Chapter 22).

Endosymbionts: mutualists and parasites. The Alpha Proteobacteria include many highly evolved intracellular symbionts, some mutualists, others parasites. As isolated bacteria, they are generally rod-shaped with aerobic metabolism, but their shape is transformed within the host cell. Intracellularly, they need to solve special problems, such as the exclusion of oxygen from nitrogen fixation, a process requiring anaerobiosis—or, in the case of pathogens, the need to resist host defenses.

Nitrogen-fixing endosymbionts of plants include genera such as *Rhizobium*, *Bradyrhizobium*, and *Sinorhizobium*. The nomenclature has undergone many changes, but the species are still generally referred to as rhizobia. Rhizobia can live freely in the soil, but they prefer to colonize plants, usually legumes such as peas or alfalfa, where they form distinctive nodule structures. Each species of bacteria colonizes a particular host range for infection. Complex chemosensory processes attract the bacteria to the surface of the host root, where their presence induces root hairs to form curls around the bacteria (**Fig. 18.28**). The curling of the root hairs enables the bacteria to form infection threads, chains of bacteria that invade the root cells. Within the host cells, the bacteria lose their cell wall and become **bacteroids**, specialized cells for nitrogen fixation. The host plant cells provide nutrients as well as protective components such as **leghemoglobin**, an oxygen-binding protein that maintains anaerobiosis within infected cells. Leghemoglobin turns the nodule interior pink (**Fig. 18.28A**).

Agrobacterium. The genus *Agrobacterium* includes plant pathogens closely related to the rhizobia. *Agrobacterium tumefaciens* is known for its ability to convert host cells to a form that produces tumors called galls (**Fig. 18.29**). The ability of *A. tumefaciens* to insert its DNA into plant genomes has made it a major tool for plant biotechnology (see Chapter 16).

Rickettsias: intracellular pathogens and mitochondria. Short coccoid rods, rickettsias lack flagella and can only grow within a host cell. The best-known rickettsia is *Rickettsia rickettsii*, the cause of Rocky Mountain spotted fever, a disease spread by ticks in the northwestern United States. *Rickettsia* species parasitize human endothelial cells (**Fig. 18.30**). The bacteria induce phagocytosis, then dissolve the phagocytic vesicle and escape into the cytoplasm. Some rickettsias propel themselves

The bacteria form infection threads that penetrate the legume cells.

through the host cell by polymerizing cytoplasmic actin behind them, a process similar to that of *Listeria* (described under Firmicutes). The actin tails eventually project outward as filopodia, extensions of host cytoplasm and membrane that protect the bacteria from host defenses while enabling them to invade adjacent cells. The rickettsias include other intracellular pathogens, such as *Coxiella burnetii*, the causative agent of human Q fever.

Genetic analysis shows that the rickettsia clade includes mitochondria. All eukaryotic mitochondria appear to be descendants of an ancient rickettsial parasite whose respiratory apparatus ultimately became essential to power eukaryotic cells.

Genomic analysis of natural ecosystems continues to reveal surprises. We can now sequence a "community genome," or **metagenome**, of numerous organisms from a given microbial community. In 2004, Craig Venter and colleagues from several institutions sequenced a billion base pairs of the metagenome from the Sargasso Sea near Bermuda. Numerous uncultured species were revealed, including free-living rickettsias. Some of these rickettsias, such as *Pelagibacter ubique* (isolate SAR11), contain proteorhodopsin, a bacterial version of the retinal-based light-driven proton pump found in halophilic archaea (discussed in Chapter 14). It was unexpected to find a nonparasitic marine rickettsia, let alone one with an archaeal form of photosynthesis.

Beta Proteobacteria: Photoheterotrophs, Lithotrophs, and Pathogens

The Beta Proteobacteria include photoheterotrophs such as *Rhodocyclus*, as well as a diverse range of lithotrophs (**Table 18.4**). Several important pathogens infect humans and other animals.

Lithotrophs: nitrifiers and sulfur oxidizers. An important group of nitrogen lithotrophs is the **nitrifiers**. Nitrifiers oxidize ammonia (NH_3) to nitrite (NO_2^-) (**Fig. 18.31A**) or nitrite to nitrate (NO_3^-). Typically, different species conduct the two reactions separately while coexisting in the soil and water. Nitrifiers are of enormous economic and practical importance for wastewater treatment, as they decrease the reduced nitrogen content of sewage. Special systems have been developed to retain nitrifier bacteria behind filters as one stage of water treatment (**Fig. 18.31B**). In the system shown, nitrifying bacteria are encapsulated in pellets to retain them within the bioreactor while the treated water flows through a filter.

The most commonly isolated ammonia oxidizers are *Nitrosomonas* species of the Beta class. *Nitrosomonas* cells conduct electron transport through extensive internal membranes, either stacked or invaginated. Related genera such as *Nitrosolobus* and *Nitrosovibrio* have also been described, some with peritrichous or polar flagella. One ammonia-oxidizing genus of the Gamma group has been found, *Nitrosococcus*. Major nitrite oxidizers also include the nonproteobacterial phylum Nitrospirae. Although genetically outside the Proteobacteria, the unusual spiral-shaped cells of Nitrospirae have a gram-negative cell envelope.

Another important group of Beta Proteobacteria is the sulfur and iron oxidizers, such as the genus *Thiobacillus* (**Fig. 18.32A**). Most are short rods or vibrios (comma-shaped). *Thiobacillus* and other sulfur-oxidizing genera can undergo a number of different reactions oxidizing

Figure 18.32 ***Thiobacillus*: iron oxidizers. A.** *Thiobacillus ferrooxidans* leaches copper and iron from molybdenite ore (SEM). **B.** In a copper mine, *Thiobacillus* species can oxidize copper ores, leaching the copper into solution for retrieval.

H_2S to S^0 and S^0 to SO_4^{2-} (see **Table 18.4**). Sulfate production creates an environment acidic enough to erode stone monuments and the interior surface of concrete sewer pipes. Sulfur oxidation is often coupled to oxidation of iron, $Fe^{2+} \longrightarrow Fe^{3+}$. The bacterium *T. ferrooxidans* is known for its role in acidification of mine water, where it contributes to leaching of iron, copper, and other minerals (**Fig. 18.32B**).

Pathogens. The Beta class includes aerobic heterotrophic cocci such as *Neisseria.* The cocci of *Neisseria* species form distinctive pairs known as **diplococci** (shown in **Table 18.1**). Most *Neisseria* species are harmless commensals of the nasal or oral mucosa, but *N. gonorrhoeae* causes the sexually transmitted disease gonorrhea. *N. gonorrhoeae* is actually a microaerophile, requiring a narrow range of oxygen concentration; it has fastidious growth requirements, necessitating cultivation on special blood-based medium. A related organism, *N. meningitidis*, may be carried asymptomatically by a quarter of the human population, but occasionally it causes meningitis, which can be fatal. Other neisserias, such as *N. sicca*, are easily isolated from skin and often presented as an unknown for identification by undergraduates.

Other members of the Beta class are important animal and plant pathogens, such as *Burkholderia*. *B. cepacia* was originally isolated from onions as a cause of bulb rot; it is now known to be a major opportunistic invader of the lungs of cystic fibrosis patients.

Gamma Proteobacteria: Photolithotrophs, Enteric Flora, and Pathogens

The Gamma Proteobacteria are well known for the Enterobacteraceae family of facultative anaerobes found in the human colon, including important pathogens. In the environment, marine species catabolize complex organic pollutants, such as petroleum hydrocarbons. Gamma Proteobacteria also include unusual phototrophs, some of which oxidize iron and nitrite.

Chromatium: sulfur and iron phototrophs. The Gamma group phototrophs, such as *Chromatium* species (**Fig. 18.33**), mainly utilize sulfide and produce sulfur, which is deposited as intracellular granules visible within the cytoplasm. Their phototrophy is entirely anaerobic. Some of the Gamma group are true autotrophs and do not use organic substrates. Some of these actually conduct phototrophy using iron (Fe^{2+}) to donate electrons. Iron phototrophy, or "photoferrotrophy," is considered an intriguing possibility for metabolism of early life (discussed in Chapter 17). *Thiocapsa* uses NO_2^-, the first nitrogen-based phototroph discovered.

Sulfur lithotrophs. The sulfur-oxidizing genus *Beggiatoa* (Gamma class) was one of the first kinds of lithotroph described by pioneer microbial ecologist Sergei Winogradsky (discussed in Chapter 1). *Beggiatoa* species oxidize H_2S to elemental sulfur, which collects as sulfur granules within the periplasm. *Beggiatoa* also stores carbon in cytoplasmic granules of polyhydroxybutyrate, a common strategy among proteobacteria. The cells of *Beggiatoa* grow as extended filaments with visible sulfur granules, forming biofilms on sulfide-rich sediment.

Enteric fermenters and respirers. The family Enterobacteriaceae, facultative anaerobes of the Gamma subdivision, include some of the most intensively studied species of all bacteria. Species are readily isolated from the contents of the human digestive tract and easily grown on laboratory media based on human food. The best-known species of Enterobacteriaceae—indeed, the best studied of all bacterial species—is the model organism *Escherichia*

Figure 18.33 ***Chromatium*: Sulfur and iron phototrophs.** **A.** *Chromatium* forms single-flagellated rods full of sulfur granules. **B.** Photoferrotrophy: Under illumination, color develops over time (1–5) as a *Chromatium* isolate oxidizes Fe^{2+} to Fe^{3+}.

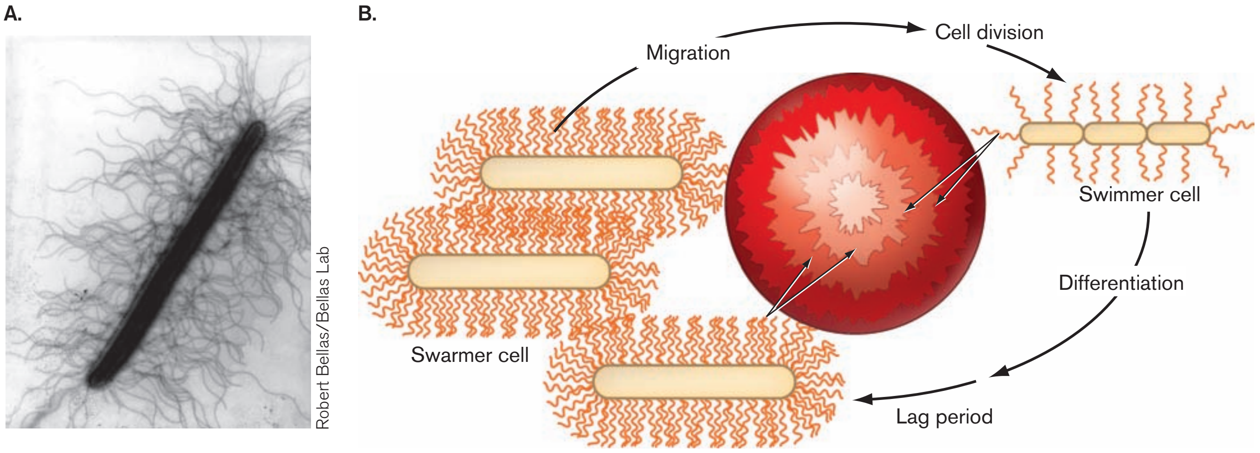
coli. Strains of *E. coli* grow normally in the human intestine, feeding on our mucous secretions and producing vitamins, such as vitamin K. But other strains, such as *E. coli* O157:H7, cause serious illness. A large proportion of the world's children die of *E. coli*-related intestinal illness before the age of 5.

The Enterobacteriaceae are gram-negative rods, although as nutrients diminish, their size dwindles almost to a coccoid form. They grow singly, in chains, or in biofilms. Many species are motile, with numerous flagella. Most strains grow well with or without oxygen, by either respiration (aerobic or anaerobic) or fermentation. They ferment rapidly on carbohydrates, generating fermentation acids, ethanol, and gases (CO_2 plus H_2) in varying proportions, depending on the species. Their presence in the intestine supports the growth of organisms utilizing these gases, including methanogens (discussed in Chapter 19.) Many strains form biofilms. Biofilm formation explains the persistence of drug-resistant infections, such as those associated with urinary catheters in long-term hospital patients.

THOUGHT QUESTION 18.8 Why do you think it took many years of study to realize that *Escherichia coli* and other Proteobacteria can grow as a biofilm?

Because of their ease of cultivation and their long study in clinical laboratories, many genera of Enterobacteraceae are familiar to students in introductory microbiology laboratory courses. A common laboratory exercise is to distinguish *Enterobacter* and *Klebsiella* species from *E. coli* by their fermentation to the pH-neutral product butanediol, which tests positive in the Voges-Proskauer test. (Fermentation is discussed in Chapter 13.) *Enterobacter* species occur more frequently in freshwater streams than in the human body, although a few species colonize the intestine and cause illness.

Proteus mirabilis and *P. vulgaris* cause bladder and kidney infections, particularly as a complication of surgical catheterization. *Proteus* species are heavily flagellated and display a remarkable **swarming** behavior (**Fig. 18.34**). Upon an



Robert Bellas/Bellas Lab

Figure 18.35 ***Pseudomonas* species form biofilms.** **A.** *Pseudomonas fluorescens* biofilm on a plant surface. **B.** Biofilm development in *Pseudomonas* species.

environmental signal, the flagellated rods grow into long-chain swarmer cells. The swarmers gather together forming "rafts" that swim together, growing into a complex biofilm.

Besides symbionts of animals, Enterobacteraceae include plant pathogens, such as *Erwinia* species. *Erwinia* species cause wilts, galls, and necrosis of a wide variety of plants, including bananas, tomatoes, and orchids (see Chapter 23).

Aerobic rods. Closely related to Enterobacteraceae are several genera of rod-shaped bacteria that are obligate respirers. Many are obligate aerobic respirers (requiring O_2 for growth), although some can use alternative electron acceptors such as nitrate. These genera metabolize an extraordinary range of natural compounds, including aromatic derivatives of lignin; thus, they have important roles in natural recycling and soil turnover.

The Pseudomonadaceae are a large and amorphous group. As the "pseudo" prefix suggests, their taxonomic unit is poorly defined and includes species whose DNA sequence has necessitated their reassignment to other groups. The Gamma class pseudomonads, such as *Pseudomonas aeruginosa* and *P. fluorescens*, respire on oxygen or nitrate and are vigorous swimmers with single or multiple polar flagella. *P. aeruginosa* can swim throughout a standard agar plate (much to the chagrin of students attempting to isolate colonies). Nevertheless, under appropriate environmental conditions, pseudomonad cells give up their motility and develop biofilms (**Fig. 18.35**; discussed in Chapter 4). Biofilms of *P. aeruginosa* cause lethal infections of the pulmonary lining of cystic fibrosis patients.

Some pseudomonad pathogens have the unusual ability to infect both plants and animals. For example, *P. aeruginosa* commonly infects plants as well as humans. *P. fluorescens* infects seedlings and causes rotting of citrus fruit, while it also appears as an opportunistic pathogen of immunocompromised cancer patients. Other pseudomonad species, however, are harmless residents of soil or sewage.

Legionella pneumophila is a well-publicized pathogen related to the pseudomonads (class Legionellales). Incapable of growth on sugars, *L. pneumophila* requires oxygen to respire on amino acids. The organism exhibits an unusual dual lifestyle, alternating between intracellular growth within human macrophages and intracellular growth within freshwater amebas (**Fig. 18.36**). Growth within amebas facilitates transmission through aerosols into the

human lung. *L. pneumophila* is an emerging pathogen that took advantage of our changing lifestyle (the prevalence of large-scale air-conditioning units with unfiltered water).

Delta Proteobacteria: Lithotrophs and Multicellular Communities

The Delta Proteobacteria include important sulfur and iron reducers such as *Geobacter metallireduscens*. Other species have complex life cycles that include multicellular developmental forms. The best-studied example is the myxobacteria. Myxobacteria have exceptionally large genomes, such as that of *Sorangium cellulosum* (12.6 Mb).

Myxobacteria. The myxobacteria, such as *Myxococcus xanthus*, are free-living soil bacteria that can grow as isolated cells or come together to form a differentiated structure for the purpose of reproduction (**Fig. 18.37**). When nutrients are plentiful, the myxobacteria grow and divide as individual cells. As nutrients run out, the cells begin to attract each other, moving into parallel formations. Myxobacteria have no flagella, but they move along a surface, a form of motility called gliding.

The formations develop into a bulging mass and the aggregating cells coalesce to form a **fruiting body** (**Fig. 18.38**). Fruiting body formation also occurs in slime molds, a class of eukaryotic microbe (discussed in Chapter 20). The myxobacteria, however, have evolved their process independently. Within the *Myxococcus* fruiting body develop durable spherical cells called **myxospores**. Ultimately, the myxospores are released to be carried on the wind to a more favorable location.

THOUGHT QUESTION 18.9 Compare and contrast the formation of cyanobacterial akinetes; firmicute endospores; actinomycete arthrospores; and myxococcal myxospores.

NOTE: Distinguish myxobacteria from *Mycobacterium*, the gram-positive genus that includes the causative agents of tuberculosis and leprosy.

Bdellovibrios parasitize bacteria. Bacteria, like eukaryotic cells, can be parasitized or preyed on by smaller bacteria. The Delta class includes *Bdellovibrio* species, which attack proteobacterial host cells. The structure of the "attack cell" is a small comma-shaped rod with a single flagellum. The attack cell attaches to the envelope of its

host, then penetrates into the periplasm, where it uses host resources to grow (**Fig. 18.39**). The growing cell produces enzymes that cross the inner membrane to degrade host macromolecules and make their components available to the bdellovibrio. The entire host cell loses its shape and becomes a protective incubator for the predator. This stage is called the bdelloplast.

Within the periplasm, the invading bdellovibrio elongates as a spiral filament while replicating several copies of its DNA. When most nutrients have been exhausted, the filament septates into multiple short cells. The cells develop flagella, and the bdelloplast bursts, releasing the newly formed attack cells.

Bdellovibrios can be isolated from sewage, soil, or marine water—any environmental source of gram-negative prey bacteria. Different species infect *E. coli* and *Pseudomonas*, as well as *Agrobacterium* and *Rhizobium* in their free-living state. They can be cultured as plaques on a top-agar plate containing host bacteria, the same procedure used to isolate bacteriophages (discussed in Chapter 6).

Epsilon Proteobacteria: Microaerophilic Helical Pathogens

Epsilon Proteobacteria include the genera *Campylobacter* and *Helicobacter*. *Helicobacter pylori* is well known today as the causative agent of gastritis and stomach ulcers (**Fig. 18.40**). Yet until recently, most microbiologists believed that bacteria could not live in the acidic stomach. The discovery of *H. pylori* as the cause of gastritis earned the Nobel Prize in Medicine, in 2005, for Barry Marshall and J. Robin Warren, of the University of Western Australia.

H. pylori and related species grow primarily on the stomach epithelium, at about pH 6, which is less acidic than the gastric contents (pH 2–4). The bacteria bury themselves in the epithelial layer and neutralize their acidic surroundings by secreting urease enzyme, which converts urea to ammonia and carbon dioxide. *Helicobacter* species form wide spiral cells (spirillum) with an unusual grouping of flagella at one end. The metabolism of

H. pylori is microaerophilic; that is, the cells grow best in a narrow range of oxygen concentration. They can be isolated through biopsy of the gastric mucosa.

Nitrospirae Oxidize Nitrite and Iron

The phylum Nitrospirae consists of gram-negative spiral bacteria that oxidize nitrite ion to nitrate. Their cell structure resembles that of the Proteobacteria, although their phylogenetic branch is deep enough for assignment to a separate phylum. Most species, such as *Nitrospira* sp. (see **Table 18.1**), are true lithotrophs or autotrophs, fixing carbon in the form of carbon dioxide or carbonate using carboxysomes. *Nitrospira* species are generally found in freshwater or salt water. Their removal of excess nitrite makes a key contribution to aquatic ecosystems.

Another important genus is *Leptospirillum*, which includes acidophilic iron oxidizers. They are also strict autotrophs, fixing carbon using Fe^{2+} as their electron donor and O_2 as the electron acceptor. Their metabolism generates acid, contributing to acid mine drainage in iron mines in Iron Mountain, California, where they grow in massive pink biofilms.

TO SUMMARIZE:

- **Proteobacteria** stain gram-negative, with a thin cell wall and an LPS outer membrane. They show wide diversity of form and metabolism, including phototrophy, lithotrophy, and heterotrophy on diverse organic substrates.
- **Alpha Proteobacteria** include photoheterotrophs (such as *Rhodospirillum*) and heterotrophs as well as methylotrophs. They include intracellular mutualists, such as rhizobia, and pathogens, such as the rickettsias. Rickettsias share ancestry with mitochondria.
- **Beta Proteobacteria** include photoheterotrophs (*Rhodocyclus*) as well as nitrifiers (*Nitrosomonas*) and sulfur iron oxidizers (*Thiobacillus*). Pathogenic diplococci include *Neisseria gonorrhea*, the cause of gonorrhea.
- **Gamma Proteobacteria** include sulfur and iron photolithotrophs (*Chromatium*) as well as members of Enterobacteraceae found in the human colon. Intracellular pathogens include *Salmonella* and *Legionella*. The pseudomonads, aerobic rods, can respire on a wide range of complex organic substrates.
- **Delta Proteobacteria** include sulfur and iron reducers (*Geobacter*), fruiting body bacteria (*Myxobacteria*), and bacterial predators (*Bdellovibrio*).
- **Epsilon Proteobacteria** are spirillar pathogens such as *Helicobacter pylori*, the cause of gastritis.
- **Nitrospirae** are gram-negative spiral bacteria that oxidize nitrite to nitrate (*Nitrospira*).

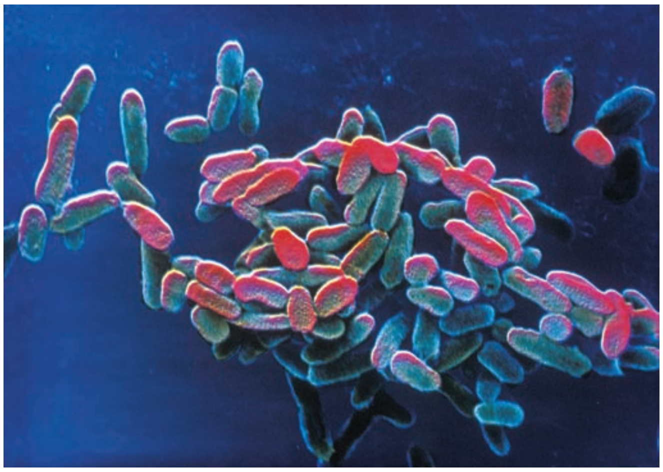
18.6 Bacteroidetes and Chlorobi

Several genera of gram-negative rods are obligate anaerobes, including *Bacteroides*, *Cytophaga*, *Flavobacterium*, and *Chlorobium*. Despite their gram-negative cell envelopes, these genera are genetically distant from Proteobacteria.

Bacteroides species, such as *B. fragilis* and *B. thetaiotaomicron*, are the major inhabitants of the human colon (**Fig. 18.41**). Their envelope polysaccharides help the bacteria evade the immune system. Their main source of energy is fermentation of a wide range of sugar derivatives from plant material, compounds indigestible by humans and potentially toxic. *Bacteroides* converts these substances into simple sugars and fermentation acids, some of which are absorbed by the intestinal epithelium. Thus, *Bacteroides* species serve two important functions for their host: They breakdown potential toxins in plant food, and their fermentation products make up as much as 15% of the caloric value we obtain from food. A third benefit of *Bacteroides* is their ability to remove side chains from bile acids, enabling return of bile acids to the hepatic circulation. In effect, our *Bacteroides* population constitutes a functional organ of the human body.

Bacteroides species cause trouble, however, when they reach parts of the body not designed to host them. During abdominal surgery, bacteria can escape the colon and invade the surrounding tissues. The displaced bacteria can form an abscess, a localized mass of bacteria and pus contained in a cavity of dead tissue. The interior of the abscess is anaerobic and often impenetrable to antibiotics.

Chlorobium species, known informally as green sulfur bacteria, are genetically related to *Bacteroides*, but their metabolism is quite different. They are strict photolithotrophs, using PS I to split electrons from H_2, H_2S, or other reduced sulfur compounds (**Fig. 18.42A**; see



©Institut Pasteur/Phototake

Figure 18.41 ***Bacteroides fragilis* cells colonize the human colon.** *B. fragilis* causes intestinal infections (cell length 1–2 μm; colorized SEM).

Figure 18.42 ***Chlorobium*: gram-negative "green bacteria."** **A.** *Chlorobium tepidum* cell containing chlorosomes. **B.** *Chlorobium* sp. cells covered with sulfur globules; cells form a cluster surrounding a non-phototrophic symbiotic bacterium.

Table 18.2). During the oxidation of sulfide, *Chlorobium* species deposit elemental sulfur extracellularly, forming attached sulfur globules (**Fig. 18.42B**). In contrast, the sulfur granules of Gamma Proteobacteria such as *Chromatium* are deposited internally.

Chlorobium species require extensive membrane systems full of photopigments for light absorption. The chlorophyll reaction centers of *Chlorobium* are contained within chlorosomes associated with the cytoplasmic membrane (**Fig. 18.42**), similar to chlorosomes of the deep-branching phylum Chloroflexi. The photopigment of *Chlorobium* is predominantly Bchl *c*, which absorbs in the blue (460 nm) and near-infrared (750 nm), thus reflecting the middle range, brownish green.

TO SUMMARIZE:

- ***Bacteroides*** bacteria are anaerobes that ferment complex plant materials in the human colon. They may enter body tissues through wounds and cause abscesses.
- ***Chlorobium*** bacteria are green sulfur phototrophs, obligate anaerobes incapable of heterotrophy.

18.7 Spirochetes: Sheathed Spiral Cells with Internalized Flagella

A unique phylum of heterotrophic bacteria is Spirochetes (or Spirochaetes). Different species of spirochetes conduct a broad range of heterotrophy, from aerobic to anaerobic; but all spirochetes have in common a distinctive cell structure consisting of a long, tight spiral, flexible like a telephone cord (**Fig. 18.43**). In many species, the spiral is so thin that its width cannot be resolved by bright-field microscopy, and the organisms can pass through a filter of pore size 2 μm.

Cell Structure of Spirochetes

The spirochete cell is surrounded by a thick outer sheath of lipopolysaccharides and proteins. The spirochete sheath is similar to a proteobacterial outer membrane, except that the periplasmic space completely separates the sheath from the plasma membrane. At each end of the cell, one or more polar flagella extend and double back around the cell body within the periplasmic space (**Fig. 18.44**). The periplasmic flagella rotate on proton-driven motors, as do regular flagella; but because they twine back around the cell body, their rotation forces the entire cell to twist around, corkscrewing through the medium.

This corkscrew motion of the cell body turns out to have a physical advantage in highly viscous environments, such as human mucous secretions or agar culture

medium. Few nonspirochetes can swim through agar at standard culture concentrations (1.5% agar); thus, growth within agar provides a way to isolate anaerobic spirochetes from environmental sources. When an environmental sample is inoculated into agar, other bacteria grow and concentrate at the injection point, whereas spirochetes migrate outward in a "veil" through the agar.

Spirochete Diversity

Spirochetes grow in a wide range of habitats, from ponds and streams to the digestive tract of animals. Aquatic systems carry free-living sugar fermenters of the genus *Spirochaeta*. A particularly interesting spirochete community is found in the termite gut, where the organisms form elaborate symbiotic associations with protists and assist digestion of cellulose.

The best-known spirochetes are those that cause human and animal diseases. The causative agent of the sexually transmitted disease syphilis is the spirochete *Treponema pallidum* (**Fig. 18.43A**). The cell of *T. pallidum* is too narrow (0.2 μm) to visualize by bright-field microscopy; either dark-field, fluorescence, or electron microscopy must be used. While *T. pallidum* is a highly virulent pathogen, other members of the genus *Treponema* are normal residents of the human and animal oral, intestinal, and genital regions.

T. pallidum is not culturable in the laboratory, but its genome sequence reveals much about its physiology. The genome of 1.1 million base pairs is highly degenerate, lacking nearly all components of biosynthesis and of the Krebs cycle; its only system for ATP production is glycolysis.

The spirochete genus *Borrelia* includes two pathogens causing serious tick-borne diseases in the United States. *Borrelia recurrentis* causes relapsing fever, and *B. burgdorferi* causes Lyme disease (**Figs. 18.43B** and **C**). *Borrelia* species have been cultured, although they grow very slowly.

A unique feature of *Borrelia* species is their multipartite genomes. Each species possesses a linear main chromosome of less than a million base pairs, plus a number of linear and circular plasmids. *B. burgdorferi*, for example, has a linear chromosome of 910,725 base pairs, with at least 17 linear and circular plasmids that total an additional 533,000 base pairs. The reason for this unusual fragmentation of *Borrelia* genomes is unknown.

Spirochetes include important pathogens of animals, such as *Leptospira*, the cause of leptospirosis, a form of nephritis (kidney inflammation) with complications in the liver and other organs. *Leptospira* cells are known for the peculiar L shape of the cell, as each end of the spirochete turns out at an angle. The genus *Treponema* also includes the causative agent of digital dermatitis in cattle and sheep. As always, however, the pathogenic species are far outnumbered by harmless flora.

TO SUMMARIZE:

- **The spirochete cell** is a tight coil, surrounded by a sheath and periplasmic space containing periplasmic flagella.
- **Motility** occurs by a flexing motion caused by rotation of the periplasmic flagella, propagated the length of the coil.
- **Spirochetes grow in diverse habitats.** Some are free-living fermenters in water or soil. Others are pathogens, such as *T. pallidum*, the cause of syphilis. Still others are endosymbionts of an animal digestive tract, such as the termite gut.

18.8 Chlamydiae, Planctomycetes, and Verrucomicrobia: Irregular Cells

Several related phyla of bacteria have eliminated or diminished cell walls. These organisms evolved independently of the mycoplasmas, and their alternative cell forms show very different environmental adaptations.

Chlamydiae: Intracellular Parasites

In the phylum Chlamydiae, the genera *Chlamydia* and *Chlamydophila* evolved a complex developmental life cycle of parasitizing host cells. *Chlamydia trachomatis* is the causative agent of a major sexually transmitted disease in the United States. It is also a cause of trachoma, an eye disease dating back to records in ancient Egypt. The related species *Chlamydophila pneumoniae* causes pneumonia and has been implicated in cardiovascular disease.

Chlamydiae alternate between two developmental stages with different functions: elementary bodies and reticulate bodies (**Fig. 18.45A**). The form of chlamydia transmitted outside host cells is called an **elementary body**. Elementary bodies resemble endospores in that they are metabolically inert, with a compacted chromosome. While lacking a cell wall, they possess an outer membrane whose proteins are cross-linked by disulfide bonds, making a tough coat that provides osmotic stability. The elementary body adheres to a host cell surface and is endocytosed (**Fig. 18.45B**).

To reproduce, the elementary body must transform itself into a **reticulate body**, named for the netlike appearance of its uncondensed DNA. The reticulate body has active metabolism and divides rapidly, but outside the cell it is incapable of infection and vulnerable to osmotic shock. To complete the infectious cycle, therefore, the reticulate bodies must develop into new elementary bodies before exiting the host. When the host cell lyses, the elementary bodies are released to infect new cells. Chlamydiae infect a wide range of host cell types, from respiratory epithelium to macrophages.

Planctomycetes: A Nucleus-like Compartment

Another cell wall-less group, the planctomycetes, evolved largely as free-living organisms. Planctomycetes are oligotrophs, heterotrophs requiring nutrients at extremely low concentration. They grow in aquatic, marine, and saline environments. Their mechanism of osmoregulation remains poorly understood.

The planctomycete cells possess multiple internal membrane compartments of unknown function (**Fig. 18.46**). An internal membrane just inside the cell membrane divides the cytoplasm into concentric portions. A double membrane surrounds the entire nucleoid, analogous to the double membrane surrounding the eukaryotic nucleus. The purpose of this segregation is unclear, however, as ribosomal translation appears to occur equally both inside and outside the planctomycete "nucleus." It remains a remarkable example of independent analogous evolution between bacteria and the eukaryotes.

Like eukaryotic protists (discussed in Chapter 20), the planctomycetes have flexible cell bodies that can assume diverse forms. For example, some *Planctomyces* species have rotary flagella, whereas *P. bekefii* cells have stalks that attach to each other to generate a starlike aggregate (**Fig. 18.46C**). Most planctomycetes reproduce by budding, a strategy typical of eukaryotic yeasts.

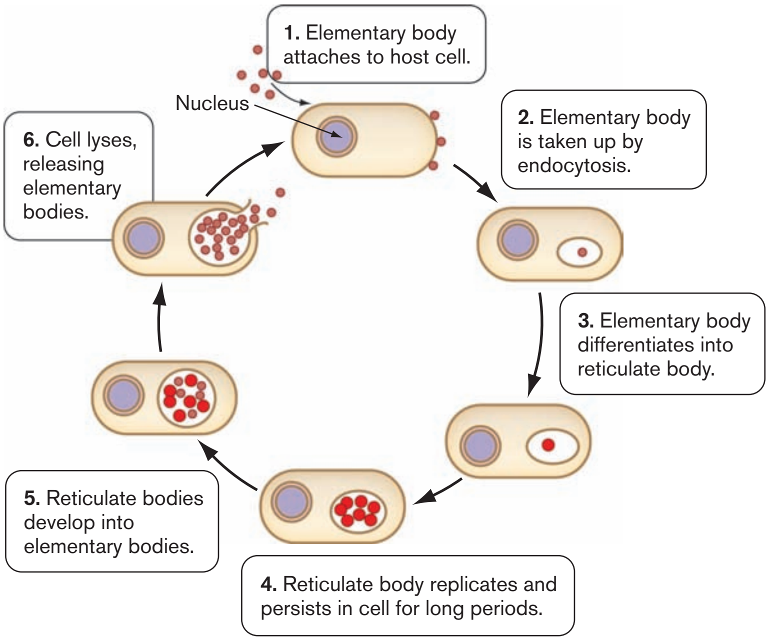
B. ***Chlamydia*** **developmental cycle**



1. Elementary body attaches to host cell.
Nucleus
2. Elementary body is taken up by endocytosis.
3. Elementary body differentiates into reticulate body.
4. Reticulate body replicates and persists in cell for long periods.
5. Reticulate bodies develop into elementary bodies.
6. Cell lyses, releasing elementary bodies.

Figure 18.45 ***Chlamydia*** **life cycle.** **A.** *Chlamydia trachomatis* multiplying within a human cell (colorized TEM). Infected cell (equivalent to step 5 in part B) contains reticulate bodies (yellow) growing and dividing, as well as newly formed elementary bodies (red). **B.** *Chlamydia* species persist outside the host as a spore-like "elementary body" that is metabolically inactive and contains compacted DNA. Upon endocytosis, the elementary body avoids lysosomal fusion and develops into a "reticulate body" in which the DNA, now uncondensed, has a reticular (netlike) appearance. The reticulate body replicates within the host cytoplasm, then develops into new elementary bodies that are released when the cell lyses.

Verrucomicrobia: Wrinkled Microbes

Verrucomicrobia, "wrinkled microbes," are irregularly shaped bacteria found in a wide variety of aquatic and terrestrial environments as well as in the mammalian gastrointestinal tract (see **Table 18.1**). Most verrucomicrobia are oligotrophs, growing heterotrophically in low-salt habitats. Some are ectosymbionts of protists, attached to the cell surface of the eukaryote, where they eject harpoon-like objects. They are rarely cultured, and until recently they failed to show up in PCR amplification of natural isolates because their rDNA sequences are poorly amplified by the standard primer sequences. Using appropriate primer pairs, Verrucomicrobia comprise 5% of all surveyed microbial sequences in some natural environments.

The verrucomicrobia have peptidoglycan cell walls, but their shape is dominated by wart-like projections containing a poorly characterized cytoskeleton. The cytoskeleton appears to contain tubulin, a cytoskeletal protein previously believed to exist only in eukaryotes. In 2002, genes encoding tubulin were found in the partly sequenced genome of *Prosthecobacter dejongeii*, a free-living member of Verrucomicrobia. The genes appear so similar to those of eukaryotes that they must have undergone horizontal transfer from a eukaryotic genome. This horizontal transfer of a eukaryotic trait may be contrasted with the independent development of a nucleus-like structure in planctomycetes.

TO SUMMARIZE:

- **Chlamydiae** are obligate intracellular parasites that undergo a complex developmental progression, culminating in a spore form called an elementary body that can be transmitted outside the host cell. Chlamydiae lack cell walls.
- **Planctomycetes** lack cell walls, and they have evolved a membrane enclosing the nucleoid, analogous to the eukaryotic nuclear membrane.
- **Verrucomicrobia** have cell projections containing tubulin. Their tubulin genes are believed to have arisen through horizontal transfer from a eukaryote.

Concluding Thoughts

Several themes emerge in the diversity of the domain Bacteria. Some phyla, such as Proteobacteria and Actinomycetes, have evolved highly diverse metabolism and cell form. Others show remarkable uniformity in cell structure (Spirochetes) or in metabolism (Cyanobacteria). At the same time, our attempts to generalize about any given clade inevitably run up against the unexpected appearance of exceptions, such as the heliobacteria, photosynthetic endospore formers that unaccountably branch from clostridia. Given the range of bacterial phenotypes, it is hard to imagine that yet more diverse forms of microbial life exist, but they do, as we shall find among the archaea (Chapter 19) and the microbial eukaryotes (Chapter 20).

CHAPTER REVIEW

Review Questions

1. Which deep-branching phyla include hyperthermophiles? Why is the actual branch position of these groups controversial?
2. Compare and contrast Chloroflexi and Cyanobacteria with respect to habitat, cell structure, and means of photosynthesis.
3. Compare and contrast the colonial and filamentous cyanobacteria with respect to life cycle and means of nitrogen fixation.
4. Name and describe three genera of Firmicutes that form endospores. Discuss the difference between single and multiple spore formers. Explain the existence of non-spore-forming species of Firmicutes.
5. Compare and contrast firmicute endospores and actinomycete arthrospores with respect to their means of production, their resistance properties, and their dispersal mechanism.
6. Describe the diverse kinds of metabolism available to different species of Proteobacteria. Explain how it is possible for some species to perform many different kinds of energy-gaining metabolism.
7. What do species of Bacteroidetes and Chlorobi have in common, and how do they differ?
8. Explain the structure and mechanism of motility typical in species of Spirochetes.
9. Discuss the properties of as many intracellular parasites as you recall from various phyla. What do they have in common, and how do they differ?
10. Describe the unique cell structure of *Planctomyces*. Explain how the traits of planctomycete cells appear analogous to aspects of eukaryotic cells.
11. How do microbiologists seek to find previously unknown kinds of bacteria? What techniques reveal unknown microorganisms?

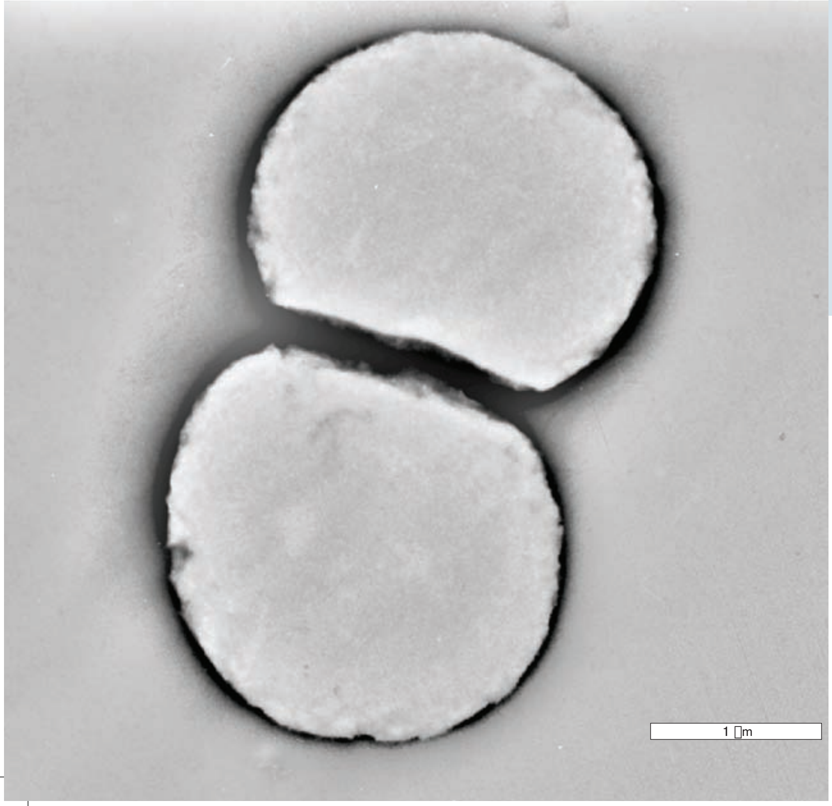
Chapter 19

Archaeal Diversity

19.1 Archaeal Traits and Diversity
19.2 Crenarchaeota: Hyperthermophiles
19.3 Crenarchaeota: Mesophiles and Psychrophiles
19.4 Euryarchaeota: Methanogens
19.5 Euryarchaeota: Halophiles
19.6 Euryarchaeota: Thermophiles and Acidophiles
19.7 Nanoarchaeota and Other Emerging Divisions

Archaea are as different from the "true" bacteria as they are from eukaryotes. These highly diverse organisms include hyperthermophiles, inhabiting the hottest environments on Earth, as well as Arctic and Antarctic psychrophiles growing beneath sea ice and in subglacial lakes. Many of the hyperthermophiles experience extreme pressure or acidity as well as extreme temperature. Most grow without molecular oxygen, as did early life on Earth. Their proposed resemblance to the earliest life-forms earned this group the name Archaea.

Still other kinds of archaea grow in soil or water, even within our own digestive tract. The haloarchaea grow in concentrated brine, coloring salt lakes red. Some have forms of metabolism unique to archaea, such as methanogenesis, the reduction of CO_2 or other small organic molecules to methane. Methanogens grow in the digestive tracts of animals and humans. Yet surprisingly, the archaeal domain seems to lack pathogens. No archaeon has yet been shown to cause disease in animals or plants.



A hyperacidophile, the archaeon *Picrophilus torridus* grows at pH 0. It was first isolated from a solfatara (volcanic steam vent) in Hokkaido, northern Japan. *P. torridus* can grow in IM sulfuric acid at temperatures up to 65°C. Its genome was sequenced by Wolfgang Liebl and colleagues at the University of Goettingen. *Source:* O. Fütterer, et al. 2004. Genome sequence of *Picrophilus torridus* and its implications for life around pH 0. *Proceedings of the National Academy of Sciences USA* 101:9091–9096. Photo courtesy of Wolfgang Liebl.

Archaea are prokaryotic microbes best known for their dominance of superheated habitats such as the hot springs of Yellowstone National Park and thermal vents at the ocean floor. Yet genetic surveys based on rRNA genes reveal archaeal species in the coldest habitats as well as the hottest. Ace Lake, Antarctica, is a well-studied cold habitat with temperatures in the range of 14–24°C and bottom anoxic layers never warmer than 2°C (**Fig. 19.1**). The lake supports a wide range of psychrophilic microbes, including methanogens and other archaea. Some of these psychrophilic archaea show surprising relatedness to the sulfur-metabolizing thermophiles found at thermal vents.

Overall, archaeal species grow in habitats at a wider range of temperature and other environmental factors than either bacteria or eukaryotes. Archaea grow in alkaline soda lakes, as well as highly acidic mine runoff streams; within oxygenated hot springs, as well as within the anaerobic human digestive tract. Extremophiles are of interest

Ricardo Cavicchioli. 2006. *Nature Reviews Microbiology* 4:331

Table 19.1 Archaeal traits absent from bacteria and eukaryotes.

Traits of archaea	Alternative traits of bacteria and/or eukaryotes	Archaea showing the trait
Cell envelope		
Membrane lipids: isoprenoid L-glycerol ethers or diethers	Membrane lipids: D-glycerol hydrocarbon diesters	All archaea
Membrane lipid chains stiffen by covalent cross-links or by forming pentacyclic rings.	Chains stiffen by unsaturation.	Most archaea
S-Layer of glycoprotein	Murein sacculus	Hyperthermophilic Crenarchaeota
S-Layer of protein, methanochondroitin, or sulfated polysaccharide	Murein sacculus	Methanogens and haloarchaea
Pseudomurein sacculus contains talosaminuronic acid; peptide bridges contain only L-amino acids.	Murein	Methanobacteriales, Methanopyrales
Metabolism		
Nonphosphorylated intermediates of sugar catabolism and synthesis (Embden-Meyerhof glycolysis in some cases)	Embden-Meyerhof pathway of glycolysis, with phosphorylation mediated by NAD or NADP (Entner-Doudoroff in some cases)	All archaea
Methanogenesis from H_2 and CO_2; or from CO, methanol, methyl sulfides, formate, or acetate	Anaerobic metabolism such as fermentation. No methane production.	Methanogens
Archaeal coenzymes: coenzymes F_{420}, F_{430}, and coenzyme M	Flavin mononucleotide, coenzyme A, others	Most methanogens
Retinal-associated light-driven membrane pumps for H^+ or Na^+	Chlorophyll-based photosynthesis	Haloarchaea
Nucleic acid structure and function		
Positive superturns generated by reverse gyrase protect DNA from extreme acid.	Negative superturns generated by gyrase	Hyperthermophilic archaea
Unique base structures in tRNA, such as the guanine analog archaeosine	tRNA bases, such as queosine, found only in bacteria and eukaryotes	Most archaea

Sources: O. Kandler and H. König. 1998. *Cell. Mol. Life Sci.* 54:305–308; C. Bullock. 2000. *Biochem. and Mol. Biol. Ed.* 28:186–191.

to biotechnology companies because their exceptionally thermostable enzymes can catalyze reactions under industrially useful conditions, such as high salt or acidity or temperatures above the boiling point of water.

While dominating certain extreme habitats, archaea are also abundant in "moderate" habitats, such as the open ocean, the soil, and the surface of plant roots. Furthermore, species of archaea display unique traits, such as energy-yielding methanogenesis and cyclic diether membranes, found only in the archaeal domain, not in bacteria or eukaryotes. Perhaps the most compelling unique feature of archaea, from the human point of view, is the complete absence of known archaeal pathogens of animals or plants. A few reports suggest the presence of methanogens associated with periodontal disease, but even in these cases, no causal relationship has been demonstrated. This lack of pathogenicity is particularly striking given the intimate association of many archaea with animal digestive systems, with marine sponges, and with the roots of plants.

In this chapter, we explore the diversity of archaeal form and function. We emphasize the unique structures and metabolism of archaeal cells. While surveying their major taxonomic categories, we introduce research techniques used to study organisms in extreme environments and those with unique forms of metabolism such as methanogenesis.

As we saw for bacteria in Chapter 18, new species of archaea continue to be discovered daily. For more detailed coverage of particular species, we recommend the following online resources: Microbial Biorealm, and the National Center for Biological Information (NCBI) Taxonomy Database.

19.1 Archaeal Traits and Diversity

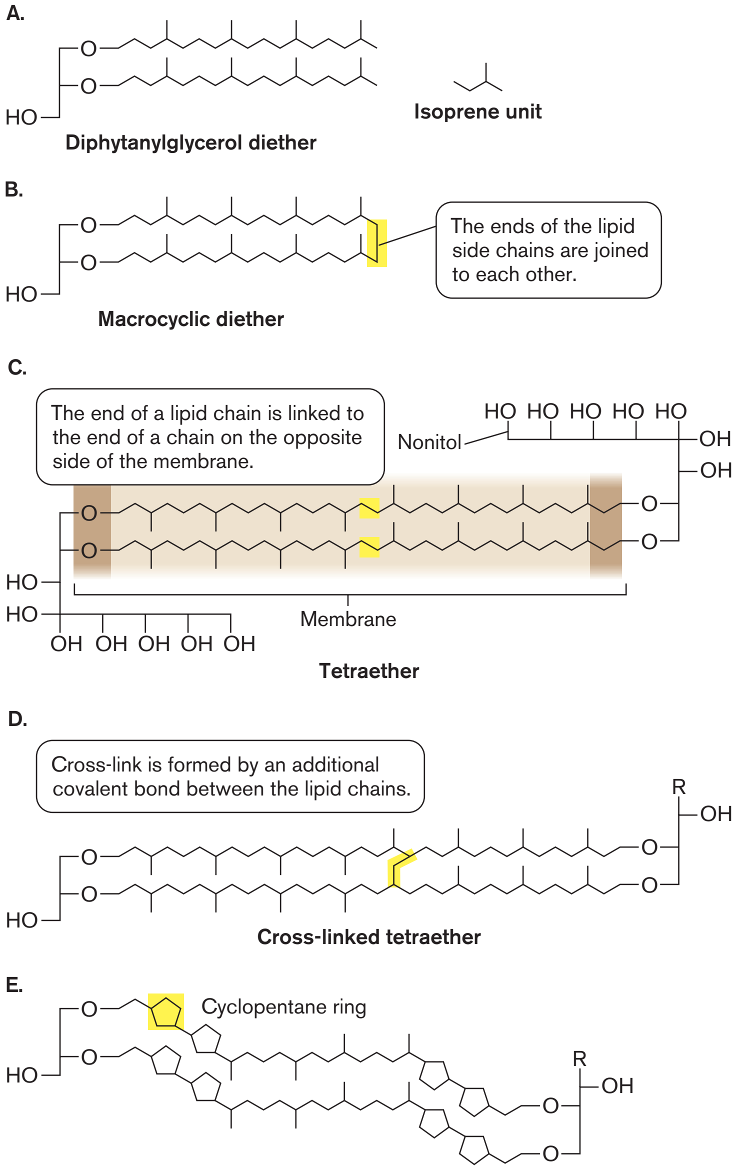
The Archaea show key features unique to this domain, as well as intriguing traits shared by eukaryotes, such as transcription factors required by eukaryotic polymerase II. Archaea show distinctive forms, from intricate cell networks to square-shaped cells. Here we summarize key traits of archaea, then outline the major phylogenetic divisions.

Archaeal Cell Structure and Metabolism

Distinctive features of archaea, sometimes called "archaeal signatures," include components of the cell membrane and envelope and certain metabolic pathways to gain energy (**Table 19.1**).

Isoprenoid membranes and cell wall. The most distinctive structure of archaea is their membrane (**Fig. 19.2**). The membrane lipids of archaea differ profoundly from those of bacteria and eukaryotes, with the exception of a few thermophilic bacteria that show evidence of horizontal transfer of genes conferring synthesis of archaeal-type lipids. Archaeal lipid structure includes:

- **L-Glycerol.** Archaeal membrane lipids incorporate L-glycerol, rather than the mirror-symmetrical form D-glycerol, which is used by bacteria and eukaryotes. The two chiral forms show similar thermal stability, but their biochemistry requires different enzymes,



The ends of the lipid side chains are joined to each other.

The end of a lipid chain is linked to the end of a chain on the opposite side of the membrane.

Cross-link is formed by an additional covalent bond between the lipid chains.

Figure 19.2 Branched-chain ether lipids are characteristic of archaeal membranes. Archaeal membranes show diverse forms of cyclization that offer different levels of protection from extremely high temperature or acidity. *Source:* R. M. Daniel and D. A. Cowan. 2000. *Cellular and Molecular Life Sciences* 57:250–264.

and thus they represent a deep divergence in ancestry. In some archaea, the glycerol is extended by six carbons, forming nonitol (nine OH groups).

- **Ether linkage.** The glycerol units are linked to side chains by ether links (R–O–R) instead of the ester links (R–COO–R) found in bacteria and eukaryotes (**Fig. 19.2A**). Ether links are much more stable than esters; in other words, their breakage requires greater input of energy.
- **Isoprenoid chains.** The side chains of archaeal lipids are branched at every fourth carbon. The methyl branches arise by condensation (C–C bond formation) of units of isoprene (see **Fig. 19.2A**). Condensed isoprene chains are called **isoprenoid** or diphytanyl chains; thus, the overall lipid is diphytanylglycerol diether. Isoprenoid branched chains increase membrane stability.
- **Tetraether-linked lipids.** In some hyperthermophiles, the ends of side chains are linked covalently, either to each other (**Fig. 19.2B**) or to a lipid on the opposite side of the membrane (**Fig. 19.2C**). Two lipid chains crosslinked across the membrane form a **tetraether**, so called because the complex contains four ether links in all. In some cases, an additional covalent bond links the two linked pairs of side chains across the middle (**Fig. 19.2D**).
- **Cyclopentane rings.** Unlike bacteria and eukaryotes, archaea lack unsaturated side chains that decrease mobility. Instead, in some species, the lipid's methyl branches cyclize, forming cyclopentane rings (**Fig. 19.2E**).

Archaea show distinctive envelope structures, such as the cell wall and S-layer. Some methanogens possess a cell wall comparable to the bacterial sacculus, a unimolecular cage of sugar chains linked by peptide bridges (discussed in Chapter 3). But the sacculus of methanogens is composed not of murein, but of a related macromolecule called **pseudomurein** or **pseudopeptidoglycan**. Pseudopeptidoglycan contains chains of alternating sugar derivatives including *N*-acetylglucosamine, as in bacterial peptidoglycan. The bacterial *N*-acetylmuramic acid, however, is replaced by a related sugar, *N*-acetyltalosaminuronic acid; and the sugar linkage is β(1,4) instead of β(1,3). As a result, these archaea are resistant to lysozyme, which degrades bacterial cell walls at the sugar linkage. The peptide cross-bridges of pseudopeptidoglycan differ as well, causing resistance to penicillin.

Other species of archaea, especially members of Crenarchaeota, possess no cell wall at all, only an S-layer composed of proteins. The shape of these cells is more flexible than that of most bacterial cells, which maintain turgor pressure against a sacculus. How archaeal cells maintain turgor pressure without a cell wall is unknown.

Unique metabolic pathways. Archaea show many distinctive metabolic pathways. Glucose is catabolized by several variants of the Entner-Doudoroff (ED) and Embden-Meyerhof-Parnas (EMP) pathways that rarely or never occur in bacteria (**Fig. 19.3**). For example, the sulfur thermophiles *Sulfolobus* and *Thermoplasma* convert glucose to gluconate without phosphorylation, ultimately generating pyruvate with no net production of ATP. On the other hand, halophilic archaea such as *Halobacterium* phosphorylate the dehydrated product of gluconate (2-oxo-3-deoxygluconate), thus channeling into the "standard" ED pathway. The ED pathway generates one molecule of pyruvate and one molecule of 3-phosphoglycerate, which produces one net ATP through the second stage of the EMP pathway. A unique variant of the EMP pathway is seen in the vent thermophile *Pyrococcus furiosus*, which oxidizes glyceraldehyde 3-phosphate using ferredoxin instead of NAD and avoids phosphorylation. The reduced ferredoxin is then used to reduce $2H^+$ to H_2 in an energy-yielding reaction.

The energy-yielding process of **methanogenesis** occurs only in archaea. Methane production by methanogenic archaea (methanogens) makes a growing contribution to global warming, as discussed in Chapter 22. Methanogenesis includes a unique pathway of carbon fixation, called the **carbon monoxide reductase pathway** because the key enzyme can fix CO as well as CO_2. A CO group is fixed into acetyl-CoA by condensation with a methyl group generated by methanogenesis. Acetyl-CoA then enters the TCA cycle. Methanogenesis also uses unique cofactors that largely replace NAD, FAD, and FMN (discussed in Section 19.4).

The only form of phototrophy in archaea is that of retinal-based ion pumps. Membrane protein complexes known as **bacteriorhodopsin** and halorhodopsin contain retinal and pumps for H^+ or Na^+ (discussed in Chapter 14). Bacteriorhodopsins are found in haloarchaea (halobacteria) such as *Halobacterium halobium*; they were named before *Halobacterium* was known to be an archaeon (discussed in Section 19.5). By contrast, the chlorophyll-based phototrophy found in bacteria and plants is completely unknown in archaea. Light-driven ion pumps were believed to be unique to archaea, until bacteriorhodopsin homologs were discovered in marine bacteria. These bacterial H^+ pumps, called proteorhodopsins, are believed to have evolved by horizontal gene transfer from archaea.

Nucleic acid structure. A distinctive feature of archaeal chromosome function is the "reverse gyrase" enzyme found in hyperthermophiles. All bacteria and eukaryotes have gyrase to maintain their DNA in an "underwound" negatively supercoiled state, but hyperthermophiles with reverse gyrase maintain positive supercoiling. The positive superturns "overwind" the DNA, enhancing stability and preventing the helix from melting into separate strands at high temperature.

Figure 19.3 Glucose catabolism in archaea. *Sulfolobus* and *Thermoplasma* species catabolize glucose to pyruvate by a modified ED pathway without phosphorylating glucose and produce no net ATP. *Halobacterium* species phosphorylate 2-keto-3-deoxygluconate and produce 1 net ATP by the EMP stage 2 pathway. *Pyrococcus furiosus* oxidizes glyceraldehyde 3-phosphate using ferredoxin instead of NAD$^+$ and avoids phosphorylation. Archaea also have distinctive modified bases in their tRNA molecules. In particular, the guanosine analog archaeosine (7-formamidino-7-deazaguanosine) is used by nearly all archaea but no bacteria or eukaryotes. Other unusual tRNA bases, such as queuosine, are found only in bacteria and eukaryotes, not in archaea.

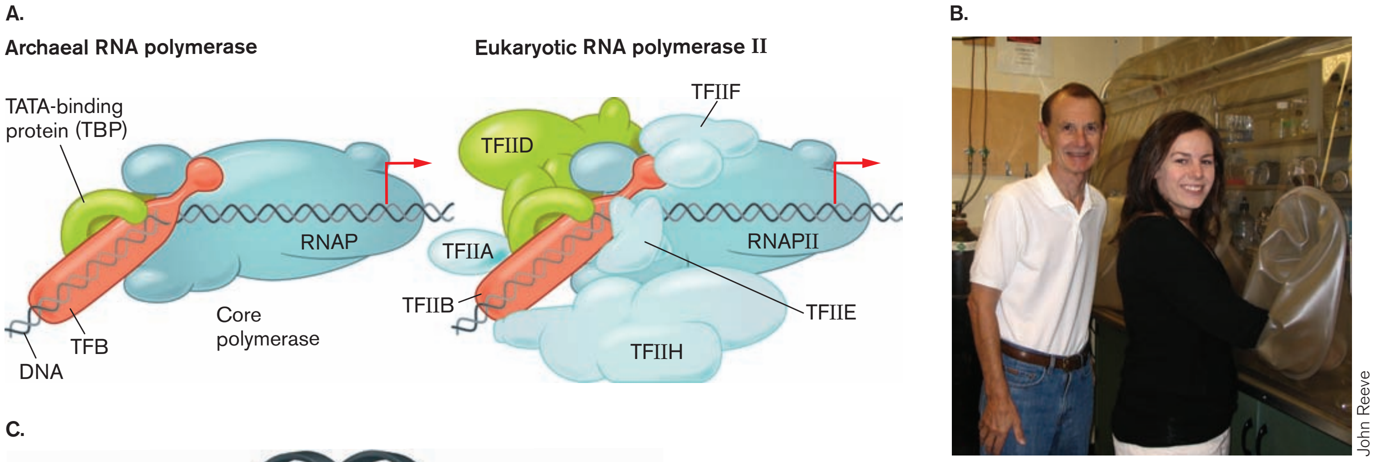
Gene Regulation Resembles That of the Eukaryotic Nucleus

The genomes of archaea generally resemble those of bacteria in size and gene density, and genes of related function are often arranged in operons. Certain tRNA gene sequences, however, are interrupted by nontranscribed sequences called introns, similar to the tRNA introns found in eukaryotes. Furthermore, the archaeal apparatus for DNA and RNA polymerases, transcription factors, and protein synthesis show remarkable similarity to those of eukaryotes. **Figure 19.4A** compares the components of an archaeal RNA polymerase (from *Sulfolobus*) with those of eukaryotic RNA polymerase II. The archaeal polymerase possesses two transcription factors (regulatory protein components) that are found in eukaryotes: TATA-binding protein (TBP) and transcription factor B



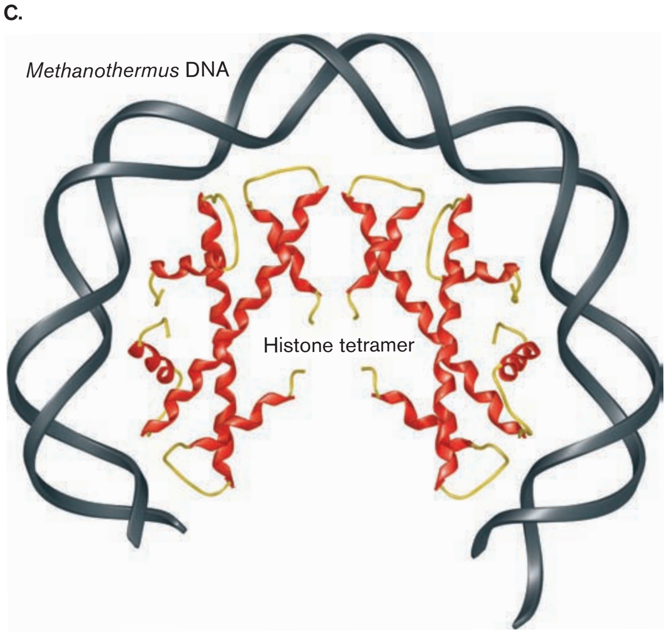


Figure 19.4 Central genetic molecules of Archaea resemble those of Eukarya. A. The core RNA polymerase subunits (RNAP) of the archaeon *Sulfolobus* show homology to those of the eukaryotic RNA polymerase II (RNAPII). The TATA-binding protein (TBP) and transcription factor B (TFB) also show homology to eukaryotic counterparts. **B.** The laboratory research group of John Reeve (left), at Ohio State University, working on the molecular biology of methanogens. **C.** Archaeal histones are found in Euryarchaeota such as the methanogens. *Methanothermus fervidus* DNA binds to histone tetramers that share descent with the histones of eukaryotes. The histone tetramer binds to specific AT-rich sequences. The peptide sequences of the archaeal histones show significant homology to the sequence of a eukaryotic histone. (PDB code: 1A7W)
Source: Kathryn A. Bailey, et al. 2002. *PNAS* 277:9293.

(TFIIB). By contrast, bacteria have no homologs of these factors. A consequence of the eukaryotic-like transcription and translation in archaea is that archaea are resistant to antibacterial antibiotics that target transcription and translation.

Another eukaryotic structure for which archaeal homologs were discovered is that of **histones**, the fundamental packaging proteins of DNA. The histone complex found in eukaryotic chromosomes contains a histone $(H3 + H4)_2$ tetramer flanked by two histone (H2A + H2B) dimers. The archaeal homologs form a $(H3 + H4)_2$ tetramer, with no H2A + H2B homologs. John Reeve and colleagues at Ohio State University (**Fig. 19.4B**) showed that isolated DNA of specific sequences can be bound and curved around a histone tetramer from the methanogen *Methanothermus fervidus* (**Fig. 19.4C**). The DNA has to bind AT-rich sequences that specifically fit the histone complex. The key sequences of the histones (the ones that bind to DNA) show homology to eukaryotic histones. Histones have since been found in many species of archaea.

Phylogeny of Archaea

The domain Archaea includes several deeply branching phyla, which are also called divisions (**Fig. 19.5**). The two best-characterized phyla are **Crenarchaeota** (known for sulfur thermophiles and marine mesophiles) and **Euryarchaeota** (known for methanogens, halophiles, and extreme acidophiles). Major groups of species are outlined in **Table 19.2**.

Crenarchaeota. The Crenarchaeota include well-studied thermophiles that metabolize sulfur, either by anaerobic reduction (such as by H_2 to form H_2S) or by aerobic oxidation (by O_2 to form sulfuric acid). Anaerobic sulfur metabolizers include moderate thermophiles (growth range about 60–80°C) as well as hyperthermophiles (90–120°C). Many of the hyperthermophiles are also barophiles, growing under high pressure at hydrothermal vents on the ocean floor; an example is *Pyrodictium abyssi*. In addition, however, ribosomal RNA gene probes reveal numerous unculturable Crenarchaeota species that are mesophiles (grow at medium temperature) or psychrophiles (grow at low temperature). Thus, the species of Crenarchaeota encompass the widest range of growth temperature of any division of life.

Figure 19.5 Archaeal divergence. Major clades diverged within the phyla (divisions) Crenarchaeota and Euryarchaeota. Other phyla are less well characterized. Divergence was measured based on small-subunit rRNA (16S rRNA) sequences.
Sources: Susan Barns, et al.1996. *PNAS* 93:9188; O. Nercessian, et al. 2003. *Environ. Microbiol.* 5:492; E. F. DeLong, et al. 1994. *Nature* 371:695.

Euryarchaeota. The phylum Euryarchaeota has a broader range of metabolism than Crenarchaeota. The most highly divergent group of Euryarchaeota, and the group most widespread in natural ecosystems, is the methanogens. Methanogens serve a key energetic role in ecosystems by offering an anaerobic mechanism to remove excess H_2 and other small-molecule reductants. Despite their common energetic pathway, methanogens show a wide range of cell form and environmental adaptations. One methanogenic clade branches to the Haloarchaea, extreme halophiles that are the only form of life to grow in concentrated brine (NaCl). Most haloarchaea, such as *Halobacterium* species NRC-1, are photoheterotrophs that can supplement their metabolism with light-driven ion pumps. Still other genera, such as *Archaeoglobus*, show mixed physiology, including components of methanogenesis linked to other pathways, such as glycolysis. The euryarchaeotes include mesophiles as well as thermophiles, such as the order Thermococcales, but few psychrophiles have been found so far. With respect to pH, the euryarchaeotes show the widest range of any clade, from *Ferroplasma* (the order Thermococcales) growing at pH 0 to *Natronococcus* growing at pH 10.

Emerging phyla. Besides the two major phyla Crenarchaeota and Euryarchaeota, we continue to discover new isolates that branch near the root of the tree. Most such isolates are unculturable, known only by their rRNA sequence. One deeply branching group obtained from a Yellowstone hot spring was designated **Korarchaeota**. Another group, **Nanoarchaeota**, includes the tiny hyperthermophile *Nanoarchaeum*, which grows symbiotically on the larger cells of a crenarchaeote, *Ignicoccus*. A genome for *Nanoarchaeum* has been sequenced, and it has proved to be one of the smallest of archaeal genomes.

THOUGHT QUESTION 19.1 If two deeply diverging clades each show a wide range of growth temperature, what does this suggest about the evolution of thermophily or psychrophily?

TO SUMMARIZE:

- **Archaeal membranes are composed of L-glycerol diether or tetraether lipids**, with isoprenoid side chains that may include cross-links or pentacyclic rings.
- **Many archaea have no cell wall, only an S-layer.** Some methanogens have cell walls of pseudomurein.
- **Glucose is catabolized by variants of the ED pathway.** Other metabolic pathways found in archaea include methanogenesis and retinal-associated light-driven ion pumps such as bacteriorhodopsin.
- **Central genetic functions of archaea resemble those of eukaryotes**, as seen in the structure of DNA and RNA polymerases and of histone-like DNA-binding proteins.
- **Two major phyla or divisions of archaea are Crenarchaeota and Euryarchaeota.** Crenarchaeota includes sulfur hyperthermophiles as well as mesophiles, while Euryarchaeota includes methanogens, halophiles, and acidophiles. Each group includes thermophiles as well as mesophiles.

Table 19.2 Representative groups of archaea.

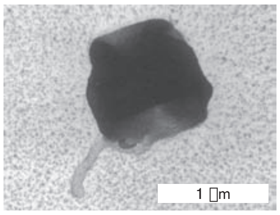
Note: Each trait applies to *most* members of the taxon described, but exceptions have evolved.

Blue-lettered terms indicate classes.

- **Bulleted terms are representative orders** within the class.

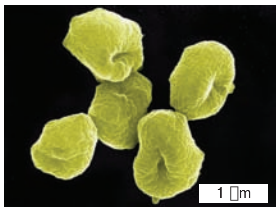
Crenarchaeota

Temperature: Hyperthermophiles and psychrophiles, as well as mesophiles
Metabolism: Sulfur and hydrogen oxidation, aerobic and anaerobic heterotrophy, ammonia oxidation
Envelope: Membrane lipids include tetraethers with crenarchaeol. Flexible S-layer surrounds membrane.



Hyperthermus butylicus

Zillig, et al. 1990. *J. Bacteriol.* 172(7):3959



***Sulfolobus* sp.**

Oliver Meckes/Nicole Ottawa

Thermoprotei. Many thermophiles in hot springs and marine vents. Also include marine mesophiles and psychrophiles.

- **Caldisphaerales.** Thermoacidophilic heterotrophs grow in hot springs.
  Caldisphaera spp.
- **Cenarchaeales.** Sponge symbionts; grow at 10°C.
  Cenarchaeum symbiosum.
- **Desulfurococcales.** Anaerobic sulfur reduction with organic electron donors. Irregularly shaped cells with glycoprotein S-layer; no cell wall.
  Aeropyrum pernix, Desulfurococcus mobilis, Hyperthermus butylicus.
  Pyrodictium abyssi and *P. occultum* grow at marine thermal vents, up to 110°C. Form three-dimensional network of cells and extracellular cannulae.
  Pyrolobus fumarii grows at marine thermal vents, up to 113°C.
  Ignicoccus islandicus. Unique periplasmic space contains membrane vesicles.
  Thermosphaera. Heterotrophic; inhibited by sulfur.
- **Nitrosopumilales.** Ammonia oxidizers, marine.
  Nitrosopumilus maritimus.
- **Sulfolobales.** Aerobic acidophiles; moderate thermophiles. Oxidize H_2S to H_2SO_4.
  Sulfolobus, Sulfurisphaera, Acidianus.
- **Thermoproteales**
  Pyrobaculum, Thermoproteus, Vulcanisaeta.

Marine pelagic plankton. Mesophiles of open ocean; includes heterotrophs and autotrophs; uncultured and largely uncharacterized.

Psychrophilic marine Crenarchaeota. Abundant in Antarctic ocean and in Arctic sea ice.

Marine benthic anaerobes. Anaerobic heterotrophs in seafloor sediment; psychrophiles. Some reduce sulfate; others conduct anaerobic methanotrophy (oxidation of methane) in association with methanogens.

Soil and plant root–associated Crenarchaeota. Many uncharacterized species.

Euryarchaeota

Temperature: Mesophiles and thermophiles; fewer psychrophiles
Metabolism: Methanogenesis, halophilic photoheterotrophs, and sulfur and hydrogen oxidizers; acidophiles and alkaliphiles
Envelope: Methanogens and halophiles have rigid cell walls of glycans, glycoproteins, or pseudopeptidoglycan.

Halobacteriales

Eye of Science

Archaeoglobi. Hyperthermophiles; metabolize sulfur and use reverse methanogenesis pathway.

- **Archaeoglobales.** Sulfate oxidation of H_2 or organic hydrogen donors. *Archaeoglobus fulgidus.*

Halobacteria (Haloarchaea). Halophiles; grow in brine (concentrated NaCl). Conduct photoheterotrophy, with light-driven H^+ pump and Cl^- pump.

- **Halobacteriales**
  Haloarcula, Halobacterium, Halococcus, Haloferax. Mesophiles at neutral pH. Grow in salterns and salt lakes. *Haloarcula marismortui; Halobacterium salinarum.*
  Haloquadra (Haloquadratum). Square-shaped mesophilic halophiles.
  Halorubrum lacusprofundi. Psychrophiles grow in subglacial Antarctic salt lakes.
  Natronococcus, Natronomonas. Alkaliphiles, grow above pH 9 in soda lakes.

Table 19.2 Representative groups of archaea (*continued*)

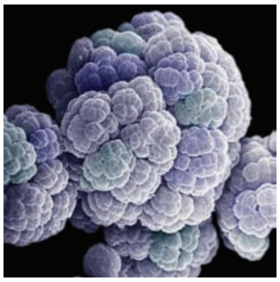
Methanoculleus nigri



©Ralph Robinson/Visuals Unlimited

Methanosarcina mazei

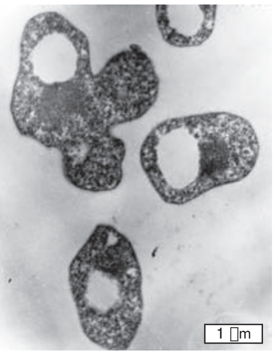
Methanogens (four classes). Generate methane from CO_2 and H_2, formate, acetate, other small molecules. Strict anaerobes. Must associate with bacteria producing their substrates.

Cell walls of pseudopeptidoglycan or polysaccharides.

Wide variety of shapes: rods, filaments, cocci, and coccoid clusters.

Wide range of anaerobic habitats: wetlands, landfills, and intestinal tracts of animals. Psychrophiles in deep-ocean floor sediment generate methane hydrates.

- **Methanobacteriales.** Lacks cytochromes; reduces CO_2, formate, or methanol with H_2.
  - *Methanobacterium* spp. have peptidoglycan cell walls.
  - *Methanobrevibacter smithii* and *Methanosphaera stadtmanae* inhabit human digestive tract. Increase caloric output of human food by reducing methanol, a breakdown product of pectin.
  - *Methanothermus fervidus.* Marine vent thermophiles.
- **Methanomicrobiales, Methanococcales, and Methanopyrales.** Lack cytochromes; reduces CO_2, formate, or methanol with H_2.
  - *Methanoculleus nigri.*
  - *Methanocaldococcus jannaschii.* Vent thermophile.
  - *Methanogenium frigidum.* Psychrophile.
  - *Methanopyrus kandleri.* Marine vent thermophile.
- **Methanosarcinales.** Possesses cytochromes; reduces methylamines and acetate (as well as CO_2 and formate) with H_2.
  - *Methanosarcina acetivorans.* Globular colonies; cell walls of sulfated polysaccharides.
  - *Methanosaeta concilii.* Filamentous colonies.
  - *Methanococcoides alaskense.* Arctic marine habitat.
  - *Methanohalophilus.* Halophile. Inhabits salt lakes, often at high pH.



Schleper, et al. 1995. *J. Bacteriol.* 177(24):7050

Picrophilus oshimae

Thermococci. Hyperthermophiles (grow above 100°C) and barophiles (up to 200 atmospheres pressure). Anaerobes; reduce sulfur.

- **Thermococcales.**

Pyrococcus abyssi, P. furiosus. Use S^0 to oxidize H_2 or organic hydrocarbons. *Thermococcus* species are closely related.

Thermoplasmata. Extreme acidophiles; oxidize sulfur from pyrite (FeS_2), generating sulfuric acid. Mesophiles or moderate thermophiles.

- **Thermoplasmatales.**

Ferroplasma acidiphilum and *F. acidarmanus* grow at 37–50°C. Oxidize sulfur from FeS_2, generating ambient pH as low as pH 0. No cell wall.

Picrophilus torridus grows above 60°C. Oxidizes sulfur, generating acid. Possesses cell wall.

Thermoplasma acidophilum grows at 59°C and pH 2.

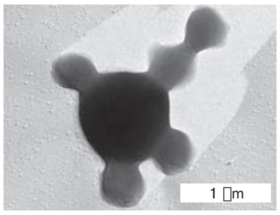
Korarchaeota

Deep-branching hyperthermophiles

Korarchaeote OPF1-KOR; SRI-306. rRNA sequences branch near the root of the archaeal tree. Original isolate was from Yellowstone hot springs.

Nanoarchaeota

Hyperthermophilic symbionts; cell size less than 400 μm



Huber, et al. 2003. *Research in Microbiology* 154:165

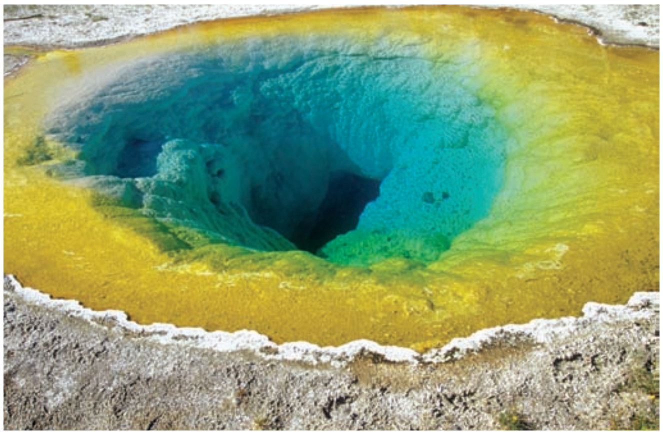
***Nanoarchaeum equitans* (attached to surface of *Ignicoccus* sp.)**

Nanoarchaeum equitans. Grows attached to cells of *Ignicoccus* sp. rRNA sequence deeply branches from common ancestor of archaea. Small genome contains only 490 kb. Grows in hydrothermal vents, up to 98°C. Uncultured; metabolism unknown.

19.2 Crenarchaeota: Hyperthermophiles

The name Crenarchaeota means "scalloped archaea," derived from the amorphous scalloped cell shapes of the first hyperthermophiles discovered. Crenarchaeotes synthesize a distinctive tetraether lipid, called crenarchaeol, containing occasional six-membered cyclic rings (**Fig. 19.6**). Crenarchaeol is found in varying amounts in all known crenarchaeotes; thus, the molecule serves as a physiological biosignature for this division.

The best-studied crenarchaeotes are members of the class Thermoprotei, which includes sulfur oxidizers, aerobic sulfur reducers, and heterotrophs (**Table 19.2**). The first members described were thermophiles; mesophiles and psychrophiles are now known as well.



©Inga Spence/Visuals Unlimited

Figure 19.7 Thermophiles colonize the edge of a hot spring. Morning Glory hot springs, Yellowstone National Park. Yellow-orange regions indicate growth of thermophiles.

Habitats for Thermophiles

Thermophiles and hyperthermophiles commonly grow in hot springs and geysers, such as those of Yellowstone National Park (**Fig. 19.7**) or the Solfatara volcanic area near Naples, Italy. A hot spring occurs where water seeps underground above a magma chamber, which heats the water to near boiling. The heated water expands and is forced upward through fissures, coming out in a heated spring. In a geyser, the water is heated under pressure. As the water escapes upward, it turns into steam, which expands and jets upward, falling into a heated pool. These heated pools and their surrounding edges generate extreme ranges of temperature, mineral content, and acidity. They support a diverse range of microbial life, including thermophilic cyanobacteria and firmicutes as well as archaea.

Several features of hot springs and geysers are important for thermophiles.

- **Reduced minerals.** The heated water dissolves high concentrations of sulfides and other reduced minerals. When the water emerges and cools, the minerals precipitate. These reduced minerals serve as rich energy sources for autotrophs.
- **Low oxygen content.** At higher temperatures, the oxygen concentration of water is decreased. Therefore, hyperthermophiles tend to be anaerobic, although there are important exceptions, such as *Sulfolobus*.
- **Steep temperature gradients.** The temperature of the water falls dramatically within a short distance from the source, creating a steep gradient. Different species of thermophiles are adapted to different temperatures and grow in separate patches at the different temperatures, causing a variegated pattern.
- **Acidity.** In some cases, hot-spring environments show extreme acidity. The acidity results from oxidation of sulfur or iron in reactions that generate strong inorganic acids such as sulfuric acid (H_2SO_4).

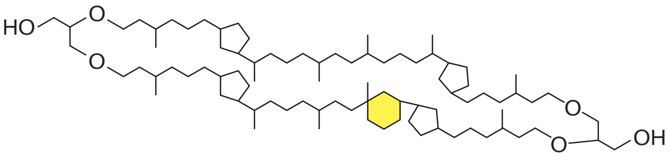


Figure 19.6 Crenarchaeol: a biosignature for crenarchaeotes. Crenarchaeol is a glycerol diphytanyl diether containing a six-membered cyclic ring.

A major subcategory of volcanic hot-spring habitats is that of submarine hydrothermal vents on the ocean floor. So-called "vent" thermophiles must evolve adaptations to high pressure under several kilometers of ocean. Pressure increases by approximately 100 atm per kilometer of ocean depth. Organisms that only grow at high pressure are called **barophiles** (discussed in Chapter 5).

Desulfurococcales: Reducing Sulfur from Hot Springs

Species of the order Desulfurococcales show distinctive cell structures and forms of metabolism (**Fig. 19.8A**; **Table 19.3**). All possess elaborate S-layers but lack a cell wall; their diphytanylglycerol membranes contain a combination of diethers and tetraethers. Many take advantage of the high temperatures that increase the thermodynamic favorability of sulfur redox reactions. An example is *Desulfurococcus mobilis*, a flagellated coccoid cell isolated from hot springs; it grows optimally at 85°C (see **Fig. 19.8A**). *D. mobilis* respires anaerobically by reducing elemental sulfur (S^0) to sulfide (HS^-). Sulfur

Figure 19.8 Hyperthermophilic crenarchaeotes. **A.** *Desulfurococcus mobilis* (shadow EM). **B.** *Ignicoccus islandicus* (TEM). Its unique periplasmic space contains membrane vesicles.

reduction is coupled to oxidizing small organic molecules such as sugars.

Another flagellated coccus, *Ignicoccus islandicus*, has an unusual cell architecture (**Fig. 19.8B**). *Ignicoccus* possesses an outer membrane surrounding its cytoplasmic membrane, with a large periplasmic space between them. The periplasmic space contains membrane-bound vesicles of unknown function. No other species is known to have a periplasmic space containing vesicles. The evolution of this structure, similar to the extra membranes of the bacterial genus *Planctomyces* (see Chapter 18), suggests a model for an intermediate stage of evolution of the eukaryotic nucleus.

Ignicoccus islandicus, unlike *Desulfurococcus*, is a marine organism, growing at temperatures as high as 98°C. It is a lithotroph, oxidizing hydrogen with sulfur:

$$H_2 + S^0 \longrightarrow H_2S$$

Most of the cultured species of Desulfurococcales are obligate anaerobes. An exception is *Aeropyrum pernix*, one of the first archaea whose genome was sequenced. *A. pernix* is an aerobic heterotroph, respiring with O_2 on complex compounds during growth at 70–100°C.

Barophilic hyperthermophiles. The most extreme hyperthermophiles are barophiles adapted to grow near hydrothermal vents at the ocean floor. The high pressure beneath several kilometers of ocean allows water to remain liquid at temperatures above 100°C; the highest known temperature for growth of an organism is 121°C. Isolation and study of such organisms require specialized research apparatus (**Special Topic 19.1**).

A common feature of thermal vents is the **black smoker** (**Fig. 19.9**). A black smoker is a chimneylike structure resulting from the upwelling of seawater superheated by an undersea magma chamber. As in a geyser aboveground, the heated water is forced upward through a small opening. Because the thermal vent is under steam pressure, the water can reach temperatures of over 400°C, enabling it to dissolve high concentrations of minerals such as iron II sulfide (FeS). When the rising water escapes, however, it immediately cools, depositing iron sulfide around the edge of the vent chimney and precipitating iron sulfide particles that cloud the water; hence the term *black smoker*. While no organism can grow at 400°C, various species of archaea are adapted to grow in the range of 100–120°C, where the vent stream meets the seawater and minerals precipitate (**Fig. 19.9B**).

Vent-adapted crenarchaeotes include *Pyrodictium abyssi* (**Fig. 19.10**), *P. occultum*, and *P. brockii*; the latter is named for Thomas Brock of the University of Wisconsin, Madison, a pioneering researcher of hyperthermophiles.

Table 19.3 Hyperthermophilic Crenarchaeota.

Species	Growth temperature (°C)	Growth pH	Cell shape	Metabolism
Aeropyrum pernix	70–100°	pH 5–9	Cocci	O_2 respiration
Desulfurococcus mobilis	78–87°	pH 6	Flagellated cocci	Anaerobic S^0 respiration or fermentation
Ignicoccus islandicus	70–98°	pH 5–7	Flagellated cocci with periplasmic space	Anaerobic lithotrophy, S^0 oxidation of H_2
Thermosphaera aggregans	65–90°	pH 5–7	Flagellated cocci in aggregates	Anaerobic fermentation
Pyrodictium brockii	85–110°	pH 5–7	Disks linked by cannulae	Anaerobic oxidation of H_2 by S^0 or $S_2O_3^{2-}$ or fermentation
Pyrodictium abyssi	80–110°	pH 5–7	Disks linked by cannulae	Anaerobic fermentation
Sulfolobus solfatericus	50–87°	pH 2–4	Irregular cocci	O_2 respiration on S^0, producing H_2SO_4

Figure 19.9 Extreme temperature and pressure: black smoker vents. A. Black smoker vents with steam escaping from "chimneys" of sulfide minerals at the Juan de Fuca Ridge on the ocean floor. **B.** Different parts of the smoker vent system support different classes of archaea.

For energy, *Pyrodictium* species reduce sulfur to H_2S, either with molecular hydrogen or with organic compounds. A membrane-bound sulfur-reducing complex and a proton-translocating ATPase have been isolated from *P. abyssi*. The complexes are extremely heat stable, exhibiting a temperature optimum of 100°C.

Pyrodictium species grow as flat, disk-shaped cells that can be as thin as 0.1 μm. The cells contain a periplasm and outer membrane with an S-layer that is coated with zinc sulfide, presumably precipitated from the vent minerals. The cell disks are interconnected by cytoplasmic extensions called **cannulae**. The cannulae can extend to more than 0.1 mm, forming complex networks of connections (**Fig. 19.10A**); in liquid culture, the networks grow into white balls up to 10 mm in diameter. A thin-section TEM of a *Pyrodictium* cell appears to show that the cannulae bridge the cytoplasm between cells (**Fig. 19.10B**).

What happens when a *Pyrodictium* cell divides? Cells of *P. abyssi* generate new cannulae as they undergo fission (**Fig. 19.11**). Some of the new cannulae form as loops connecting the two daughter cells while simultaneously

Special Topic 19.1 Research on Deep-Sea Hyperthermophiles

To study hyperthermophiles from black smoker vents requires specialized equipment and methods. The isolation of such organisms is a challenge because their habitats endanger our own survival. Undersea vent systems must be approached by a special submersible device with a robotic arm. An example is the Environmental Sample Processor from the Monterey Bay Aquarium Research Institute (**Fig. 1**). The robotic system samples temperature and other properties of fluid emerging from a black smoker hydrothermal vent. It can then sample organisms for study. An advanced version of this device can actually process the organism's DNA. Thus, the DNA can be obtained from vent-adapted microbes that could not survive transfer to a laboratory at sea level. The robotic sample processor is supported by NASA as a model for a future space probe to explore one of Jupiter's satellites, Europa, considered a possible source of extraterrestrial life.

Engineer Gene Massion, from the Monterey Bay Aquarium Research Institute, deploys the submersible Environmental Sample Processor with robotic collection arm at an ocean site off the coast of Maine. *Source*: Courtesy of Monterey Bay Aquarium Research Institute.

Organisms that do survive transport to sea level must nonetheless be maintained at high pressure and temperature to ensure viability. In the laboratory, all devices for microscopy and cultivation (if possible) must also be maintained under pressure and at high temperature. **Figure 2A** shows a microscope system with a high-temperature and high-pressure cell installed, from the Marine-Earth Data and Information Department of the Japan Agency for Marine-Earth Science and Technology. Organisms are cultured in a pressurized cell such as the Deep Aquarium (**Fig. 2B**). The culture must be provided with reduced minerals and gases needed for growth of vent microbes.

pushing the two cells apart. In this fashion, the cell division process expands the cell network.

NOTE: Two genera of vent thermophiles have similar names but only distant genetic relatedness: *Pyrodictium abyssi*, a crenarchaeote, and *Pyrococcus abyssi*, a euryarchaeote.

The intricate cell network of *P. abyssi* is an example of a single-species biofilm. Other forms of single-cell and multicellular biofilms are found at hydrothermal vents. *Thermosphaera aggregans* forms colonies so tightly bound that they cannot be dissociated by protease treatment or sonication (**Fig. 19.12A**). Biofilms of other unidentified hyperthermophiles line the chimneys of black smoker vents (**Fig. 19.12B**).

THOUGHT QUESTION 19.2 What might be the advantages of flagellar motility for a hyperthermophile living in a thermal spring or in a black smoker vent? What would be the advantages of growth in a biofilm?

Sulfolobales: High Temperature and Extreme Acid

The crenarchaeote order Sulfolobales includes species that respire by oxidizing sulfur (instead of reducing it, like *Desulfurococcus*). These organisms, such as *Sulfolobus* species, grow at 80–90°C within hot springs and solfateras (volcanic vents that emit only gases). Ken Stedman and colleagues at Portland State University study *Sulfolobus solfatarious*, a species that grows at 80°C and pH 3 (**Fig. 19.13**). *S. solfataricus* oxidizes H_2S to sulfuric acid:

$$2S^0 + 3O_2 + 2H_2O \longrightarrow 2H_2SO_4 \longrightarrow 4H^+ + 2SO_4^{2-}$$

As a result of sulfuric acid production, the pH of the organism's surroundings falls to pH 2–3, effectively excluding all but acidophiles. While other archaea grow at higher temperatures (up to 120°C) or lower pH (below pH 0), *Sulfolobus* is of interest as a "double extremophile," requiring both high temperature and extreme acidity simultaneously.

Sulfolobus cells have a membrane composed mainly of tetraethers with cyclopentane rings (see **Fig. 19.2E**). Tetraether membranes are commonly seen in acidophilic thermophiles, probably because they are exceptionally impermeable to protons. Remarkably, *Sulfolobus* has no cell wall, only an S-layer of glycoprotein (**Fig. 19.14A**). Like all archaea, these organisms are nonpathogenic to animals and plants, yet they secret toxins deadly to competitor strains of *Sulfolobus*.

Sulfolobus species are not obligate autotrophs; they can also grow heterotrophically on sugars or amino acids. In fact, many species are easily cultured in tryptone broth at 80°C, pH 3. Their internal pH is typically pH 6.5; thus, they maintain more than three units of pH difference across their membrane. The full metabolic potential of this organism is revealed by annotation of its genome, which reveals homologs of sugar and amino acid transporters as well as the non-ATP-forming Entner-Doudoroff pathway of glucose catabolism. Genes are present for enzymes to oxidize HS^- and $S_2O_3^{2-}$ as well as S^0. The main redox carrier for respiration appears to be ferredoxin (instead of NADH, which is relatively unstable at high temperature).

Image courtesy of Ken Stedman

Figure 19.13 Isolating *Sulfolobus* from Yellowstone. A researcher holds a collecting tube at length to obtain samples from a steaming spring, Rabbit Creek, at Yellowstone National Park.

THOUGHT QUESTION 19.3 What problem with cell biochemistry is faced by acidophiles that conduct heterotrophic metabolism?

Because *Sulfolobus* species are readily cultured, their metabolism and ecology have been studied extensively, revealing unexpected features. Some species show multiple origins of replication of their DNA; for example, *S. solfataricus* and *S. acidocalderius* each use three active replication origins. The presence of multiple origins in some archaea may be related to the closer affinity of archaeal DNA management to that of eukaryotes.

Another interesting discovery was that of archaeal viruses. *Sulfolobus* species are attacked by fuselloviruses, the best-studied class of archaeal viruses to date (**Fig. 19.14B**). Fuselloviruses generally resemble bacteriophages

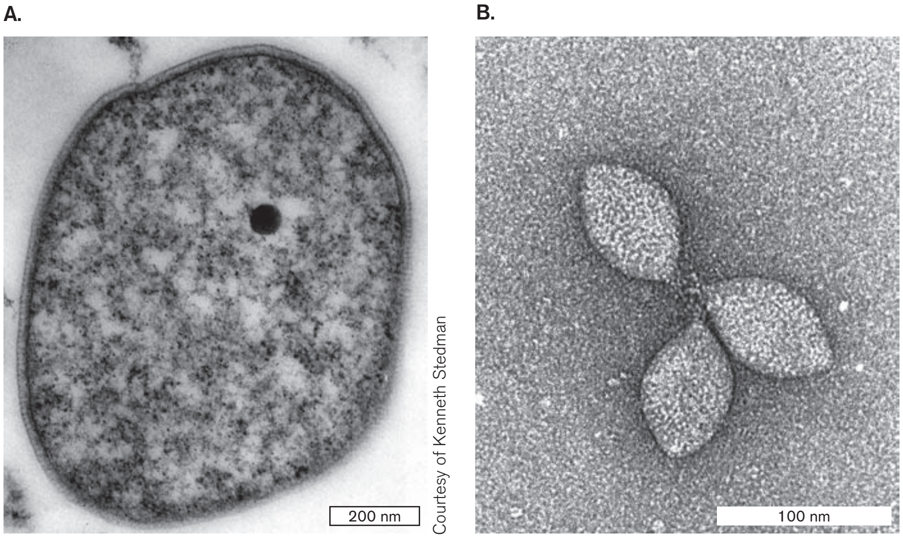

Figure 19.14 ***Sulfolobus.***

Stedman, et al. 2003. *Research in Microbiology* 154:295

in size and function, but their capsid is spindle-shaped, forming a cone at each end. Spindle-shaped capsids are common in archaeal viruses, but never seen in bacteriophages. Since the discovery of fuselloviruses, numerous other archaeal viruses have been discovered in high-temperature environments, including icosahedral, tailed, and filamentous forms. All have in common genomes consisting of double-stranded DNA. This suggests that only double-stranded DNA is stable enough for virus particles to persist at high temperature. Viruses of mesophilic archaea are only beginning to be explored.

THOUGHT QUESTION 19.4 What conclusions might be drawn if viruses of mesophilic archaea are found to have RNA genomes? What if they all have DNA genomes only?

Other Thermophilic Crenarchaeotes

The class Thermoprotei includes two other orders of thermophiles (as well as mesophiles and psychrophiles; see next section). Caldisphaerales is an order of thermoacidophiles first isolated from a Philippine hot spring at Mount Maquiling. Members of Caldisphaerales, such as *Caldisphaera*, typically grow at pH 3 up to 80°C. Unlike *Sulfolobus* species, *Caldisphaera* species are anaerobes or microaerophiles, tolerating only low concentrations of oxygen. They grow by fermentation or anaerobic respiration. Another order, **Thermoproteales**, includes hyperthermoacidophiles isolated from marine vents. *Thermoproteus* species grow up to 97°C at pH values lower than pH 3. Their rod-shaped cells are less than 0.3 μm in length, one of the smallest cell types known. Their metabolism is autotrophic, gaining energy by reducing sulfur with H_2 to H_2S. A related species, *Pyrobaculum islandicum*, grows in temperatures up to 103°C, although at less acidic pH (pH 5–7). New thermophilic crenarchaeotes continue to be discovered.

TO SUMMARIZE:

- **Crenarchaeol** is a tetraether containing a six-membered ring, found in varying amounts in all known species of the division Crenarchaeota.
- **Habitats for hyperthermophiles** include hot springs and submarine hydrothermal vents. Vent organisms are barophiles as well as thermophiles.
- **Desulfurococcales includes diverse thermophiles.** Most are anaerobes that use sulfur to oxidize hydrogen or organic molecules.
- ***Pyrodictium* species show unusual networked cells.** Disk-shaped cells are interconnected by cytoplasmic bridges called cannulae.
- **Sulfolobus species are aerobic thermoacidophiles.** *Sulfolobus* species oxidize sulfur to sulfuric acid or catabolize organic compounds.
- **Caldisphaerales and Thermoproteales include anaerobic hyperthermophilic acidophiles.**

19.3 Crenarchaeota: Mesophiles and Psychrophiles

For two decades, crenarchaeotes were thought to be largely restricted to high temperatures. In 1992, however, fluorescent DNA probes based on rRNA sequences revealed mesophilic archaea growing throughout the ocean. Edward DeLong and colleagues first found archaea in the Pacific Ocean off the coast of North America; a survey in 2001 of marine archaea at the Hawaii Time-Series Station found high numbers of crenarchaeotes (**Fig. 19.15**). The abundance of crenarchaeotes varied according to season

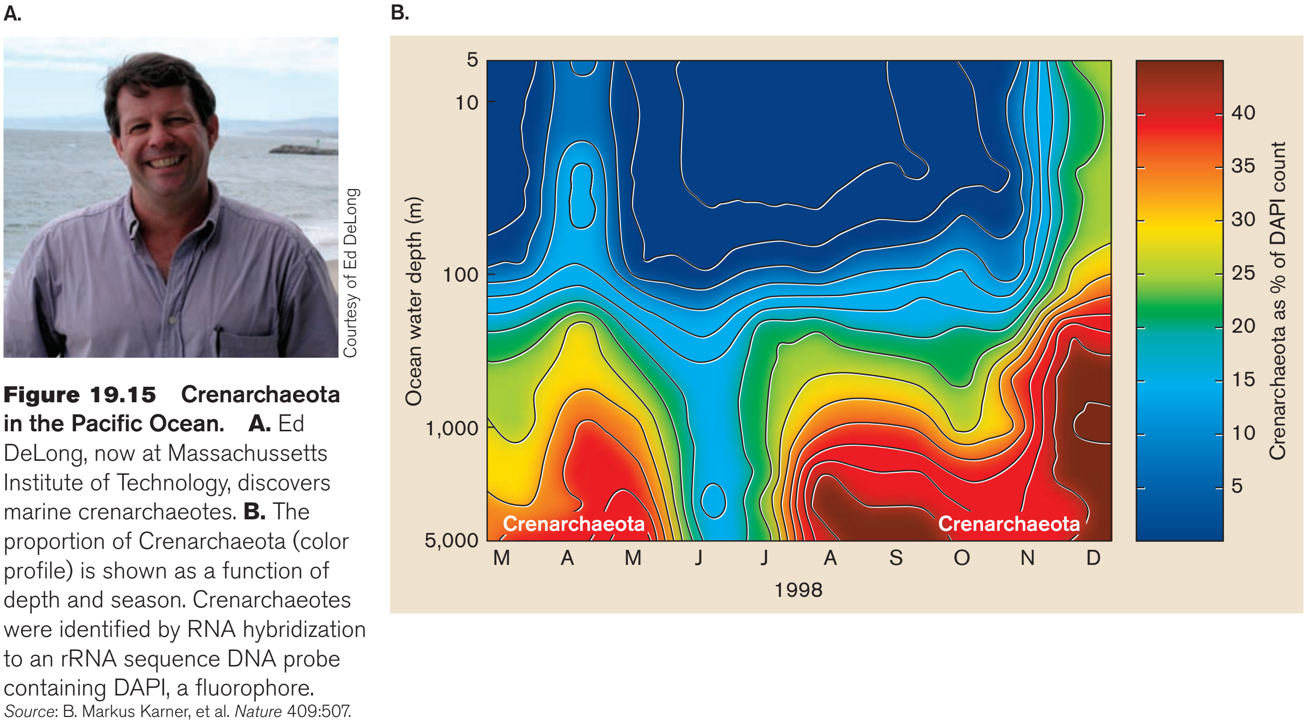

Figure 19.15 Crenarchaeota in the Pacific Ocean. **A.** Ed DeLong, now at Massachussetts Institute of Technology, discovers marine crenarchaeotes. **B.** The proportion of Crenarchaeota (color profile) is shown as a function of depth and season. Source: B. Markus Karner, et al. *Nature* 409:507.

and increased with depth, typically comprising 40% of the total microbial population at depths of 1,000 m, where temperatures are cold. The high proportion of ribosomal RNA in these cells indicates that they are metabolically active, even at the relatively cold temperatures of the ocean. These uncultivated mesophiles and psychrophiles are probably the predominant species of Crenarchaeota on Earth. In addition, crenarchaeotes are now known to be present in many dryland environments as well, including soil and the surfaces of plant roots.

Psychrophilic Crenarchaeotes

Some of the psychrophilic crenarchaeotes found by DeLong and colleagues exhibit a remarkable symbiosis with marine animals such as the sponge (**Fig. 19.16**). The crenarchaeote *Cenarchaeum symbiosum* inhabits the sponge *Axinella mexicana* (**Fig. 19.16B**). Like other marine crenarchaeotes, *C. symbiosum* has yet to be grown in pure culture in the laboratory. The contributions of the microbe to its sponge host are unknown, but the sponge and its symbiotic crenarchaeotes can be cocultured in an aquarium for many years.

Even colder habitats were explored by Alison Murray and colleagues at the Desert Research Institute, who found psychrophilic crenarchaeotes growing in sea ice off Antarctica (**Figs. 19.17** and **19.18**). Archaea and bacteria were collected from ice and seawater at a temperature of –1.8°C; the water remains liquid below zero because of the high salt concentration. Cells were concentrated by filtration, and concentrated samples were analyzed to quantify the number of cells and classify them. The microbes collected were identified based on fluorescence microscopy using probes of PCR-amplified rDNA, revealing both bacteria and archaea. Typically, 20% of the isolates are crenarchaeotes; occasional euryarchaeotes are found as well.

Figure 19.18 **Identifying Antarctic psychrophiles.** **A.** Antarctic psychrophiles are observed by epifluorescence microscopy, with DAPI stain for DNA. The small spherical cells are approximately 0.5 μm in diameter. **B.** DNA of a psychrophilic archaeon is isolated and genes are identified. Microarray hybridization identifies which genes are turned on (expressed) or turned off (not expressed).

Most psychrophilic crenarchaeotes remain uncultivated, but the new technologies of genomics and micromanipulation now make it possible to study uncultivated organisms. The DNA of a single cell taken directly from the field can be amplified by PCR to generate a DNA library for genomic sequencing. Microarrays show which genes are expressed in these organisms and provide insights as to the molecular basis of life at cold temperatures.

Yet another important psychrophilic environment is the marine benthos, or seafloor sediment. At temperatures of about 2°C, seafloor strata show crenarchaeotes that are anaerobic heterotrophs, sulfate reducers, and anaerobic methanotrophs (methane oxidizers). Methanotrophs are particularly crucial in recycling the methane produced by seafloor methanogens (euryarchaeotes, discussed in Section 19.4).

Ammonia-Oxidizing Crenarchaeotes Affect Global Nitrogen

From a global standpoint, the most significant crenarchaeotes discovered recently may be the marine ammonia oxidizers of the order Nitrosopumilales. The first known ammonia-oxidizing crenarchaeote, *Nitrosopumilus maritimus*, was isolated from a marine aquarium in 2005 by David Stahl and colleagues at the University of Washington, Seattle. The organism gains energy by aerobically oxidizing ammonia to nitrite:

$$2NH_3 + 3O_2 \longrightarrow 2NO_2^- + 2H_2O + 2H^+$$

In 2006, Ann Pearson and colleagues from Harvard University and Scripps Institution of Oceanography showed that crenarchaeote ammonia oxidizers are widespread throughout the oceans. They are also common in soil. Ammonia-oxidizing crenarchaeotes fix carbon dioxide as well as ammonia, thus potentially making a substantial contribution to global cycles of carbon and nitrogen.

TO SUMMARIZE:

- **Oceans, soil, plant roots, and animals** provide habitats for mesophilic and psychrophilic crenarchaeotes.
- **Psychrophiles in marine sediment** play a key role in recycling methane hydrates produced by methanogens.
- **Ammonia-oxidizing crenarchaeotes** contribute to global nitrogen cycling.

19.4 Euryarchaeota: Methanogens

The second major branch of known archaea is Euryarchaeota, the "broad-ranging archaea" (**Table 19.2**). The euryarchaeotes are dominated by the **methanogens**, a vast array of species that derive energy through reactions producing methane. Biogenic methane has actually been observed since 1776, when the Italian priest Carlo Campi and physicist Alessandro Volta (1745–1827) investigated bubbles of "combustible air" from a wetland lake. Volta wrote:

> Being in a little boat on Lake Maggiore, and passing close to an area covered with reeds, I started to poke and stir the bottom with my cane. So much air emerged that I decided to collect a quantity in a large glass container. . . . This air burns with a beautiful blue flame.

Volta noted that methane arose from wetlands containing water-saturated decaying plant material. In 1882, the German medical researcher Hermann Von Tappeiner (1847–1927) combined plant materials with ruminant stomach contents (a source of methanogens) and showed that both components were essential to produce methane. During the late nineteenth century, in England, methane was collected from manure and sewage and used as a fuel for streetlamps.

Methanogens: Different Paths to Methane

Different species generate methane from different substrates, such as CO_2 and H_2 or small organic compounds, generally fermentation products of bacteria. Each pathway of methanogenesis generates a small free energy change ($\Delta G^{\circ\prime}$) that is just enough to drive processes of carbon fixation and biosynthesis. All types of methanogenesis are poisoned by molecular oxygen and therefore require extreme anaerobiosis. Major substrates and reactions include:

Carbon dioxide: $CO_2 + 4H_2 \longrightarrow CH_4 + 2H_2O$

Formic acid: $4CHOOH \longrightarrow CH_4 + 3CO_2 + 2H_2O$

Acetic acid: $CH_3COOH \longrightarrow CH_4 + CO_2$

Methanol: $4CH_3OH \longrightarrow 3CH_4 + CO_2 + 2H_2O$

Methylamine:
$4CH_3NH_2 + 2H_2O \longrightarrow 3CH_4 + CO_2 + 4NH_3$

Dimethyl sulfide:
$2(CH_3)_2S + 2H_2O \longrightarrow 3CH_4 + CO_2 + 2H_2S$

In CO_2 reduction, the most common form of methanogenesis, carbon dioxide plus molecular hydrogen combine to form water and methane. CO_2-reducing methanogens are autotrophs, growing solely on CO_2 and H_2 with a source of nitrogen and other minerals. Methanogenesis from other carbon sources, such as formate, acetate, or methanol, is heterotrophic, and generates CO_2 as a product in addition to methane. The nitrogen-containing substrate methylamine generates ammonia in addition to methane and CO_2, whereas the sulfur-containing substrate dimethyl sulfide generates hydrogen sulfide.

Note that only a narrow range of substrates supports methanogenesis. For unknown reasons, most methanogens lack the vast array of alternative pathways found in soil bacteria such as *Rhodopseudomonas* or *Streptomyces*. Thus, methanogens generally require close association with bacterial partners to provide their substrates. They usually grow in habitats with minimal resource flux, where hydrogen and carbon dioxide gases can be trapped for their use. Removal of these gases then enhances bacterial metabolism. This kind of metabolic partnership is called "syntrophy."

Many kinds of methanogens can be cultured in the laboratory. Their culture poses special challenges because the reactions of methanogenesis are halted by oxygen. To exclude oxygen, all growth and manipulation of cultures must be performed in an anaerobic chamber. Furthermore, methanogens that use CO_2 and H_2 as substrates must receive a steady supply of these gases. Even more challenging is the culture of hyperthermophilic methanogens, such as *Methanopyrus*, a vent hyperthermophile that grows at 98°C. For these organisms, both high temperature and high pressure must be maintained.

Thermophiles, mesophiles, and psychrophiles. Methanogens include four classes, of which five major orders are shown (**Table 19.4**). The amount of divergence within an order can be nearly as great as that between orders. Particularly striking is the wide range of growth temperatures among closely related species. Thermophiles and even hyperthermophiles branch from closely related mesophiles; for example, the order Methanobacteriales includes *Methanobrevibacter ruminantium* (37–39°C), *Methanobacterium thermoautotrophicum* (50–75°C), and *Methanothermus fervidus* (60–97°C).

Methanogens Show Diverse Cell Forms

Despite their metabolic similarity, methanogens display an astonishing diversity of form, perhaps as diverse as the entire domain of bacteria (**Fig. 19.19**). For example, *Methanocaldococcus janaschii* cells grow as cocci with numerous flagella attached to one side, while *Methanosarcina barkeri* form peach-shaped cocci lacking flagella. *Methanothermus fervidus* cells are short, fat rods without flagella, and

Table 19.4 Methanogens.

Representative species	Growth temperature (°C)	Growth pH	Cell shape	Substrates for methanogenesis
Methanobacteriales				
Methanobrevibacter ruminantium	37–39°	pH 6–9	Chains of short rods	H_2 and CO_2
Methanobacterium thermoautotrophicum	50–75°	pH 7–8	Filaments of long rods	H_2 and CO_2, formate
Methanothermus fervidus	60–97°	pH 6–7	Rods	H_2 and CO_2
Methanosarcinales				
Methanosarcina barkeri	20–50°	pH 5–7	Aggregates of cocci	H_2 and CO_2, methanol, methylamine, acetate
Methanosaeta concilii	10–45°	pH 6–8	Filaments of rods	Acetate
Methanohalophilus zhilinae	45°	pH 8–10	Cocci	Methanol, methylamine, dimethyl sulfide
Methanococcales				
Methanococcus vaniellii	20–40°	pH 7–9	Cocci with flagella	H_2 and CO_2
Methanocaldococcus jannaschii	48–94°	pH 6–7	Cocci with flagella	H_2 and CO_2
Methanomicrobiales				
Methanoculleus olentangii	30–50°	pH 6–8	Cocci	Acetate, complex nutrients
Methanospirillum hungatei	20–45°	pH 6–7	Spirillum	Acetate
Methanopyrales				
Methanopyrus kandleri	84–110°	pH 6–8	Long rods (2–14 μm)	H_2 and CO_2

Sallis, et al. 2003. *Bioresource Technology* 89:255

Figure 19.19 **Methanogens show a wide range of shapes.** **A.** *Methanosarcina barkeri*, a lobed coccus form lacking flagella (TEM). **B.** *Methanothermus fervidus*, a short bacillus (SEM). **C.** *Methanobacterium thermoautotrophicum*, an elongate bacillus (SEM).

Methanobacterium thermoautotrophicum grows as elongate rods reminiscent of the bacterial genus *Bacillus*. Still others, such as *Methanospirillum hungatei*, form wide spirals. The morphological diversity of methanogens may be explained in part by their rigid cell walls that can maintain a distinctive shape.

The composition of methanogen cell walls is much more diverse than those of bacteria. *Methanobacterium* species have a cell wall composed of pseudopeptidoglycan, a structure in which chains of alternating amino sugars are linked by peptide cross-bridges analogous to those of peptidoglycan. On the other hand, *Methanosarcina* species have a cell wall composed of sulfated polysaccharides. The genera *Methanomicrobium* and *Methanococcus* have protein cell walls.

Filamentous methanogens form chains of large cells similar to those of filamentous cyanobacteria. Filamentous methanogens, such as *Methanosaeta*, perform a key function in the treatment of sewage waste (**Fig. 19.20**). In waste treatment, the raw sewage first undergoes aerobic respiration by bacteria, converting the organic materials to small molecules such as CO_2 and acetate, followed by anaerobic digestion of the remainder. The bacteria performing anaerobic decomposition become trapped in filaments of *Methanosaeta*, which convert bacterial fermentation products such as acetate into methane and CO_2. The methanogenic filaments serve a key function by trapping bacteria into granules that settle out from the liquid.

Anaerobic Habitats for Methanogens

Methanogens grow in soil, in animal digestive tracts, and in marine floor sediment. A major methanogenic environment is the anaerobic soil of wetlands (**Fig. 19.21A**). The wetlands that generate the most methane are typically disturbed or artificial wetlands, particularly rice paddies, which contain high levels of added fertilizer that bacteria convert to the substrates used by methanogens. From the standpoint of the organism, methane is an incidental by-product, but this product has great significance for our biosphere as a greenhouse gas (discussed in Chapter 22).

Methanogenesis in soil and landfills. Chinese farmers have found that one way to decrease methane production is to drain the soils used for rice production. Changsheng Li and colleagues at the University of New Hampshire showed in experimental plots that drained soil produces less methane. The drained soil receives more oxygen, which blocks methanogenesis. Draining soil also stimulates rice root development and accelerates decomposition of organic matter in the soil to release nitrogen. Sufficiently dry rice paddy soil can actually become a sink for atmospheric methane, thanks to methane-oxidizing bacteria.

Another major source of methanogens is landfills (**Figs. 19.21B** and **C**). Landfills such as those outside New York City are among the largest structures on Earth made by humans. They are rich in organic wastes, which bacteria ferment to CO_2, H_2, and short-chain organic molecules that methanogens convert to methane. As a result, large amounts of gas can build up and spontaneously combust, causing explosions. To avoid explosions, the methane needs to be piped out. In some cases, as in the Los Reales landfill in Tucson, Arizona, it can be collected and used to generate electricity.

Figure 19.21 Terrestrial habitats for methanogens. A. Chinese farmers plant rice in waterlogged soil, an ideal anaerobic habitat for methanogens. **B.** The Puente Hills Landfill Gas Recovery Facility in California. Methane gas from the landfill is burned to generate electricity. **C.** Methane gas from a landfill near Kearny, New Jersey, is pumped through a series of pipes and recovery wells.

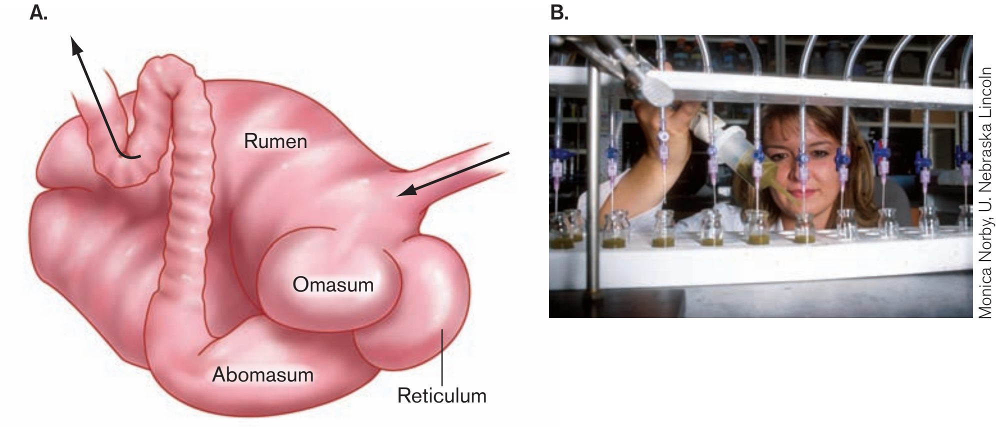
Digestive methanogenic symbionts. Numerous methanogens also grow within the digestive fermentation chambers of animals such as termites and cattle (**Fig. 19.22A**; discussed in Chapter 21). Termites have to aerate their mounds continually in order to remove methane; when a rainfall temporarily clogs the mound, it can be ignited by lightning and explode. Cattle support methanogenesis within their rumen and reticulum; a common veterinary trick is to insert a cannula and light a flame on the escaping gas. Bovine methanogenesis diverts carbon from meat production, and it makes a significant contribution to global methane.

Research on rumen microbiology focuses on attempts to suppress growth of methanogens. For example, Steven Ragsdale and his graduate student Bree DeMontigny at the University of Nebraska, Lincoln, test potential chemical inhibitors of methanogenesis on samples of rumen fluid (**Fig. 19.22B**). The rumen fluid is maintained in vials that serve as artificial rumens. The artificial rumens allow researchers to assess how well the proposed methane-blocking compounds might perform in an actual bovine rumen.

Human digestion. Recent research reveals key contributions of methanogens to human digestion. Most humans test positive for methanogens, primarily the species *Methanobrevibacter smithii* and *Methanosphaera stadtmanae*. These archaea constitute about 10% of gut anaerobes. *M. smithii* increases the efficiency of digestion by consuming excess reduced products (formate and H_2) from bacterial mixed-acid fermentation (discussed in Chapter 13). High levels of H_2 inhibit bacterial NADH dehydrogenases and thus decrease the proton potential for ATP production. *M. stadtmanae* consumes methanol, a potentially toxic byproduct of bacterial degradation of pectin, a major fruit polysaccharide. Thus, methanogens may enhance the growth of human enteric bacteria.

If methanogens influence the fermentation efficiency of gut flora, do they affect the amount of caloric content

Figure 19.22 Methane production in the bovine rumen. A. Methanogens grow with the community of fermentative bacteria in the rumen and reticulum of ruminating animals. **B.** Bree DeMontigny, a graduate student in animal science working with Steven Ragsdale, pipets rumen fluid samples into vials that serve as "artificial rumens." The vials will be incubated and then assayed for the amount of methane formed.



Monica Norby, U. Nebraska Lincoln

we obtain from food? In 2006, Buck Samuel and Jeffrey Gordon at Washington University, St. Louis, conducted an experiment to test the effect of methanogenesis on energy balance in gnotobiotic (germ-free) mice. The gnotobiotic mice were colonized with *Bacteroides thetaiotaomicron*, an anaerobic bacterium that ferments complex polysaccharides from the plants we consume. The mice were colonized in the presence or absence of *M. smithii*, which consumes H_2 through methanogenesis. Mice colonized with both *B. thetaiotaomicron* and *M. smithii* were found to make more fat after consuming the same quantity of food as those colonized solely with *B. thetaiotaomicron*. This result is in contrast with the case of the bovine rumen, in which methanogenesis draws off so much carbon as to decrease fermentation efficiency. The results suggest interesting hypotheses for future study of weight control in humans.

Figure 19.23 Methane hydrate. A crystalline form of methane and water generated by benthic methanogens; a potential source of fuel.

Methane hydrates on the seafloor. Psychrophilic marine methanogens grow at or beneath the seafloor. These seabed methanogens generate large volumes of methane that seep up slowly from the sediment. Under the great pressure of the deep ocean, the methane becomes trapped as **methane gas hydrates**, which are crystalline materials in which methane molecules are surrounded by a cage of water molecules (**Fig. 19.23**). The methane hydrates accumulate in vast quantities. If a large part of this methane were to be released, it could greatly accelerate global warming.

Methane hydrates are also of interest as a potential source of fuel to be mined for the generation of electricity.

Biochemistry of Methanogenesis

With all the roles that methanogens play in our environment and in human digestion, much effort goes into better understanding of how methanogenesis works. Knowledge of methanogenic biochemistry may help us develop controls for these processes, such as methanogen-specific antibiotics to minimize methane output from cattle.

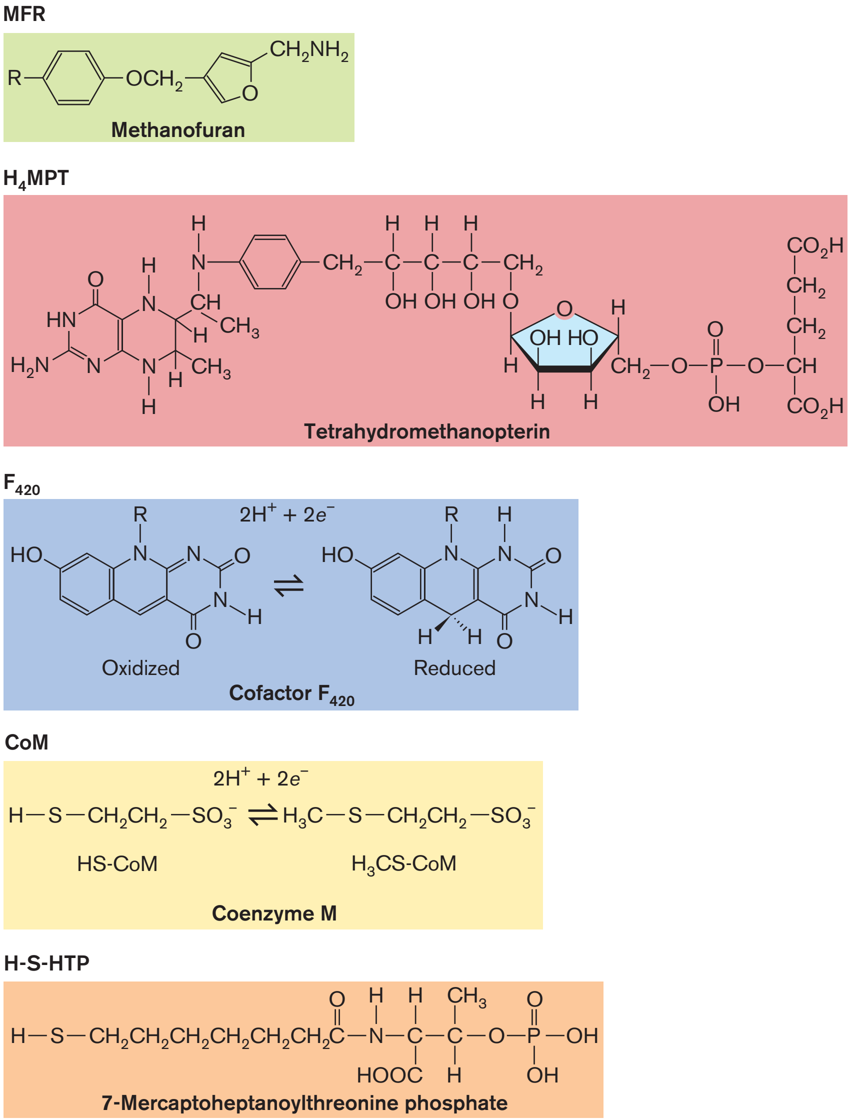

Figure 19.24 Cofactors for methanogenesis. Cofactors specific for methanogenesis transfer the hydrogens and the increasingly reduced carbon to each enzyme in the pathway.

Cofactors for methanogenesis. The process of methanogenesis uses a series of specific cofactors to carry each carbon from CO_2 (or other substrates) as it becomes progressively reduced by hydrogen. The hydrogen atoms also require redox carriers. Most of the cofactors are unique to methanogens, although the general types of structure resemble redox cofactors we have seen in Chapter 14 (**Fig. 19.24**). For example, cofactor F_{420} is a heteroaromatic molecule (containing nitrogens in the aromatic rings) that undergoes a redox transition by acquiring or releasing two hydrogens, a transition similar to that of the nicotinamide ring of NADH. HS-coenzyme M plays a role similar to that of HS-CoA.

Methanogenesis from CO_2. The formation of methane from CO_2 and H_2 (**Fig. 19.25**) is technically a form of anaerobic respiration in which H_2 is the electron donor and CO_2 is the terminal electron acceptor (discussed in Chapter 14). The process fixes CO_2 onto the cofactor methanofuran (MFR), then passes the carbon stepwise from one cofactor to the next, each time losing an oxygen to form water or gaining a hydrogen carried by another cofactor.

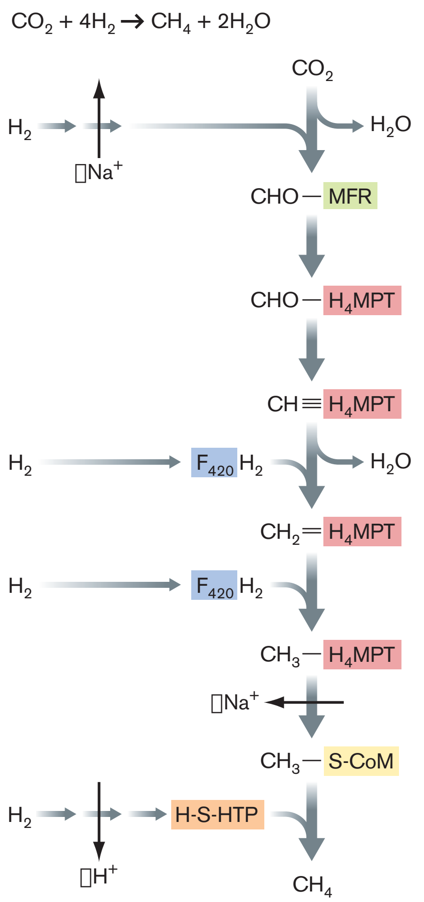

Figure 19.25 Methanogenesis from CO_2 and H_2. Carbon dioxide is hydrogenated and deoxygenated in a stepwise fashion. The initial incorporation of H_2 requires a coupled sodium potential (□Na^+). A later step generates proton potential (□H^+). All steps of the reaction require specific enzymes (not shown).

The first step in the conversion of CO_2 and H_2 to methane is fixing the carbon onto methanofuran (see **Fig. 19.25**). This requires placement of protons onto the oxygen to form water. The flow of protons may be coupled to the transmembrane gradient of sodium ion, which is required for this step. Most methanogens require Na^+ for growth, unlike bacteria, many of which can grow without sodium. A higher external Na^+ concentration provides a sodium potential (□Na^+) that drives the two steps of methanogenesis. The sodium requirement of methanogens is something they share with another division of Euryarchaeota, the halophiles (discussed in Section 19.5).

Another important feature of methanogenesis is that the enzymes that catalyze each step require several transition metals. For example, the hydrogenase that reduces F_{420} requires both nickel and iron. The enzyme that catalyzes the reaction

$$CO_2 + \text{methanofuran} + 3H \longrightarrow \text{CHO-methanofuran} + H_2O$$

requires either molybdenum or tungsten, depending on the species; some species have two alternative enzymes, depending on which metal is available. Another metal, cobalt, is required for a B_{12}–related cofactor that participates in methane production from methanol and methylamines.

THOUGHT QUESTION 19.5 What do the multiple metal requirements suggest about the evolution of methanogens?

Methanogenesis from acetate. Methane production from acetate is particularly important for wastewater treatment, where most of the substrate consists of short-chain bacterial fermentation products. The acetate methanogenesis pathway is not fully understood, but the initial incorporation of H_2 probably requires a coupled gradient of sodium ion, as it does for CO_2 methanogenesis. The two carbons from acetate enter different pathways, which eventually converge:

$$CH_3\text{-S-CoM} + \text{H-S-HTP} \longrightarrow CH_4 + \text{CoM-S-S-HTP}$$

TO SUMMARIZE:

- **Methanogens gain energy through redox reactions that generate methane** from CO_2 and H_2, formate, and acetate. They require association with bacterial species that generate the needed substrates.

- **Methanogens have rigid cell walls of diverse composition in different species**, including pseudopeptidoglycan, protein, and sulfated polysaccharides.
- **Species of methanogens show a wide range of different shapes**, including rods (single or filamentous), cocci (single or clumped), and spirals.
- **Methanogens inhabit anaerobic environments** such as wetland soil, marine benthic sediment, and animal digestive organs.
- **Biochemical pathways of methanogenesis** involve transfer of the increasingly reduced carbon to cofactors that are unique to methanogens.

19.5 Euryarchaeota: Halophiles

In the saturated salt water of Utah's Great Salt Lake or Israel's Dead Sea, swimmers float with their heads well above the dense brine; but few living things can grow (**Fig. 19.26**). The main inhabitants of high salt environments are extremely halophilic archaea, or **haloarchaea**. Most haloarchaea are members of **Halobacteriales**, an order that was named before the archaea were classified as distinct from bacteria. The order Halobacteriales includes species of haloarchaea that diverge among the methanogens (see **Fig. 19.5**). The halophiles, however, do not conduct methanogenesis, but grow as photoheterotrophs, using light energy to drive a retinal-based ion pump to establish a proton potential. Their photopigments color salterns, brine pools evaporated to mine salt (**Fig. 19.27**).

The halophilic archaea require at least 1.5 M NaCl or equivalent ionic strength, and most grow optimally at near saturation (about 4.3 M, seven times the concentration of seawater). Most are colored red by bacterioruberin, which protects cells from damage by light (**Fig. 19.28**). Thus, their growth colors their habitat red.

Alison Wright

Figure 19.26 A high-salt environment. A swimmer floats with her head up in the highly concentrated brine of the Dead Sea, in Israel.

Haloarchaeal Form and Physiology

Halophilic microbes need some way to maintain turgor pressure—that is, to avoid cell shrinkage as cytoplasmic water runs down the osmotic gradient toward external high salt. Most bacterial halaophiles compensate for high external salt by uptake or synthesis of other kinds of osmolites, such as small organic molecules. Haloarchaea,

however, adapt to high external NaCl by maintaining a high intracellular concentration of potassium chloride (about 4 M KCl). Potassium ion concentrations are moderately high in most microbial cells (commonly 200 mM), but the exceptionally high KCl concentration within haloarchaea requires major physiological adaptations:

- **High GC content of DNA.** High salt concentration decreases the fidelity in base pairing of DNA. Because the triple hydrogen bonds of GC pairs hold more strongly, the exceptionally high GC content of haloarchaea (above 60% for most species) may protect their DNA from denaturation in high salt.
- **Acidic proteins.** Most haloarchaeal proteins are highly acidic, with an exceptional density of negative charges at their surface. The high negative charge maintains a layer of water in the form of hydrated potassium ions (K^+). This unusual hydration layer keeps the acidic proteins soluble in the high salt in the cytoplasm.

The high salt content of haloarchaea provides a convenient way to lyse cell contents for analysis: Simply transfer cells into low-salt buffer, and they fall apart owing to osmotic shock. This technique provides a quick way for beginning students to isolate DNA. This and other techniques have made the organism *Halobacterium* a model system for molecular biology education (**Special Topic 19.2**).

The properties of diverse halophiles are presented in **Table 19.5**. The haloarchaea are generally uniform with respect to temperature range (mesophilic). With respect to pH, two categories are found: halophiles that grow at neutral pH and those that are alkaliphiles, growing in soda lakes above pH 9.

With respect to cell shape, haloarchaea display considerable diversity. Some species form symmetrical rods, as in *Halobacterium* NRC-1, the model system studied by Shiladitya DasSarma and colleagues at the University of Maryland. Other species form pleomorphic cells, flattened like pancakes; and still others form regular cocci (*Haloferax*, **Fig. 19.29A**). A few species grow as flattened

Table 19.5 **Haloarchaea.**

Representative species	NaCl range (M)	Growth temperature (°C)	Growth pH	Cell shape	Location of isolate
Halobacterium salinarum	3.0–5.2	35–50°	pH 7	Rods	Salted cow hide
Halorubrum lacusprofundi	1.5–5.2	1–44°	pH 7	Long rods (12 μm)	Deep Lake, Antarctica
Haloarcula valismortis	3.5–4.3	40°	pH 7.5	Pleomorphic rods	Salt pools, Death Valley, CA
Haloarcula quadrata	2.7–4.3	53°	pH 7	Square flat; pleomorphic	Sabkha, Sinai, Egypt
Halococcus morrhuae	2.5–5.2	30–45°	pH 7	Cocci	Dead Sea, Israel
Haloferax volcanii	1.5–5.2	40°	pH 7	Pleomorphic flat	Dead Sea, Israel
Natronobacterium gregoryi	2.5–5.2	37°	pH 9.5	Rods	Lake Magadi, Kenya
Natronococcus occultus	1.4–5.2	30–45°	pH 9.5	Cocci	Lake Magadi, Kenya
Natronomonas pharaonis	2.0–5.2	45°	pH 9–10	Rods	Wadi Natrun, Egypt

Special Topic 19.2 Haloarchaea in the High School Classroom

A halophilic archaeon, *Halobacterium* NRC-1, has found surprising applications as a teaching tool for precollege education. Teaching microbiology and biotechnological concepts has become crucially relevant at all grade levels. Microbes relate to many precollege content areas, including hygiene, food production and preservation, environmental science, genetics, and biotechnology. But many of the bacteria traditionally used by educators are reported to cause occasional illness in immunocompromised individuals, such as children with diabetes. Archaea such as *Halobacterium* have never caused a documented illness in humans.

Halobacterium has further advantages for education. It grows readily at room temperature on inexpensive broth medium supplemented with concentrated NaCl, which excludes most contaminants. It produces attractive colonies with mutants that show interesting color phenotypes (**Fig. 1**). And its cells lyse readily in water for instant extraction of DNA as well as other cellular components, such as gas vesicles and purple membrane.

For use in high schools, teachers require training and a kit of materials and instructions. Educator Priya DasSarma has developed such a series of kits and leads workshops to train teachers (**Fig. 2**). DasSarma and her husband, Shiladitya DasSarma, at the University of Maryland, have studied *Halobacterium* for two decades, developing the tools of genetics and molecular biology to investigate halobacterial physiology, including sequencing its genome. Now Priya DasSarma has developed a set of hands-on laboratory exercises that enable students to frame experimental questions and test them. Available from Carolina Biological Supply Company, the kit's exercises teach a wide range of concepts in microbiology, such as exponential growth and competition, colony formation, mutation, motility, DNA function, antibiotic sensitivity and resistance, bioinformatics, and genetic transformation and complementation.

In DasSarma's workshop, students and teachers learn to use the microbe for inquiry-based teaching by asking fundamental questions about what the students can see. Why do cells turn from a beautiful pink to a deep red when put under pressure, such as by centrifugation? The pink color is caused by light scattering from intracellular gas vesicles and light absorption by red carotenoid pigments; gas vesicles collapse under pressure, revealing the bright red pigment. The purpose of the gas vesicles is to keep the cells afloat in their natural habitat, such as the Great Salt Lake, where cells use sunlight for energy. On agar plates, why are some *Halobacterium* colonies pink and others red, while others are sectored like a pie? Pink colonies contain gas vesicles that scatter light, whereas a red colony derives from a cell containing an insertion element in a gas vesicle gene. Red sectors arise from spontaneous gas vesicle mutations in a fraction of cells within a colony; the mutants' descendants grow outward in a red wedge.

For advanced students, the *Halobacterium* cultures can be grown and lysed in distilled water and the DNA spooled out. The DNA is then run on electrophoretic gels to reveal plasmids. In other experiments, plasmid DNA can be used to transform a genetic strain to a new genotype. The availability of a completely sequenced genome permits a wide range of teaching applications.

squares, the only microbial cells known to be square (*Haloquadra walsbyi*) (**Figs. 19.29B, C**). The basis for maintaining the various shapes is unknown. In oligotrophic (low-nutrient) environments, it is likely that the greater surface-to-volume ratio gives flattened cells a competitive edge in obtaining nutrients.

The cell envelopes of most haloarchaea contain rigid cell walls of glycoprotein, as do some of the methanogens. Most species possess flagella for phototaxis and **gas vesicles** for maintaining their buoyancy in the upper layer of the water column. Unlike phospholipid vesicles, the gas vesicles are made entirely of protein, and they are filled with air.

Different Hypersaline Habitats Support Different Haloarchaea

Not all hypersaline (high-salt) habitats are alike. They differ with respect to pH, temperature, and the presence of other minerals, such as magnesium ion. Different kinds of hypersaline habitat support different species of haloarchaea (**Table 19.5**). Major types of habitat include:

- **Thalassic lakes.** Thalassic lakes (Greek *thalassa*, meaning "ocean"), such as the Great Salt Lake, in Utah, contain saturated salts with essentially the same ionic proportions as the ocean: Na^+ and Cl^- (NaCl) predominate, followed by Mg^{2+}, K^+ and SO_4^{2-}. Thalassic lakes support genera such as *Halobacterium*.
- **Athalassic lakes.** Athalassic lakes, such as the Dead Sea in Israel, contain higher proportions of magnesium ions. These habitats favor genera such as *Haloarcula*, which require 100 mM Mg^{2+} for growth and grow best at magnesium concentrations above 1 M.
- **Solar salterns.** These are artificial pools of brine, or saturated NaCl, that evaporate in the sun, precipitating halite (salt crystals) for commercial production. Commercial evaporation pools for salt actually benefit from the red microbes, whose light absorption accelerates heating and evaporation.
- **Brine pools beneath the ocean.** Undersea brine pools collect near geothermal vents, as in the Gulf of Mexico, Mediterranean Sea, and Red Sea. These hypersaline regions contain salts brought up by vent water. They support hyperthermophilic halophiles, most of which have not yet been cultured.
- **Alkaline soda lakes** such as Lake Magadi in Kenya, where carbonate salts drive the pH above pH 9. These lakes support alkaliphilic haloarchaea such as *Natronobacterium*.
- **Antarctic brine lakes.** Reaching temperatures as low as –18°C, Antarctic brine lakes support growth of cold-adapted halophiles such as *Halorubrum lacusprofundi*.
- **Underground salt deposits** contain micropockets of salt-saturated water where halophiles may survive for thousands of years.
- **Salted foods** such as meat and fish and salt-cured hides can be spoiled by species such as *Halobacterium*.

Retinal-Based Photoheterotrophy

Most haloarchaea are photoheterotrophs, in which light-directed energy acquisition supplements respiration on complex carbon sources. Respiration occurs with oxygen or anaerobically with nitrate. A typical habitat for haloarchaea starts out as a pool with moderate salt content, containing a range of bacterial and archaeal species with varied tolerance to salt. As the pool evaporates, the salt concentrates, and the various bacteria die and lyse, releasing cell components that the haloarchaea can metabolize. The halophiles supplement their utilization of organic substrate energy by using light-driven ion pumps.

Light is captured by retinal-containing transmembrane proteins called **bacteriorhodopsin** (**BR**), and the chloride pump **halorhodopsin** (**HR**) (**Fig. 19.30**). (The role of light-driven ion pumps in phototrophy is discussed in Chapter 14.) The proton pump bacteriorhodopsin was named to indicate that it was a prokaryotic version of the better-known eukaryotic retinal rhodopsins; the name was chosen before the domain Archaea was recognized. The chloride pump halorhodopsin was discovered and named in reference to the chloride ion (a halide.) The two proteins are homologs with similar structure and mechanism. In the cell membrane, they form complexes that aggregate in patches called purple membrane.

Each bacteriorhodopsin proton pump contains seven alpha helices that traverse the membrane, surrounding a buried molecule of retinal, the same light-absorbing molecule found in photoreceptors of the human retina. Light absorption triggers a conformational change that enables a proton from the cytoplasmic face to be picked up by an aspartate residue. Subsequent proton transfer through the molecule leads to release of the proton outside the cell. Halorhodopsin has a similar structure, in which chloride (instead of H^+) is pumped *into* the cell instead of outward.

The net result of proton transfer by bacteriorhodopsin is generation of a proton motive force that can run a proton-driven ATPase, storing energy as ATP (**Fig. 19.30B**). The halorhodopsin pumps chloride ions in the reverse direction, into the cell. Because chloride is negatively charged, this contributes to the proton motive force. Light-driven chloride pumps are unique to haloarchaea. Unimolecular proton pumps driven by light were thought to be restricted to haloarchaea until homologs

were found to be widespread among marine species of gammaproteobacteria. These proteorhodopsins appear to have been obtained through horizontal transmission from archaea (discussed in Chapter 14).

Haloarchaea also possess homologs of bacteriorhodopsin that serve as sensory devices, the sensory rhodopsins I and II. These proteins, too, each have seven alpha helices containing retinal. When the sensory rhodopsins absorb light, they signal the cell to swim using its flagella (discussed in Chapter 3). The activated sensory rhodopsins direct the cell to swim toward red light, the optimum range for photosynthesis, and away from blue to ultraviolet light, which causes photooxidative damage to DNA. The rhodopsins signal through the chemotaxis machinery to the flagellar motor, using histidine kinase enzymes that phosphorylate regulatory proteins (see **Fig. 19.30B**). This response to light, or phototaxis, is an important model for archaeal molecular regulation.

The photosynthesis and phototaxis systems can be seen in the context of the overall metabolic map of *Halobacterium* NRC-1 (**Fig. 19.31**). The map is based on its genome sequence, published in 2000 by Wailap Ng and colleagues at the University of Maryland (the first haloarchaeal genome to be completed). In the metabolic map, the proton-translocating ATPase is seen to be driven by the proton potential generated through bacteriorhodopsin. Alternatively, a proton potential can be generated by the respiratory chain, through consumption of organic foods. Glucose catabolism occurs by the semiphosphorylated Entner-Doudoroff pathway, in which the intermediate 2-keto-3-deoxygluconate is formed and then phosphorylated, completing the pathway with one net molecule of ATP produced.

The *Halobacterium* genome reveals homologs for a number of genes known to encode transporters of organic food molecules such as sugars and amino acids. In addition, the genome shows a number of cation and anion transporters. Some transporters move in needed molecules such as phosphate, whereas others pump out harmful substances such as arsenate. Efflux of inorganic toxins is particularly critical for growth in evaporating brine, where the concentrations of trace metals are increasing.

Applications of Haloarchaea

Haloarchaeal proteins and other cell components have found applications in research and industry. Some examples include:

- **Bacteriorhodopsin photoswitch.** The use of bacteriorhodopsin as a photoswitch is a model system for nanoscale experimental electronic circuits and memory devices.
- **Antibiotics.** Haloarchaea produce antibacterial agents called halocins, which accelerate the death and lysis of surrounding bacteria, whose components can be metabolized by the halophiles. Halocins have potential applications in antibacterial drug development.
- **Gas vesicles for antigen presentation.** Haloarchaea gas vesicles can be genetically engineered to serve as vehicles for antigen presentation. Gas vesicles containing proteins with fused antigen peptides are purified from the cells and used to elicit antibody response.

TO SUMMARIZE:

- **Haloarchaea are extreme halophiles**, growing in at least 1.5 M NaCl. They are isolated from salt lakes, solar salterns, underground salt micropockets, and salted foods.
- **Halobacteria show diverse cell shapes**, including slender rods (*Halobacterium*), cocci (*Haloferax*), and flat squares (*Haloquadra*). The cell envelopes of most haloarchaea contain rigid cell walls of glycoprotein.
- **Molecular adaptations to high salt** include DNA of high GC content and acidic proteins (proteins with a high number of negatively charged residues).
- **Retinal-based photoheterotrophy** involves the proton pump bacteriorhodopsin or the chloride pump halorhodopsin. Both pumps contain retinal for light absorption.

19.6 Euryarchaeota: Thermophiles and Acidophiles

Besides the methanogens and halophiles, the phylum Euryarchaeota includes a number of hyperthermophiles that superficially resemble the crenarchaeotes, although their genetic divergence from these organisms is deep. Some of the euryarchaeotes are acidophiles that grow under the most extreme acidic conditions on Earth.

Thermococcales Species Provide "Vent Polymerase"

A major group of hyperthermophilic euryarchaeotes is the order Thermococcales, including genera such as *Thermococcus* and *Pyrococcus* (**Fig. 19.32A**). These genera are most commonly isolated from submarine solfataras, volcanic vents that emit only gases. Most are anaerobes fermenting complex carbon sources, such as peptides or carbohydrates. Their growth is accelerated by using elemental sulfur as a terminal electron acceptor for anaerobic respiration:

$$2H^+ + 2e^- + S^0 \longrightarrow H_2S$$

Alternatively, these species can oxidize molecular hydrogen with sulfur:

$$H_2 + S^0 \longrightarrow H_2S$$

Most species grow at temperatures well above 90°C; *Pyrococcus woesei*, for example, grows at temperatures as high as 105°C.

Species of Thermococcales are the source of "vent polymerases" for PCR amplification. They now replace the enzyme Taq polymerase obtained from the Yellowstone hot-spring bacterium *Thermus aquaticus*, which only grows at temperatures up to 90°C. The Taq enzyme has only limited stability at or above 95°C, but DNA poly-

Figure 19.32 Hyperthermophilic Euryarchaeota. A. *Pyrococcus horikoshii* (TEM), isolated from a hydrothermal vent at the Okinawa Trough (TEM). **B.** *Archaeoglobus fulgidus* (TEM).

merases with greater stability at higher temperatures and increased accuracy in replication have been produced from vent-dwelling archaea such as *Pyrococcus furiosus* and *Thermococcus litoralis*. These "vent polymerases" now allow higher-temperature denaturation and synthesis of GC-rich sequences that were difficult to amplify with the original enzyme.

The first member of Thermococcales whose genome was sequenced was *Pyrococcus abyssi*. (Remember to distinguish *Pyrococcus abyssi* from the crenarchaeote *Pyrodictium abyssi*.) The sequence was completed in 1999 by Daniel Prieur, Patrick Forterre, and colleagues at Genoscope, the French National Sequencing Center. The genome of *Pyrococcus abyssi* reveals an especially high number of eukaryotic homologs for DNA replication, transcription, and protein translation. Examples include the Eukarya-like primase, helicase, and endonuclease for generation of Okazaki fragments in the lagging strand of DNA synthesis. At the same time, the genome also shows bacterial homologs for cell division and DNA repair. Thus, *P. abyssi* offers a striking view of mixed heritage from the common ancestor of the three domains.

Pyrococcus species possess enzymes conducting most of the classic conversions of the EMP pathway of glycolysis; but several steps use enzymes unrelated to those in bacteria. Examples include two ADP-dependent enzymes, glucokinase and phosphofructokinase, as well as the phosphate-independent enzyme glyceraldehyde 3-phosphate ferredoxin oxidoreductase. The glyceraldehyde 3-phosphate conversion is unique in that it sidesteps the use of inorganic phosphate, required at this step by bacterial glycolysis (see **Fig. 19.3**).

Pyrococcus and other members of Thermococcales have enzymes requiring tungsten, a metal requirement rare outside the archaea. (Tungsten is present in elevated concentrations at hydrothermal vents.) Another unusual feature of *Pyrococcus* is that both proton motive force generation and the ATPase appear to involve H^+/Na^+ antiport. This dependence on sodium is a trait shared with the methanogens and the halophiles.

THOUGHT QUESTION 19.6 Compare and contrast the metabolic options available for *Pyrococcus* and for the crenarchaeote *Sulfolobus*.

Archaeoglobus Runs Methanogenesis in Reverse

A hyperthermophile with unusual metabolic characteristics is *Archaeoglobus fulgidus*, of the order Archaeoglobales (**Fig. 19.32B**). The genome of *A. fulgidis* reveals an exceptionally complex array of metabolic pathways, including an acetyl-CoA degradation pathway involving "reverse methanogenesis" (**Fig. 19.33**). All the enzymes and cofactors of a methanogen are present, but instead of generating methane from CO_2, they run in reverse, converting the methyl group of acetate to CO_2. The energy required for reversal is gained through fermentation of carbohydrates and through anaerobic respiration with sulfate, which is successively reduced to sulfite and sulfide. This system provides more energy than methanogenesis when organic substrates are available.

Thermoplasmatales

The order **Thermoplasmatales** includes thermophiles and acidophiles with no cell wall and no S-layer—only a plasma membrane. How they maintain their cells against extreme conditions is poorly understood. An example is the moderate thermophile isolated from self-heating coal refuse piles, *Thermoplasma acidophilum*, growing at 59°C and pH 2. The cells have flagella and are motile, but it is unclear how the flagella maintain a torque against the membrane without a rigid envelope for support. The metabolism of *T. acidophilum*, like that of *Pyrococcus*, is based on S^0 respiration of organic molecules.

The genome sequence of *T. acidophilum* contains just 1.5 million bp, one of the smallest known for a free-living organism. It shows substantial evidence of lateral transfer from the crenarchaeote *Sulfolobus*, a hyperthermophile that shares the same range of habitats. Lateral transfer between distant relatives turns out to be common among the hyperthermophiles, causing some controversies in their classification.

Another acidophilic genus of the order Thermoplasmatales is *Ferroplasma*. *Ferroplasma* species are found in mines containing iron pyrite ore (FeS_2). Using dissolved Fe^{3+} as an oxidizing agent in the presence of H_2O, they oxidize the sulfur to sulfuric acid. The chemical equation is

$$FeS_2 + 14Fe^{3+} + 8H_2O \longrightarrow 15Fe^{2+} + 2SO_4^{2-} + 16H^+$$

The reaction generates pH values below pH 0 (1 M H^+). This degree of acidity is enough to dissolve a metal shovel within a day.

The amorphous cells of *Ferroplasma acidarmanus* grow in biofilms that form long streamers into streams draining from the mine (**Fig. 19.34**). The oxidative disintegration of iron-bearing ores can be useful for leaching of minerals, but it also causes acid mine drainage into aquatic systems (discussed in Chapter 22).

Figure 19.34 **The extreme acidophile: *Ferroplasma*.** **A.** *Ferroplasma acidiphilum* grows at pH 0 (TEM). **B.** Streamers of *F. acidarmanus* anchored to deposits of pyrite within the Iron Mountain mine. The stream is about a meter across, its water about pH 0. This level of acidity will dissolve a metal shovel in a day.

TO SUMMARIZE:

- **Thermococcales includes hyperthermophiles and acidophiles.** Most species use sulfur to oxidize complex organic substrates.
- ***Pyrococcus* and *Thermococcus* are the source of vent polymerases** for polymerase chain reaction (PCR).
- **Tungsten is commonly used by enzymes** of species of Thermococcales.
- ***Archaeoglobus* species (order Archaeoglobales) run methanogenesis in reverse.** The methyl group of acetate is oxidized to CO_2.
- **Thermoplasmatales includes extreme acidophiles.** *Ferroplasma* oxidizes iron pyrite ore (FeS_2) in a process that generates concentrated sulfuric acid, causing acid mine drainage.

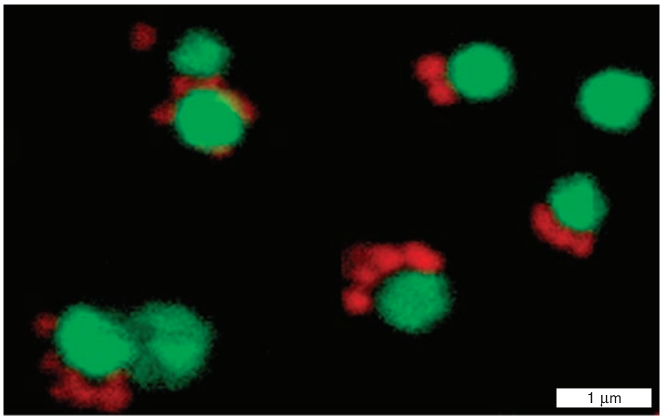
19.7 Nanoarchaeota and Other Emerging Divisions

New archaeal species continue to be discovered through PCR-amplified rDNA probes. Some of their sequences diverge more deeply than the divergence between Crenarchaeota and Euryarchaeota. Most such strains are uncultivated, and little is known of them other than their rRNA sequence. Nevertheless, new techniques of genome sequencing enable us in some cases to read most of a genome from a single cell. The genomes of such mystery strains may provide clues as to their needs for cultivation.

Deep-Branching Hyperthermophiles

A deep-branching division is Korarchaeota, which includes hyperthermophiles isolated by Susan Barns and Norman Pace from Obsidian Pool at Yellowstone. Unfortunately, the isolates remain unculturable, and nothing more is known of them beyond their rDNA sequence.

Another deep-branching clade is Nanoarchaeota, represented so far by the species *Nanoarchaeum equitans* (**Fig. 19.35**). *N. equitans* shows about equal sequence similarity to both Crenarchaeota and Euryarchaeota and thus appears to represent a distinct division. The organism consists of exceptionally small cells that are obligate symbionts of the crenarchaeote *Ignicoccus*. The nanoarchaeal genome is exceptionally small (under 500 kb), typical of a dependent organism that has lost numerous genes through degenerative evolution and dependence on a host. It has not been established whether *N. equitans* is parasitic on *Ignicoccus* or whether it makes a metabolic contribution to its host.



Huber, et al. 2003. *Research in Microbiology* 154:165–171

Figure 19.35 ***Nanoarchaeum equitans*, a hyperthermophilic symbiont of *Ignicoccus*.** Fluorescent probes to the DNA of *Ignicoccus* (green) and *N. equitans* (red) distinguish the two species.

Concluding Thoughts

Overall, species of archaea inhabit a wider range of environments than either bacteria or eukaryotes, from extreme heat to extreme cold, from high pH to extreme acid. Their metabolism includes unique capacities, such as methanogenesis. Nevertheless, it is important to remember that we probably know less about the actual scope of Archaea than we do about the other two domains because so many members remain uncultured. We recognize two major divisions, the crenarchaeotes, including sulfur-metabolizing hyperthermophiles as well as marine mesophiles and psychrophiles; and the euryarchaeotes, including methanogens, halophiles, and sulfur-metabolizing extremophiles. New deep-branching isolates continue to be discovered, potentially representing entire new divisions. Much of what we call Archaea remains to be explored.

CHAPTER REVIEW

Review Questions

1. What distinctive structures are seen in the archaeal cell membrane and envelope?
2. Which aspects of archaeal genetics resemble that of bacteria, and which aspects have more in common with eukaryotes?
3. Compare and contrast the two major divisions of archaea, Crenarchaeota and Euryarchaeota.
4. Outline the genetic phylogeny and key traits of these groups of archaea: haloarchaea, methanogens, Thermococcales, Thermoplasmatales.

5. What are some specific physiological adaptations found in hyperthermophiles? Psychrophiles? Extreme acidophiles?
6. Outline three different specific types of mutualism involving an archaeal symbiont.
7. Explain how different archaea contribute to cycling of nitrogen and sulfur in ecosystems.
8. Explain what is known and what is unknown about these groups of archaea: marine pelagic crenarchaeotes; marine benthic anaerobes; soil and plant root–associated crenarchaeotes. What kinds of experiments may reveal further traits of these organisms?

Chapter 20

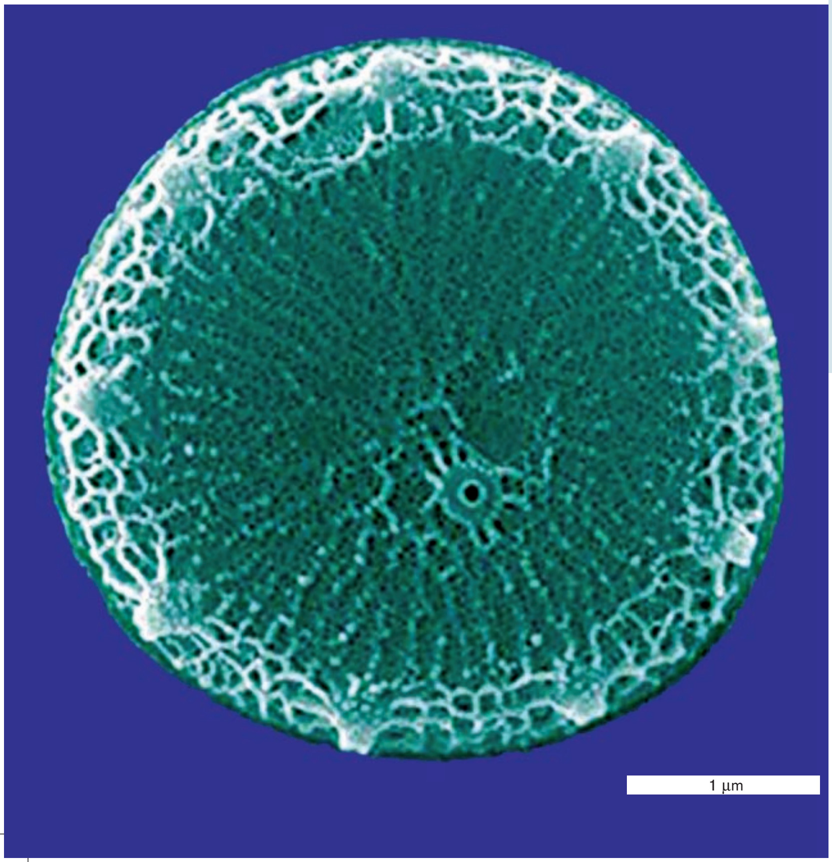
Eukaryotic Diversity

20.1 Phylogeny of Eukaryotes
20.2 Fungi
20.3 Algae
20.4 Amebas and Slime Molds
20.5 Alveolates: Ciliates, Dinoflagellates, and Apicomplexans
20.6 Trypanosomes, Microsporidia, and Excavates

The domain Eukarya encompasses a breathtaking range of size and form, from giant whales and sequoias to microbial fungi, algae, and protists. Some eukaryotic microbes are single cells as small as the smallest bacteria.

Fungi include multicellular forms such as mushrooms, as well as unicellular yeasts and filamentous *Penicillium* and *Neurospora*. Fungal filaments interconnect the roots of forest plants, forming a vast underground network of nutrients. Algae conduct photosynthesis using chloroplasts. Algae include broad sheets of kelp as well as unicellular phytoplankton. Many algae turn out to be secondary endosymbionts—protists whose ancestors engulfed preexisting algae whole, only to assimilate them and utilize their prey's chloroplasts.

Protists include amebas, zigzag-swimming euglenas with their chloroplasts, paramecia with hundreds of cilia, and stalked vorticellae whose rings of cilia draw prey toward the mouth. Most protists are free-living, but some are deadly parasites, such as the trypanosome of sleeping sickness, and the plasmodium of malaria.

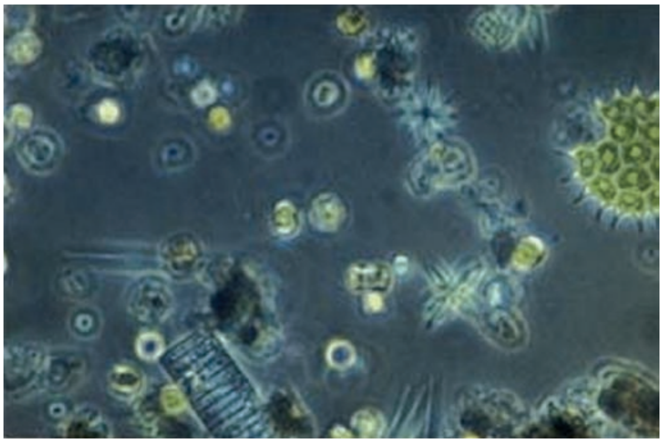


Diatoms are algae with silicate shells of intricate symmetry. They account for 40% of marine carbon productivity. *Thalassiosira pseudonana* was the first diatom whose genome was sequenced, by Virginia Armbrust and colleagues through an international collaboration involving twenty-four institutions (2004). The structure of diatoms such as *T. pseudonana* is now used for model systems of silica-based nanotechnology. *Source*: SEM image courtesy of the U.S. Department of Energy Joint Genome Institute.

When we think of eukaryotes, we think first of plants and animals consisting of complex multicellular bodies. Macroscopic multicellular eukaryotes provide most of the food we consume, from breakfast cereal to beef. But eukaryotes also include microbes, such as algae and protists. While we rarely eat these directly, marine and aquatic algae and protists form the core of a vast food web supporting fish and other metazoan seafood, a major food source of protein. A drop of pond water reveals these microbial eukaryotes in their extraordinary diversity of form (**Fig. 20.1**): filamentous algae with spiral choroplasts, silica-shelled diatoms and radiolarians with intricate symmetry, predators with engulfing mouths, and parasites with syringe-like injectors. Of the three domains of life, Eukarya shows the greatest range of size and shape.

In Chapter 20, we explore the diversity of eukaryotic microbes, including essential partners in ecosystems as well as parasites that cause devastating pathology. Recall that the structure of eukaryotic cells is defined by the presence of the nucleus and other membrane-bound organelles, which enable eukaryotic cells to grow a thousandfold larger than those of prokaryotes (for review, see Appendix 2). Despite their extraordinary range of form and cell structure, the metabolism of eukaryotes is less diverse than that of either bacteria or archaea. Most eukaryotes are either oxygenic phototrophs or heterotrophs growing on complex carbon sources. All descended from an ancestral cell that incorporated a bacterial endosymbiont giving rise to mitochondria, the source of aerobic respiration.

This chapter presents the phylogeny of major groups of eukaryotes, including the branching of animals and plants from the microbial family tree. We explore the form and function of key microbes, including fungi, amebas and slime molds, algae, and various classes of parasites. As in Chapters 18 (Bacteria) and 19 (Archaea), we can show only representative examples of major clades of Eukarya. For further exploration, we recommend the NCBI Taxonomy Database and the Microbial Biorealm.



Jack Hall

20.1 Phylogeny of Eukaryotes

Our view of the domain Eukarya, including its relation to Bacteria and Archaea, has undergone several transitions over the past century, as discussed in Chapter 1. Classification of eukaryotes has always been a challenge for several reasons. Complex eukaryotic cells frequently lose structures through reductive (degenerative) evolution. Thus, for example, a clade originally characterized by possession of flagella often includes members that lack flagella. In addition, superficially similar forms of organisms have evolved independently in distantly related taxa; this is called convergent evolution. For example, the "water molds" that grow on aquarium fish superficially resemble fungi, but they actually evolved in a clade that includes brown algae and diatoms.

Modern classification is based on DNA sequence. The size and complexity of eukaryotic genomes has hindered the completion of their genomes. Nevertheless, genomic data brings us near a consensus view of eukaryotic descent, including the branching of our own human species.

Historical Overview of Eukaryotes

For most of human history, life was understood in terms of macroscopic multicellular eukaryotes: animals (creatures that move to obtain food) and plants (rooted organisms that grow in the sun). Fungi, which lack photosynthesis, were nonetheless considered a form of plant because they grow on the soil or other substrate. Thus, **mycology**, the study of fungi, was often included with botany, the study of plants. But the basis of fungal growth was poorly understood, and their mystery was often associated with magic, as seen in the Victorian painting in **Figure 20.2A**, depicting fairies upon a "fairy ring" of mushrooms.

In the eighteenth and nineteenth centuries, microscopists came to recognize microscopic forms of fungi such as hyphae (filaments of cells) and unicellular yeasts. Furthermore, unicellular protozoa (originally considered "microscopic animals") and algae (considered microscopic plants) became a hugely popular subject for observation (**Fig. 20.2B**). The cellular dimensions of eukaryotes are typically ten- to a hundred-fold larger than those of bacteria, and their form and motility offer intriguing subjects for observation. They are nonetheless microscopic in that visualization of their details requires light microscopy. And so, unicellular and microscopic forms of fungi, protozoa, and algae came to be included in the subject of microbiology.

By the mid-twentieth century, a growing number of biochemical and molecular discoveries led us to redefine these organisms. For example, the motile organisms defined as protozoa often contain chloroplasts and fit the classification of algae. On the other hand, slime molds, originally classified with fungi, show form and motility more typical of protozoa. In 1866 Ernst Haeckel at the University of Jena classified protozoa and motile forms of algae as **protists**. Lynn Margulis, at the University of Massachusetts, Amherst, in 1978, defined "protoctista" as

the protists plus slime molds and oomycetes, organisms previously classified with fungi. Today, the term *protist* remains the most useful, although it now includes several distantly related clades (**Fig. 20.3**).

The shifting definitions of microbial eukaryotes are sorted out by molecular phylogeny. Eukaryotic genomes are harder to sequence because they are typically severalfold larger than those of prokaryotes, and 50–90% of their DNA consists of noncoding sequences. Thus, eukaryotic genomes take longer to sequence and are more challenging to annotate than those of prokaryotes.

Furthermore, the evolution of eukaryotes includes multiple events of **endosymbiosis**, in which an engulfed cell evolved into an essential organelle. An endosymbiotic incorporation of a proteobacterium by the ancestor of all eukaryotes gave rise to mitochondria. A later incorporation of a cyanobacterium by the ancestor of plants and algae gave rise to chloroplasts. Much later, several lineages

of protists took up chloroplast-bearing algae, which now show varying stages of evolution as organelles. The lineage of algae derived from a single endosymbiotic event are **primary endosymbionts** (the Viridiplantae in **Fig. 18.3**), while the protists that later incorporated algae are **secondary endosymbionts** (green asterisk in **Fig. 18.3**).

While uncertainties remain, a consensus view of eukaryotic phylogeny has emerged based on a combination of DNA sequence comparison, protein trees, and the appearance of specific gene fusions and deletions. In the current consensus model:

- **Fungi** refer to the "true fungi," or Eumycota. Fungi, multicellular animals, and a few protist-like organisms such as microsporidia form a clade called Opisthokonta (**opisthokonts**).
- **Plants** include land plants and primary endosymbiont algae, known as Viridiplantae.
- **Protists** include all other eukaryotic microbes, such as amebas and ciliates, as well as secondary endosymbiont algae and certain organisms formerly classed with fungi (slime molds and oomycetes). Protists include about six to eight clades as distinct from each other as they are from Opisthokonta or Viridiplantae.

The consensus phylogeny based on DNA sequence analysis is shown in **Figure 20.3**. The distinct clades of protists include amebas and slime molds (Amoebozoa), shelled amebas (Cercozoa), ciliates and dinoflagellates (Alveolata), oomycetes, brown algae, and diatoms (Heterokonta), and a growing number of other groups not as well characterized (such as Excavata and Euglenozoa). The "rank" of these major groups is less well defined than for major groups of bacteria and archaea, for which more sequence data are available.

Table 20.1 outlines major groups of eukaryotic microbes, including their relationships to multicellular animals and plants. We now summarize key traits of each major group. Diversity within each group is explored in the sections that follow.

Opisthokonts: Animals and Fungi Share One Clade

Where do humans and other multicellular animals fit into this taxonomy? Surprisingly, genomic analysis relates animals more closely to fungi than to protists, which had been considered the "microscopic animals."

The position of animals ("metazoa") among the eukaryotic microbial clades is of interest because it suggests which contemporary microbes most closely resemble our own cells. The degree of relatedness can help define microbial model systems for probing key questions of human cell biology, such as the basis of cancer and aging.

As we saw in Chapter 17, the first measure of species relatedness is based on DNA sequences encoding ribosomal RNA, particularly small-subunit rRNA. For eukaryotes, however, rRNA sequences yield ambiguous results, in part because of differing rates of change among different clades. So researchers have searched the genomes for stronger clues to relative divergence—that is, which clade diverged earliest from the others. A particularly strong clue would be the appearance of a gene insertion or deletion unique to a particular clade. Such a sequence indicates that all species containing the gene insertion or deletion must have diverged after their common ancestor branched from the outgroup.

Animals and fungi share several key gene insertions and deletions, as discovered by Sandra Baldauf and colleagues at the University of York. Baldauf focused on a short sequence insertion in a key gene encoding a protein translation factor, elongation factor 1α (EF-1α) (**Fig. 20.4**). The inserted DNA, encoding 12 amino acids, appears in all sequenced genomes of animals and fungi and is absent from all plants and most protists. It is present in a few organisms, such as microsporidians, that were previously considered protists. This gene sequence, as well as several others, support the grouping of animals, fungi, and microsporidians together in one clade, the opisthokonts (see **Fig. 20.3**).

Animal and fungal cells also share a structural feature distinguishing them from protists: the presence of an unpaired flagellum. Both animals and fungi include species showing a uniflagellar stage in their life cycle (in contrast to protists, most of which have flagella in pairs). In the case of humans, the uniflagellar stage is the spermatozoan. Similarly, some species of fungi generate uniflagellar reproductive cells called **zoospores**. As a whole, the clade including single-flagellar members is termed "opisthokont" based on the Greek words meaning "backward spear," referring to the appearance of the backward-pointing flagellum.

Among opisthokonts, the microbes that diverged most recently from animals (600 million years ago) appear to be the choanoflagellates. The prefix *choano-*, meaning "funnel," refers to the collar of filaments surrounding the flagellum. The collared cells of choanoflagellates closely resemble the choanocyte cells of colonial sponges, an ancient form of animal (**Fig. 20.5**). Furthermore, choanoflagellates form colonies that crudely resemble the colonial structure of sponges. Genetic studies of choanoflagellates reveal several genes found only in animals. Thus, choanoflagellates may represent a "missing link" between animals and the microbial eukaryotes.

NOTE: Eukaryotic flagella are whiplike organelles composed of microtubules and surrounded by a membrane, their action powered by ATP along the entire filament. Prokaryotic flagella are rotary helical filaments composed entirely of protein subunits; their rotation is powered at the base by proton motive force.

Figure 20.4 Alignment of peptide sequences for EF-1α reveals insertion in opisthokont species. An insertion of 11–17 amino acid residues appears in the EF-1α sequence of animals, fungi, and microsporidians (known collectively as opisthokonts) but not in plants or most protists. This finding suggests that opisthokonts have a common ancestor that diverged from the eukaryote lineage before divergence of the plants and nonopisthokont protists. Source: S. L. Baldauf. 1999. *American Naturalist* 154:S178.

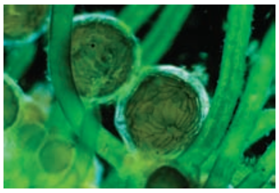
  Stachybotrys, known as "black mold," contaminates homes.
  Morels and truffles: Large fruiting bodies are highly valued foods.
- **Basidiomycota:** Basidiospores form primary mycelium; fuses to form secondary mycelium. Generates large fruiting body called a mushroom. Examples: *Lycoperdon* is edible; *Amanita* is extremely poisonous.
  Cryptococcus neoformans is a yeast-form basidiomycete, an opportunistic pathogen.
- **Zygomycota:** Nonmotile gametes grow toward each other and fuse to form the zygote (zygospore). Saprophytes or insect parasites. Some form mycorrhizae, a mutualistic association with plant roots.
- **Lichens:** Mutualistic association between an ascomycete and green algae (*Trebouxia*) or cyanobacteria (*Nostoc*).

Microsporidia. **Protist parasites that inject spores through tube into host cells, causing microsporidiosis.**
- ***Encephalitozoon* species:** Commonly infect AIDS patients.

Other protists: Corallochytrium, Ichthyosporea, and Nucleariidae

Viridiplantae (primary endosymbiotic algae and plants)

Include algae and multicellular plants. Chloroplasts arose from a primary endosymbiont.



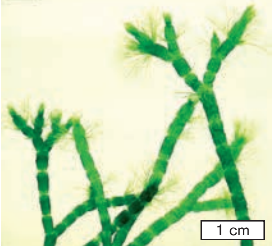
John Clegg/Science Photo Library

Charophyte

Plants. **Adapted to growth on land.**
Nonvascular plants: Mosses, ferns
Vascular plants: Gymnosperms, angiosperms

Charophyta (stoneworts). **Multicellular algae with rhizoids that adhere to sediment. Form green mats with crust of calcium carbonate; hence called "stonewort."**

Table 20.1 Representative groups of eukaryotes (*continued*)



Cymopolia barbata

S. Berger/Heidelberger Institut

Chlorophyta (green algae). Chlorophyll a confers green color. Inhabit upper waters.

Unicellular with paired flagella:

Chlamydomonas is a unicellular green alga; a model system for research on algae.

Volvox forms colonies of flagellated cells.

Multicellular:

Ulva grows in large sheets.

Spirogyra forms chains of cells.

Cymopolia forms calcified stalks with filaments.

Palmaria palmata

Edward Kinsman/Photo Researchers, Inc.

Rhodophyta (red algae). Phycoerythrin obscures chlorophyll, colors the algae red. Absorption of blue-green light enables colonization of deeper waters.

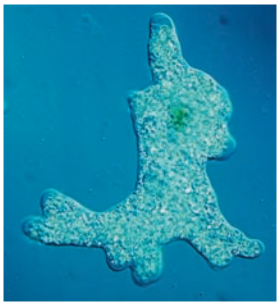
Porphyra form sheets edible by humans.

Sebdenia and *Plocamium* form branched fronds.

Mesophyllum forms coralline algae, hardened by calcium carbonate crust; resembles coral.

Amoebozoa or Lobosea (protists: amebas and slime molds)

Lobe-shaped (lobose) pseudopods driven by sol-gel transition of actin filaments.



***Chaos carolinense* (size: 1–2 mm)**

©Michael Abbey/Visuals Unlimited

Amebas. Unicellular. No microtubules to define shape. Life cycle is primarily asexual. Predators in soil or water.

Ameba proteus, Pelomixa, and *Chaos chaos* are giant free-living amebas in soil and water; they consume small invertebrates.

Entamoeba histolytica is an intestinal parasite.

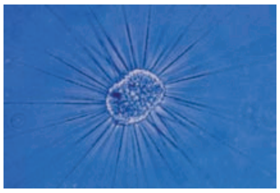
Acanthamoeba is a soil predator, an opportunistic parasite causing meningitis.

Mycetozoa. Slime molds. Upon starvation, amebas aggregate to form a fruiting body, which undergoes meiosis and produces spores.

- **Cellular slime mold.** Multicellular fruiting body alternates with single-celled amebas.
  - *Dictyostelium discoideum*. Provides an important model system for multicellular development.
- **Plasmodial slime mold.** Multinucleate plasmodium alternates with single-celled amebas.
  - *Physarum polycephalum*. In aqueous environment, amebas generate flagella.

Cercozoa (protists: amebas with filament-shaped pseudopods)

Filament-shaped (filose) pseudopods. Some species have a test (shell) of silica or other inorganic materials.



***Actinophrys sol* (cell size 30–90 μm)**

©Arthur Siegelman/ Visuals Unlimited

Foraminifera form spiral tests. Fossil "forams" are an indicator of petroleum deposits.

Radiolaria form thin pseudopods (filopodia) reinforced by microtubules, radiating starlike from the center. Some possess inorganic skeletons or spicules.

Euglyphida are amebas with a test.

Chlorarachniophyceae have algal endosymbionts.

Alveolata (protists with cortical alveoli)

Cortex contains flattened vesicles called alveoli, reinforced below by lateral microtubules.

***Vorticella* (length 1 mm)**

©Wim van Egmond/ Visuals Unlimited

Ciliophora. Common aquatic predators. Reproduce by conjugation, in which micronuclei are exchanged, then regenerate macronucleus for gene expression. Macronuclear DNA may be cut into thousands of segments.

Paramecium, Spirostomum, and *Oxytricha* are covered with cilia.

Didinium has two equatorial rings of flagella.

Vorticella and *Stentor* are stalked, with a mouth ringed by cilia.

Suctorians such as *Acineta* have knobbed tentacles.

(*continued*)

Table 20.1 Representative groups of eukaryotes (*continued*)

Ceratium tripos* and *Ceratium furca

Dinoflagellata. Secondary or tertiary endosymbiont algae, from ancestral engulfment of red algae and diatoms. Cortical alveoli contain stiff plates. Pair of flagella, one of which wraps around the cell.

Free-living marine and aquatic dinoflagellates such as *Peridinium* spp. supplement their photosynthesis with predation. Some produce bioluminesence. Blooms of marine dinoflagellates generate the "red tide."

Zooxanthellae such as *Symbiodinium* spp. are endosymbionts of corals, providing essential nutrition through photosynthesis. "Coral bleaching" is a serious condition in which the zooxanthellae are expelled under environmental stress. Zooxanthellae also inhabit clams, flatworms, mollusks, and jellyfish.

Apicomplexa (formerly sporozoa). Parasites with complex life cycles. Lack flagella or cilia; possess apical complex for invasion of host cells. Vestigial chloroplasts.

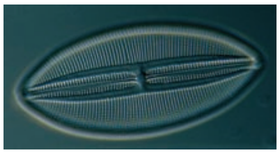
Plasmodium falciparum causes malaria.

Toxoplasma gondii causes feline-transmitted toxoplasmosis.

Cryptosporidium parvum is a water-borne opportunistic parasite.

Heterokonta (protists with pair of dissimilar flagella)

Paired flagella of dissimilar form, one much shorter than the other.



©Wim van Egmond/Visuals Unlimited

Diatom

Great Lakes Envir. Lab/NOAA

***Paraphysomonas* sp.**

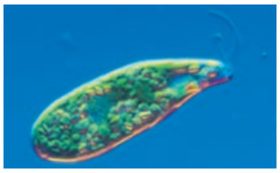
Secondary endosymbiont algae. Free-living in marine and aquatic systems. Mixotrophic; combine photrophy with heterotrophy.

- **Bacillariophyta:** Diatoms. Possess intricate silicate shells with radial symmetry (centric) or bilateral symmetry (pennate).
- **Phaeophyceae:** "Brown algae" such as kelps and Sargassum weed. Stems and fronds extend for many meters.
- **Chrysophyceae:** "Golden algae," pale-colored flagellates such as *Ochromonas* spp. and *Paraphysomonas* spp.
- **Xanthophyceae:** "Yellow-green algae" and other less-studied forms of phytoplankton.

Oomycetes. Water molds. Superficially resemble fungi; often infect fish or plants. *Phytophthora infestans* destroyed potato crops and caused the Great Irish Famine.

Euglenozoa or Discicristata (protists with disk-shaped cristae)

Usually possess a deep feeding groove. Disk-shaped cristae of mitochondria.



©Michael Abbey/Visuals Unlimited

Euglena gracilis

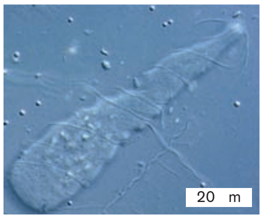
Euglenida. Free-living flagellates. Some contain a secondary endosymbiotic chloroplast. *Euglena gracilis* is a common aquatic flagellate.

Trypanosoma. Parasites. Cause sleeping sickness and Chagas' disease.

Leishmania. Parasites. Cause leishmaniaisis.

Excavata (protists lacking mitochondria)

Parasitic flagellates that have lost mitochondria and Golgi through degenerative evolution. Usually possess a deep feeding groove.



L. Amaral-Zettler, L. Olendzenski, and D. J. Patterson. MBL (micro*scope)

***Pyrsonympha* sp.**

Diplomonadida and Retortamonadida. Human intestinal parasites. Highly degenerated cells, lacking mitochondria. *Giardia lamblia.* Cause of diarrhea from contaminated drinking water.

Oxymonadida and Parabasalidea. Symbionts of termite gut. *Pyrsonympha.*

Fungi (Eumycota) consist of cells with chitinous cell walls that grow in chains called **hyphae** (singular, hypha). Fungi range from single-celled organisms, such as yeast, to complex multicellular forms, such as mushrooms. The deepest-branching clade of fungi, Chytridiomycota, produces the uniflagellar zoospores that define opisthokonts. Other fungi, however, generate nonmotile reproductive cells, a result of reductive evolution.

Several taxa that historically were grouped with fungi (for example, slime molds) are now classified genetically with protist clades. Slime molds generate populations of cells that migrate into a unified structure called a **fruiting body** for production of reproductive cells. Slime molds are now grouped with amebas (Amebozoa, discussed in Section 20.4). Water molds, plant and animal pathogens of the family Oomycetes, are now recognized as protists (see Section 20.2).

Algae Evolved by Engulfing Phototrophs

Algae are commonly defined as single-celled plants and simple multicellular plants lacking true stems, roots, and leaves. Algal cells contain **chloroplasts** or plastids, membrane-bounded organelles of photosynthesis derived from a cyanobacterium (**Fig. 20.6**). In Earth's biosphere, algae plus bacterial phototrophs form the foundation of all marine and aquatic ecosystems, producing the majority of oxygen and biomass available for Earth's consumers.

The "green plants" (Viridiplantae) include primary endosymbiont algae descended from a common ancestor containing a chloroplast. The chloroplasts of primary endosymbionts are enclosed by two membranes (**Fig. 20.6A**), the inner membrane (from the ancestral phototroph's cell membrane) and the outer membrane (from the host cell membrane as it enclosed its prey). Both **green algae** (**chlorophytes**) and **red algae** (**rhodophytes**) are primary endosymbionts. Their plastids have diverged from their common ancestor to utilize pigments absorbing different ranges of the light spectrum. Genetically, the green algae are the most closely allied with plants.

Several major taxa traditionally considered to be algae turn out to be secondary endosymbionts derived from protist hosts. The symbiotic history is most evident in the **cryptophyte algae** (**Fig. 20.6B**), which still retain a vestigial nucleus, or **nucleomorph**, derived from the engulfed cell. Their plastid is surrounded by two extra membranes, one from the primary endosymbiont (engulfed alga) cell membrane and one from the secondary host. Other secondary endosymbiont algae include the **chrysophytes**, such as kelps and diatoms. The **dinoflagellates**, photoheterotrophs of the protist clade Alveolata, are secondary or tertiary endosymbionts, decended from a flagellate that consumed one or more types of algae. Dinoflagellates also engage in "kleptoplasty," or "plastid stealing," in which the plastid of a digested prey is retained long enough to derive some photosynthetic energy but ultimately consumed. The variety of endosymbiosis among protists provides clues as to how the original chloroplast evolved within the ancestral algae.

Protists Form Many Divergent Clades

The protists are now known to include several distantly related categories of eukaryotes (see **Table 20.1**). All protists are heterotrophs, commonly predators or parasites, although many also conduct photosynthesis as secondary endosymbionts (algae). Protists are important producers and consumers in marine, aquatic, and soil food webs. In ecology, phototrophic protists are termed phytoplankton and heterotrophs are termed zooplankton, although many in fact are "mixotrophs" that act as both producers and consumers.

Amebas are unicellular organisms of highly variable shape that form **pseudopods**, locomotory extensions of cytoplasm bounded by the cell membrane. Their size can reach several millimeters, visible to the unaided eye. There are two major groups of amebas: Amoebozoa and Cercozoa (see **Table 20.1**). The Amoebozoa or Lobosea, the most familiar kind of amebas, have lobed pseudopods, pseudopods that extend lobes of cytoplasm through cytoplasmic streaming. Most lobed amebas are free-living in aquatic habitats, but some cause human diseases such as meningitis. Lobed amebas also include slime molds, in which individual amebas converge to form a fruiting body. The second group of amebas, the Cercozoa, have

Figure 20.6 **Chloroplast evolution: primary and secondary endosymbiosis.** **A.** Green algae (Chlorophyta) and red algae (Rhodophyta) contain chloroplasts (green) that evolved from engulfed cyanobacteria. Primary host cytoplasm is colored yellow; primary host nuclear membrane is colored brown. **B.** Cryptophyte algae contain chloroplast (green), vestigial primary host cytoplasm (yellow), and vestigial nucleus or nucleomorph (brown) from the engulfed primary endosymbiont.

thin, filamentous pseudopods, often radially arranged like a star, as in heliozoan amebas. Some cercozoans, such as the foraminiferans, form inorganic shells called tests. Fossil foraminiferan tests are common in rock formations derived from ancient seas. Foraminiferan shells formed the white cliffs of Dover in Britain and the stone used to build the Egyptian pyramids.

The **Alveolates** include ciliated protists (ciliates), dinoflagellates, and apicomplexans. Alveolates are known for their complex outer covering, or cortex. The cortex contains networks of vesicles called **cortical alveoli** (**Fig. 20.7A**). Alveoli store calcium ion and in some species grow protective plates. Organisms equipped with paired cilia or flagella are known as **flagellates** and **ciliates**, respectively. Flagella and cilia are essentially equivalent organelles composed of microtubules and enveloped by the cell membrane (**Fig. 20.7B**), although cilia are shorter and more numerous than flagella, and usually cover a broad surface. Alveolata also includes a major group of parasites that no longer possess flagella, the **apicomplexans**. A well-known apicomplexan parasite is *Plasmodium falciparum*, which causes malaria.

Heterokonts (the Heterokonta) are named for their pairs of differently shaped flagella (see **Table 20.1**). Flagellated members of this clade possess two flagella of unequal length and different structure. They include many voracious zooplankton. Nonflagellated heterokonts include the oomycetes, or water molds (formerly classed with fungi), as well as diatoms and kelps (secondary endosymbiotic algae with chloroplasts). **Diatoms** are single cells with unique bipartite shells that fit together like a Petri dish. The shells of diatoms form an infinite variety of different patterns for different species. **Kelps**, also known as brown algae, extend multicellular sheets floating at the water's surface. The kelp known as sargassum weed is famous for its growth in the Sargasso Sea.

Some protists, such as the Euglenozoa or Discicristata (discicristates) and the Excavata (excavates), show extensive evolutionary reduction. The Euglenozoa have mitochondria with distinctive disk-shaped cristae (membrane pockets). They include euglenas, free-living flagellates with a relatively simple cortex. Other Euglenozoa are parasites such as the trypanosomes that cause sleeping sickness and Chagas' disease. The Excavata lack mitochondria altogether, although traces of mitochondrial genes persist in their nuclei. Excavata include the diplomonads such as *Giardia lamblia*, a common contaminant of water supplies.

NOTE: "Algae" may refer to primary algae, or "true algae," as well as secondary endosymbiont algae that derive from protist clades. Fungi (the "true fungi," or Eumycota) are opisthokonts. Several fungus-like organisms have been reclassified within protist clades.

Newly Discovered Eukaryotes as Small as Bacteria

Genes from natural communities continually reveal new species of microbial eukaryotes in previously unknown divisions. Many of the new isolates are single cells as small as bacteria, designated nanoeukaryotes (3–10 μm) and picoeukaryotes (0.5–3 μm). Their genomes in some cases appear comparably downsized; for example, the picoeukaryote *Ostreococcus tauri*, a chlorophyte alga, has a genome of only 8 Mb, barely twice that of the bacterium *Escherichia coli*. Genetic analysis shows that these miniaturized eukaryotes branch deeply from all groups in the phylogenetic tree, potentially doubling the known number of major eukaryotic taxa.

Furthermore, eukaryotes are emerging in "extreme" environments previously believed to be restricted to bacteria and archaea, ranging from Antarctic sea ice to the hyperacidic Tinto River in Spain. The next decade may substantially reshape our overall understanding of the domain Eukarya.

TO SUMMARIZE:

- **Opisthokonta** includes true fungi (Eumycota) and multicellular animals (Metazoa), as well as certain kinds of protists.
- **Viridiplantae** includes green plants and primary endosymbiont algae.
- **Several groups of protists** are Amoebozoa, the unshelled amebas; Cercozoa, shelled amebas; Alveolata, ciliates and flagellates with complex cortical structure; Heterokonta, the kelps, diatoms, and flagellates with nonequivalent paired flagella; and Discicristata and Excavata, primarily parasites showing evolutionary reduction.
- **Many protists are phototrophs as well as heterotrophs**, based on secondary or tertiary endosymbiosis derived from engulfed algae.

20.2 Fungi

Fungi provide essential support for all communities of multicellular organisms. Fungi recycle the biomass of wood and leaves, including substances such as lignin, which other organisms may be unable to digest. Underground fungal filaments called mycorrhizae extend the root systems of most plants, forming a nutritional "internet" that interconnects the plant community (discussed in Chapter 21). Within animal digestive systems, fungi ferment plant materials. On the other hand, pathogenic fungi infect plants and animals, and they contribute to the death of immunocompromised human patients. Still other fungi produce antibiotics such as penicillin, as well as food products such as wine and cheeses (discussed in Chapter 16).

Subtle details of the fungal cell are exploited as targets for antifungal agents. For example, fungal membranes contain ergosterol, an analog of cholesterol not found in animals or plants. Inhibitors of ergosterol biosynthesis, such as the triazoles, are used to treat fungal infections.

The following traits are common to most fungal cells:

- **Absorptive nutrition.** Most fungi cannot ingest particulate food, as do protists, because their cell walls cannot part and re-form, like the flexible pellicle of amebas and ciliates. Instead they secrete digestive enzymes, then absorb the broken-down molecules from their environment.
- **Hyphae.** Most fungi grow by extending multinucleate cell filaments called hyphae (**Fig. 20.8A**). As a hypha extends, its nuclei divide mitotically without cell division, generating a multinucleate cell. Hyphae grow by cytoplasmic extension and branching. A branched mass of extending hyphae is called a **mycelium**.
- **Cell walls containing chitin.** Chitin is an acetylated amino-polysaccharide of immense tensile strength, stronger than steel (**Fig. 20.8B**). Its strength derives from multiple hydrogen bonds between fibers. Chitinous cell walls enable fungi to penetrate plant or animal cells, including tough materials such as wood. Inhibitors of chitin synthesis, such as the polyoxins and nikkomycins, are used as antibiotics against fungal infections.

Fungal Hyphae Absorb Nutrients

At the growing tip of a hypha, the cell membrane expands by incorporating vesicles generated by the endoplasmic reticulum (**Fig. 20.9A**). The vesicle fusion provides phospholipids and proteins to extend the membrane surface area, allowing the cytoplasm to expand rapidly. Expansion of cell membrane and cytoplasm is driven by uptake of hydrogen ions in exchange for potassium ions (**Fig. 20.9B**). Molecules that deregulate K^+/H^+ exchange, such as nystatin, serve as antifungal agents.

Figure 20.9 Cellular basis of hyphal extension. **A.** Section through growing tip of a hypha (TEM). Vesicles collect at the tip, where they fuse into the cell membrane, enabling extension. **B.** Hyphal extension is regulated by uptake of protons and extrusion of potassium ions at the tip of the apical growth zone. The absorption zone takes in nutrients, while the storage zone synthesizes and stores cell constituents.

Just behind the hypha's growing tip lies its absorption zone. The absorption zone takes in nutrients from the surrounding medium, such as the cytoplasm of an invaded animal cell. Behind the absorption zone, the older part of the hypha collects and stores nutrients. The tubular shape of the hypha is maintained by a protein cytoskeleton consisting of alpha- and gamma-tubulin.

Unicellular Fungi

Despite the advantages of hyphae for resource acquisition, various species are unicellular, or can grow either with or without hyphae. These unicellular fungi are known as **yeasts**. Examples of yeasts include baker's yeast, *Saccharomyces cerevisiae* (**Fig. 20.10A**), used to leaven bread and to brew wine and beer (for more on food microbiology, see Chapter 16). Other yeasts, such as *Candida albicans* (**Fig. 20.10B**), are important members of human vaginal flora. Some are important opportunistic pathogens, occurring frequently in AIDS patients; for example, *Pneumocystis carinii* is a yeast-form ascomycete, whereas *Cryptococcus parvum* is a yeast-form basidiomycete (discussed shortly).

Yeasts such as *S. cerevisiae* provide major research subjects for eukaryotic biology. For example, the Nobel Prize in Physiology or Medicine in 2001 was won by yeast researchers Leland Hartwell and Paul Nurse (shared with Tim Hunt, studying sea urchins). Their work revealed key molecules of the eukaryotic cell cycle, relevant to concerns of human medicine such as cancer.

Some yeasts reproduce by **budding**, in which mitosis of the mother cell generates daughter cells of smaller size. The mother cell acquires a bud scar where the smaller one pinched off. After generating a limited number of buds,

C. Yeast alternation of generations

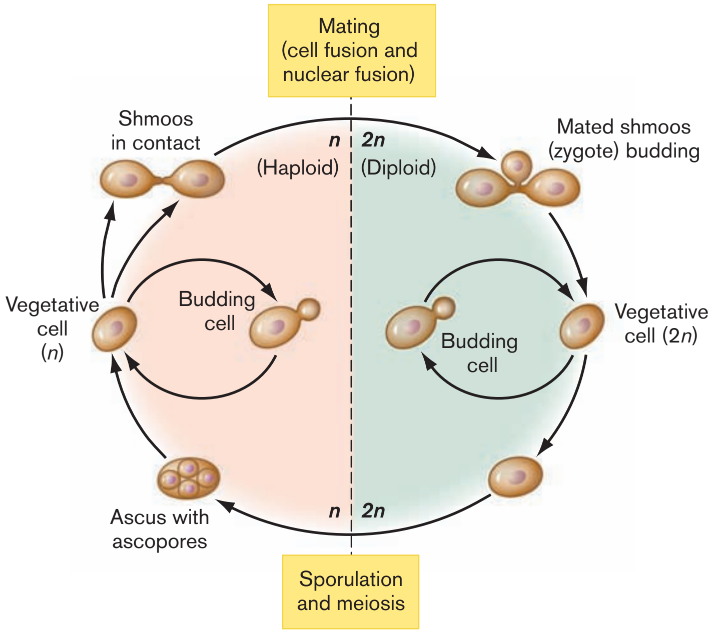

Figure 20.10 Yeast are nonmycelial fungi. A. Baker's yeast, *Saccharomyces cerevisiae*, reproduces by budding. Note bud scar next to budding daughter cell. SEM. **B.** *Candida albicans*, a common inhabitant of the human vaginal tract, alternates between unicellular and filamentous forms (SEM). **C.** In the life cycle of baker's yeast, haploid cells reproduce many generations by budding.

the mother cell senesces and dies. Thus, yeasts provide a unicellular model system for the process of aging.

THOUGHT QUESTION 20.1 Why would yeasts remain unicellular? What are the relative advantages and limitations of hyphae?

Some yeasts are asexual, whereas others can undergo sexual **alternation of generations** (**Fig. 20.10C**). This life cycle alternates between generation of a haploid population, with a single copy of each chromosome (*n*), and a diploid population, with a diploid chromosome number (2*n*). In the haploid generation, haploid spores divide and proliferate by mitosis, forming a haploid mycelium. Under environmental signals such as starvation, mating factors induce the haploid cells to differentiate into gamete forms called "shmoos." Gametes of two different mating types fuse, and their nuclei combine to form a zygote. In the diploid generation, the zygote divides mitotically, generating a population of diploids that appear superficially similar to haploid cells. Under stress, particularly desiccation, the diploids undergo meiosis. Meiosis generates an **ascus** that contains four haploid spores.

Many fungi and protists undergo modified versions of alternation of generations, utilizing a wide variety of haploid and diploid structures to accomplish essentially the same genetic tasks. In many fungi, the haploid form predominates; for example, ascomycetes such as *Aspergillus* and *Neurospora* form mainly haploid mycelia. Some fungi lack sexual reproduction entirely. An example is the famous *Penicillium* mold, an asexual ascomycete, from which the antibiotic penicillin is derived. Species that lack sexual life cycles were traditionally classified as "imperfect" fungi. We now know that such species in fact evolved independently from several different fungal clades. Today, asexual species are called **mitosporic fungi** because they generate spores only by mitosis.

THOUGHT QUESTION 20.2 Why would some fungi have lost their sexual life cycle? What are the advantages and limitations of sexual reproduction?

Fungi: Mycelia, Mushrooms, and Mycorrhizae

Different species of fungi show vastly different forms, from the familiar mushrooms, fruiting bodies that can weigh several pounds, to the mycelia of pathogens and the symbiotic partners of algae in lichens. Major phyla of fungi include Chytridiomycota, Zygomycota, Ascomycota, and Basidiomycota. A phylum formerly classified with fungi, Oomycota (Oomycetes), has been reclassified as heterokont protists.

NOTE: The major groups of fungi are also named with the alternative suffix *-etes*: Chytridiomycetes, Zygomycetes, Ascomycetes, Basidiomycetes.

Chytridiomycota: motile zoospores. The deepest branching clade of fungi is Chytridiomycota (the chytrids), which share with animals and choanoflagellates the motile, flagellated reproductive form known as a zoospore. The zoospore form has been lost by other fungi.

Chytrid species include bovine rumen inhabitants whose hyphae penetrate tough plant material, facilitating digestion. An example is *Neocallomastix* species (**Fig. 20.11A**). Unlike most fungi, *Neocallomastix* is an obligate anaerobe whose mitochondria have evolved into **hydrogenosomes**, organelles that ferment carbohydrates in a pathway generating H_2. Hydrogenosomes are a unique adaptation of certain anaerobic fungi and protists.

Other chytrids are aerobic animal pathogens. **Figure 20.11B** shows the skin of a frog infected by the chytridiomycete *Batrachochytrium dendrobatidis*. *B. dendrobatidis* has caused a widespread die-off of frogs in Central and South America, in an epidemic associated with global warming. The mycelium of *B. dendrobatidis* grows within the frog skin, producing capsules full of diploid zoospores called zoosporangia. Each zoosporangium protrudes through the skin surface, ready to expel zoospores in search of a new host.

The life cycle of a chytrid includes both haploid (gametophyte) and diploid (sporophyte) mycelia (**Fig. 20.11C**). Haploid mycelia produce motile gametes that detect each other by sex-specific attractants. The gametes fuse to produce a motile zygote. The zygote forms a cyst, a cell with arrested metabolism that can persist for long periods. In a favorable environment, the cyst germinates to form a diploid mycelium, or sporophyte. The sporophyte generates zoosporangia full of zoospores. There are two alternative forms of zoosporangia: those that produce diploid zoospores, which form cysts and regenerate the diploid mycelium, and those that undergo meiosis to produce haploid zoospores. The haploid zoospores generate a haploid mycelium (gametophyte) capable of producing haploid gametes.

Frog skin cells are penetrated by discharge tubes of diploid zoosporangia about to release zoospores. **C.** Life cycle of a chytrid.

Zygomycota: nonmotile sporangia. The **zygomycetes** and other non-chytridiomycete fungi generate nonmotile spores. Nonmotile spores require transport by air or water or ballistic expulsion (expulsion under pressure) from a spore-bearing organ, called the **sporangium**. A common zygomycete is the bread mold *Rhizopus* (**Fig. 20.12A**). Most zygomycetes, such as *Mucor* species, are soil molds that decompose plant material or other fungi or the droppings of animals (**Fig. 20.12B**). These modest molds fill important niches in all terrestrial ecosystems. Others, particularly *Glomales* species, form mutualistic associations with plant roots known as **vesicular-arbuscular mycorrhizae**. Mycorrhizae expand the roots' absorptive capacity (see Chapter 21). Most trees and crop plants require mycorrhizae for optimal growth.

The life cycle of a zygomycete parallels that of a chytrid in its alternative options of haploid (n) and diploid ($2n$) forms (**Fig. 20.12C**). The mechanics differ, however, owing to the lack of motile gametes. The haploid spore (sporangiospore) is disseminated through air currents. A sporangiospore does not directly undergo sexual reproduction; it grows into a haploid mycelium. The haploid mycelium then forms special hyphae whose tips differentiate into gamete cells. The gametes cannot separate from the filament; instead, two gamete-bearing hyphae must grow toward each other in order to fuse and form a **zygospore**. The zygospore undergoes meiosis and generates the sporangium, a haploid structure that releases **sporangiospores**.

THOUGHT QUESTION 20.3 What are the advantages and limitations of motile gametes, as compared to nonmotile spores?

Ascomycota: mycelia with paired nuclei. The **ascomycete** fungi are famous in the history of science as well as in the culinary arts (**Fig. 20.13**). The bread mold *Neurospora* was used by George Beadle and Edward Tatum in the 1940s to formulate the one gene–one protein theory. In *Neurospora*, meiosis produces pods (asci) of **ascospores** aligned in rows that reflect the ordered tetrads of meiotic division. The tetrad patterns were used by geneticists to demonstrate the segregation and independent assortment of chromosomes. In other species, by contrast, the asci are packed in large mushroom-like fruiting bodies known as morels (*Morchella hortensis*) and truffles (*Tuber aestivum*). The ascospores of such fruiting bodies are spread by animals attracted by their delicious flavor. Human collectors traditionally use muzzled pigs to detect and unearth the famous underground truffles.

Figure 20.13 Ascomycetes produce large fruiting bodies. A. The culinary delicacies known as morels are fruiting bodies of the species *Morchella hortensis*. The dark pits of the morel are lined with asci. **B.** Ascomycete asci containing ascospores (stained red). **C.** The life cycle of an ascomycete alternates between the diploid and haploid forms. The diploid mycelium produces asci, within which the haploid ascospores are formed.

The ascomycete life cycle (**Fig. 20.13C**) includes a phase in which each cell possesses a pair of separate nuclei, one from each parent (chromosome number is designated $n + n$). The "dikaryotic" (paired-nuclei) phase is generated by haploid mycelia in which male and female reproductive structures fuse, followed by migration of all the male nuclei into the female structure. The paired nuclei then undergo several rounds of mitotic division while migrating into the growing mycelium. In the mycelial tips, the paired nuclei finally fuse (becoming $2n$) and the mycelial tips develop into asci. Each ascus then undergoes meiosis in which the haploid products segregate in the same order that the meiotic chromosomes separated.

Some ascomycetes, such as *Aspergillus* and *Penicillium* species, form small asexual fruiting bodies called conidiophores for airborne spore dispersal (**Fig. 20.14**). While *Penicillium* is known for antibiotic production, *Aspergillus* is a growing medical problem as an opportunistic pathogen of immunocompromised patients. Conidiospore-forming ascomycetes are the major form

Figure 20.14 ***Aspergillus*.** **A.** *Aspergillus* forms a microscopic asexual fruiting structure called a conidiophore, containing spores in its spherical tip. **B.** Colony of *Aspergillus nidulans* on an agar plate.

of mold associated with dampness in human dwellings; they caused massive damage to homes flooded in the wake of Hurricane Katrina (**Special Topic 20.1**).

Basidiomycetes: cells with paired nuclei form mushrooms. The **basidiomycetes** are known for the exceptional size and diversity of their aboveground fruiting bodies, known as "true" mushrooms (**Fig. 20.15**). Mushrooms produce some of the world's deadliest poisons, such as alpha-amanitin, which inhibits RNA polymerase II. Alpha-amanitin is produced by the amanita, or "destroying angel," a taste of which is usually fatal. Other mushroom species include some of the world's most prized culinary delights, such as the portobello. Many grow in soil, while others, such as *Piptoporus*, grow on tree bark. Some mushrooms have evolved elaborate insect-attracting structures and odors, such as the "starfish stinkhorn," with its ring of bright red horns.

Figure 20.15 Mushrooms and other basidiomycetes form large, complex fruiting bodies. **A.** The amanita makes one of the most dangerous toxins known, alpha-amanitin, an inhibitor of RNA polymerase II. **B.** *Aleuria* mushrooms releasing spores from their gills, to be carried on the wind. **C.** The "starfish stinkhorn" forms a smelly mass of spores that attracts insects for dispersal.

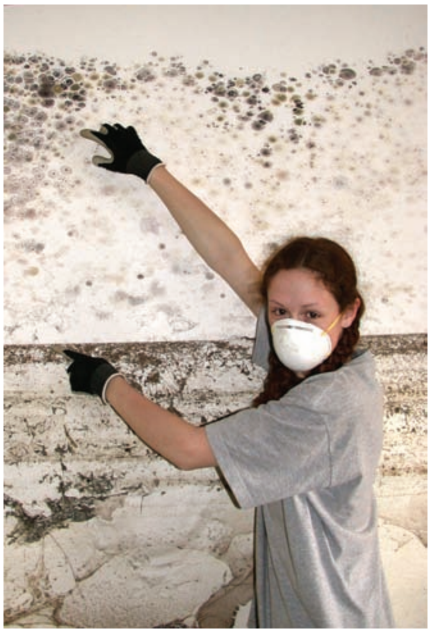
Special Topic 20.1 Mold after Hurricane Katrina

In the wake of Hurricane Katrina in 2005, much of the city of New Orleans was flooded. Entire neighborhoods were submerged for days or weeks. The flooding of homes full of drywall and organic materials made ideal conditions for the growth of "mold," which generally consists of airborne ascomycete fungi. Mold grew not only on materials submerged, but also on the surfaces above, exposed to water-saturated air. **Figure 1** shows how mold grew up to three feet above the floodline (the highest level submerged) within the kitchen of a flooded home. Unfortunately, most homeowner insurance policies only covered damage "up to the floodline."

Mold growing on damp surfaces releases spores into the air. Inhaled mold spores cause respiratory problems, even at relatively low levels (such as 2,000 spores per cubic meter). In New Orleans, after the waters receded, the mold counts in air within homes reached as high as 650,000 spores per cubic meter. Such spore levels cause asthma attacks and hypersensitivity pneumonitis, a condition in which fever rises and the lungs fail. All remediation workers were advised to wear an N95 mask respirator. The Natural Resources Defense Council (NRDC) found that even after flooded homes underwent full removal of contaminated items, including furniture, carpets, and drywall down to the studs, airborne spore counts still reached 70,000.

The most common types of mold found by the NRDC researchers were ascomycetes such as *Cladosporium* (**Fig. 2**). *Cladosporium* species form black or dark green colonies of conidia that readily break off and become airborne. Other ascomycetes found at high levels included *Aspergillus* and *Penicillium* species. These organisms occur at low levels even in clean air. Their spores cause allergy attacks and infect immunocompromised individuals. Some ascomycete molds produce mycotoxins, fungal toxins that cause long-term health effects. In addition, some flooded homes showed significant levels of *Stachybotrys* species, known as "black mold," a possible cause of neurological problems and immune suppression. Once such molds establish growth, their eradication is a major challenge.



Joan Slonczewski

George Barron

Figure 2 *Cladosporium* mold. Conidiophores (branched hyphae) producing conidia (asexual spores) of *Cladosporium cladosporioides* (spore size 5–20 μm; light micrograph).

The mushroom itself is only the fruiting body of the basidiomycete, whose life cycle involves transitions between n, $n + n$, and $2n$ (**Fig. 20.16A**) similar to those of ascomycetes (see **Fig. 20.13C**). In the basidiomycete, however, the fruiting body consists largely of cells with paired nuclei ($n + n$). A few of the paired nuclei fuse to form diploid cells ($2n$) called basidia, which line the gills of the mushroom. The basidia undergo meiosis to form haploid **basidiospores** (*n*). Some types of basidia can release basidiospores under pressure, whereas other basidiospores are transmitted by wind (see **Fig. 20.15B**).

The basidiospores germinate to form underground mycelium. This haploid "primary mycelium" generates gametes that ultimately fuse to form $n + n$ "secondary mycelium." The primary and secondary mycelia may radiate underground, unseen, until their tips generate mushrooms aboveground, at points approximately equidistant from the origin. The result is a mysterious "fairy ring" of mushrooms (see **Fig. 20.2A**). In fact, these invisible underground hyphae of basidiomycetes and zygomycetes contribute mycorrhizae to extend the root systems of trees (**Fig. 20.16B**).

Figure 20.16 Mushroom life cycle. A. Haploid basidiospores generate primary mycelium underground, where they form gametes. Gametes of opposite mating types fuse their cytoplasm only, forming secondary mycelium. The parental nuclei remain separate throughout many generations of mitosis during development of the fruiting body or mushroom. As the mushroom matures, the basidia undergo nuclear fusion and meiosis, forming progeny basidiospores. **B.** The underground secondary mycelia of some mushrooms form mycorrhizae with tree roots. Mycorrhizae enhance and extend the absorptive power of the roots.

Oomycota superficially resemble fungi. The **oomycetes**, or water molds, were originally classified as fungi based on the superficial similarity of their infective filaments to fungal hyphae, and the fungus-like appearance of their infections of plants and animals. The term *oomycete* means "egg fungi," referring to the large round egg-like form of the female gamete (**Fig. 20.17A**). The oomycete genus *Phytophthora* ("plant destroyer") includes serious plant pathogens. Destruction of potato crops by *Phytophthora infestans* was largely responsible for the Great Irish Famine in the 1840s, in which a million people died and many others migrated to the United States. Today, another species of *Phytophthora* causes "sudden oak death," the loss of tens of thousands of oaks and other trees on the west coast of the United States (**Fig. 20.17B**).

Despite superficial similarities between oomycetes and fungi, their cell forms and DNA sequences show fundamental differences. Oomycete cell walls contain no chitin, being composed primarily of glucans and cellulose. DNA analysis shows that oomycetes are heterokonts, a class of protists with pairs of dissimilar flagella (Heterokonta, major category in Table 20.1). The heterokont cell form is seen in the primary and secondary zoospores (**Fig. 20.17C**). Oomycetes and fungi offer an interesting case of convergent evolution.

THOUGHT QUESTION 20.4 Compare the life cycle of an oomycete (**Fig. 20.17C**) with that of a chytridiomycete (**Fig. 20.11C**). How are they similar, and how do they differ?

TO SUMMARIZE:

- **Fungi form hyphae with cell walls of chitin.** Hyphae absorb nutrients from decaying organisms or from infected hosts. Some fungi remain unicellular; these are called yeasts, or mitosporic fungi.
- **Chytridiomycete fungi have motile zoospores.** Motile reproductive forms are a trait shared with animals. Flagellar motility has been lost by other fungi through reductive evolution.
- **Zygomycete fungi form haploid mycelia.** Hyphal tips differentiate into gametes and grow toward each other to undergo sexual reproduction. Some zygomycetes form mycorrhizae that connect the roots of plants.

Figure 20.17 Oomycetes are fungus-like pathogens. **A.** *Phytophthora infestans*, cause of potato late blight. **B.** Oak tree in California dying of *Phytophthora ramosum* infection, known as "sudden oak death." **C.** Life cycle of an oomycete. C.

- **Ascomycete fungal mycelia form paired nuclei.** Within the hyphal cells, the paired nuclei fuse, followed by meiosis and development of ascospores. Some ascomycetes form fruiting bodies called conidia.
- **Basidiomycete fungi form mushrooms.** Cells with paired nuclei (secondary mycelium) form large fruiting bodies called mushrooms. The paired nuclei fuse to form the diploid basidium, which generates haploid basidiospores. The basidiospores develop underground hyphae or mycorrhizae that interconnect plant roots.
- **Oomycetes are heterokont protists.** Oomycete cells lack chitin, and their reproductive forms include motile cells with pairs of dissimilar flagella. They form infective filaments that superficially resemble fungi.

20.3 Algae

Algae serve as primary producers in all ecosystems, most crucially for aquatic and marine habitats. In aquatic and marine ecology, the algae, together with photosynthetic bacteria, are known as **phytoplankton** (see Chapter 21). All algae possess chloroplasts. The primary endosymbiotic algae, or "true algae," are products of a single ancestral endosymbiosis that also gave rise to land plants. The biochemistry and cell structures of true algae and land plants are similar; thus, the study of photosynthesis in the alga *Chlorella* by Martin Kamin, Melvin Calvin, and others has advanced our understanding of plant physiology (discussed in Chapter 15).

Other photosynthetic eukaryotes, or secondary endosymbiotic algae, arose from protists that engulfed a primary or secondary endosymbiont. Secondary endosymbionts show "mixotrophic" nutrition, involving both phototrophy and heterotrophy. For example, dinoflagellate "algae" are voracious predators on smaller protists. The heterokont algae, diatoms and kelps, are covered in this section. Dinoflagellates are covered under alveolates (Section 20.5).

Green Algae, or Chlorophyta

The primary endosymbiotic algae include two major clades: Chlorophyta, or green algae, and Rhodophyta, or red algae, although not all members of each group appear green or red, respectively. In most cases, the chlorophytes appear green because the color of their chlorophyll *a* is not obscured by secondary pigments.

Unicellular green algae. An important model system for genetics and phototaxis is *Chlamydomonas reinhardtii*, a unicellular alga common in freshwater systems as well as Antarctic pools. The genetics of cell cycle regulation in *C. reinhardtii* provides clues to the role of homologous regulators in human tumor cells.

C. reinhardtii possesses a symmetrical pair of flagella, a common pattern for green and red algae and their gametes (**Fig. 20.18A**). The alga swims by beating its flagella

Figure 20.18 A single-celled green alga: *Chlamydomonas reinhardtii*. **A.** *Chlamydomonas* has a green chloroplast and grows as a photoautotroph (cell diameter, 10–20 μm). A symmetrical pair of flagella pulls the cell forward. **B.** *Chlamydomonas* reproduces asexually as haploid cells, or it generates gametes that fuse into a zygote that immediately undergoes meiosis to regenerate haploid cells.

back toward the cell, like a breast stroke. *Chlamydomonas* cells are mostly haploid, reproducing by asexual cell division (**Fig. 20.18B**). Sexual reproduction occurs by fusion of opposite mating types to form a zygote, which loses flagella and forms a spiny protective coat. The zygote undergoes meiosis to regenerate haploid cells.

The cell ultrastructure of *Chlamydomonas* is typical of algal cells (**Fig. 20.19**). The nucleus is cupped by a single chloroplast, which is surrounded by a double membrane. The double membrane indicates a primary endosymbiont; the inner membrane derives from the ancestral bacterium, and the outer membrane derives from the engulfing host. Within the chloroplast is a pyrenoid, an organelle that concentrates bicarbonate (HCO_3^-) and converts it to CO_2 for fixation. The pyrenoid is surrounded by one or more starch bodies for energy storage. The starch is

The single chloroplast fills much of the cell and wraps around the nucleus. Within the chloroplast lies a pyrenoid, a structure for concentrating bicarbonate ion for conversion to CO_2. The pyrenoid is surrounded by starch bodies that store high-energy compounds. A contractile vacuole maintains constant osmotic pressure. **B.** Electron micrograph of *C. reinhardtii* shows the nucleus, contractile vacuole, chloroplast, pyrenoid, and other organelles. *Source*: Ohad, et al. 1967. Rockefeller U. Press.

broken down to sugars as needed, followed by glycolysis and respiration in the mitochondria. Osmolarity is maintained by the contractile vacuole. The *Chlamydomonas* cell is encased in a cell wall predominantly composed of glycoprotein. Other green algae have cellulose cell walls, similar to those of plants.

Filamentous green algae. An example of a filamentous alga is *Spirogyra*, a common pond dweller known for its spiral chloroplasts (**Fig. 20.20A**). *Spirogyra* species form long, unbranched chains of cells. Like *Chlamydomonas*, the haploid form predominates; but unlike the unicellular alga, *Spirogyra* forms neither flagellated gametes nor zoospores. Instead, its sexual reproduction requires alignment of two stalks of opposite mating type (**Fig. 20.20B**). Cells **conjugate** (form cytoplasmic bridges) between the two stalks. The "male" gametes are those whose cytoplasm inserts through the conjugation bridge to join that of the "female" gamete. As the gametes fuse, a row of empty cell walls is left behind (**Fig. 20.20C**). The zygote eventually hatches and germinates a new chain of cells.

Sheet-forming green algae. Some forms of marine algae grow in undulating sheets. An example familiar to beach bathers is the "sea lettuce" *Ulva* (**Fig. 20.21A**). Sheets of *Ulva* can extend over many square meters, although they are only two cells thick (see **Fig. 20.21A** inset). The *Ulva* life cycle consists of classic alternation of generations between haploid and diploid forms (**Fig. 20.21B**). Haploid sheets of cells (the gametophyte) produce symmetrically biflagellate gametes, similar to unicellular *Chlamydomonas*. But when *Ulva* gametes fuse, the zygote grows into an immense diploid sheet of cells. This sporophyte (diploid multicellular body) appears similar in form to the gametophyte. The sporophyte eventually undergoes meiosis, releasing haploid zoospores with two pairs of flagella. The zoospores undergo mitosis and regenerate the gametophyte.

Like the fungi, marine and freshwater algae show many complex and beautiful forms. Colonial algae such as *Volvox* (**Fig. 20.22A**) generate geodesic spheres of biflagellate cells similar to *Chlamydomonas*. Their flagella point outward from the colony, propelling it forward and drawing nutrients across its surface. Each cell of *Volvox* connects by cytoplasmic bridges to five or six of its neighbors. The colony reproduces by generating daughter colonies within the sphere, which grow until the outer sphere falls apart, liberating the daughters.

Other green algae, such as *Cymopolia*, form long calcified stalks punctuated by tufts of green filaments, where most of the photosynthesis occurs (**Fig. 20.22B**). Yet another group, the **siphonous algae**, are known for forming long, siphon-like tubes and fronds without cell partitions—in effect, giant organisms that are unicellular (**Fig. 20.22C**). The siphonous species *Caulerpa taxifolia* has become a notorious pest, destroying coastal communities in the Mediterranean Sea and off the coast of California. Originally bred for aquariums, *C. taxifolia* is exceptionally cold resistant and produces toxins that prevent grazing.

Figure 20.23 **Red algae: *Porphyra*.** **A.** *Porphyra* forms large multicellular sheets. **B.** Known as *nori*, the harvested and dried red sheets are used to wrap sushi, a Japanese delicacy.

Red Algae, or Rhodophyta

Red algae, or rhodophytes are colored red by the photopigment phycoerythrin. Phycoerythrin absorbs efficiently in the blue and green range, which green algae fail to absorb. Because the shorter wavelengths of blue and green penetrate to greater depths, the red algae can colonize deeper marine habitats than green algae.

Rhodophytes include unicellular, filamentous, and multicellular forms. Several kinds are human food sources. *Porphyra* forms large sheets harvested in Japan for use as nori, for wrapping sushi, a delicacy that includes rice, vegetables, and uncooked fish (**Fig. 20.23**). Red algae contain valuable polymers called sulfated polygalactans (sugar polymers with sulfate side chains). Sulfated polygalactans include agar, used to solidify microbial growth media; agarose, a processed sugar derivative used to form electrophoretic gels; and carrageenan, an additive used in processed foods.

Rhodophytes such as *Plocamium* form delicate branched filaments (**Fig. 20.24A**). Still others, the **coralline algae**, calcify their fronds into hardened shapes similar to corals (**Fig. 20.24B**). The calcified bodies of corallines grow at greater depths than corals, and they often form the foundation for coral reefs.

THOUGHT QUESTION 20.5 How are coralline algae able to grow at greater depths than coral?

Algae serve as symbiotic partners for many important living systems. For example, certain algae grow in intimate association with fungi to form unified structures called **lichens**, important colonizers of dry and cold habitats (discussed in Chapter 21). A form of algal-fungal ground cover similar to lichens is **cryptogamic crust**, common on desert soil. Still other algae grow within the cells of paramecia, hydras, and corals, providing photosynthetic nutrition in exchange for protection.

Secondary Endosymbiotic Algae: Diatoms and Kelps

Several phototrophs long classified as algae have since been reclassified as protists that once engulfed a primary endosymbiotic alga. Their cell structure shows two traits that distinguish them from primary endosymbionts:

- **More than two membranes surround the chloroplast.** The extra membranes derive from the cell membrane of the engulfed alga.
- **Mixotrophic metabolism includes heterotrophy.** By contrast, the primary endosymbionts are near-obligate autotrophs, catabolizing only the simplest substrates, such as acetate.

Several major groups of secondary-symbiont algae are heterokonts (stramenopiles). These include the diatoms, phylum Bacillaraceae; the brown algae, or Phaeophy-

Figure 20.24 **Diverse red algae.** **A.** *Plocamium* forms delicate feather-like fronds. **B.** The coralline alga *Mesophyllum* forms calcified fronds that provide a foundation for coral reefs.

ceae, such as kelps; the golden algae, or Chrysophyceae, mainly pale-colored flagellates; the yellow-green algae, or Xanthophyceae; and other less studied forms of phytoplankton. Flagellated species of heterokont algae always show a pair of differently shaped flagella. Typically, one flagellum is brush-like with side branches, while the other is shorter, often wrapped around the cell, its function uncertain.

Diatoms, or Bacillariophyta. Diatoms are unicellular heterokonts found ubiquitously in aquatic and marine waters. The cell grows a unique kind of bipartite shell called a **frustule**. The frustule is composed of silica (cross-linked silicon dioxide, SiO_2). Frustules of decomposed diatoms eventually sediment on the ocean floor, where they contribute to sedimentary rocks or wash up to shore as beach sand. Their diverse species show high sensitivity to environmental parameters such as pH, and the frequency of their shells in sediment can be used to track a lake's environmental history.

Frustules of different species form an extraordinary range of shapes with intricate pore formations (**Fig. 20.25A**). The shapes fall into two classes, either centric, with radial symmetry, or pennate, with bilateral symmetry. All, however, pose a unique challenge to cell division: As the diatom grows and fissions, each daughter cell receives one parental half of the frustule while forming a new half fitting *within* the parental half, like the bottom dish of a Petri plate (**Fig. 20.25B**). Thus, each generation results in an inexorable decline in size of the organism. As its cell size reaches a critical point, the diatom must undergo meiosis to generate gametes. When the gametes fuse, they form a zygote that expands to the original size of the diatom before forming the first frustule.

Brown algae, or Phaeophyceae. Brown algae, such as kelps, possess vacuoles of leucocin, an oily lipid for energy storage whose color gives the organism a brown or yellow tint. Kelps are familiar to ocean bathers as the long, dark brown blades that root near the beach until the surf rips the blades off and tosses them ashore (**Fig. 20.26A**). Kelps support important communities of multicellular organisms, known as kelp forests. The most famous kelp forests are those of the unrooted **sargassum weeds**, which float upon the Sargasso Sea. Sargassum consists of stalks with photosynthetic blades and round gas bladders to keep the organism afloat (**Fig. 20.26B**). Sargassum supports a complex food chain of invertebrate and vertebrate animals, including worms, crabs, and fish.

TO SUMMARIZE:

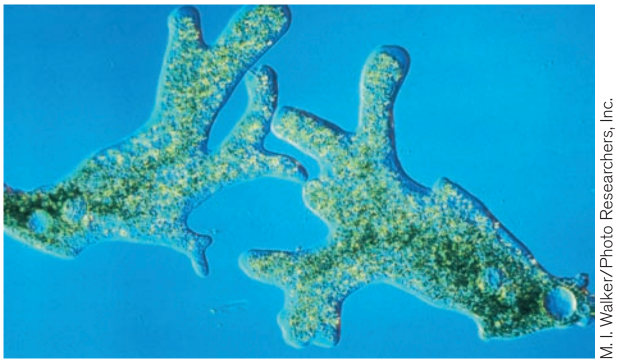
- **Chlorophyta (green algae)** absorb red and blue light and grow near the top of the water column. Green algae include unicellular, filamentous, and sheet forms.
- **Rhodophyta (red algae)** have the accessory photopigment phycoerythrin, which absorbs green and longer-wavelength blue light, enabling growth at greater depths. Red algae include species of diverse forms, many of which are edible for humans.
- **Secondary endosymbiotic algae** are derived from protists that had engulfed primary symbiotic algae. They are mixotrophs, combining phototrophy and heterotrophy.
- **Diatoms are heterokonts with silicate shells called frustules.** Diatoms replicate by an unusual division cycle generating successively smaller frustules.
- **Kelps are heterokonts that grow in long sheetlike fronds.** Kelps play an important role in the ecology of the open ocean as well as the ecology of marine beaches.

20.4 Amebas and Slime Molds

The ameba is familiar to most of us as an apparently amorphous form of microscopic life, capable of engulfing and consuming prey in a dramatic fashion (**Fig. 20.27**). While the ameba's shape is exceptionally variable, the pseudopods, or "false feet," that it extends, far from being amorphous, are complex structures that undertake highly controlled and specific movements. Most amebas are free-living predators in soil or water. They extend in size up to 5 mm, large enough to consume bacteria, algae, ciliates, smaller amebas, and even invertebrates such as rotifers. A few are dangerous parasites of humans or animals. Furthermore, free-living amebas can harbor bacterial pathogens such as *Legionella pneumophila*, which contaminates water supplies and air ducts. The bacteria cause legionellosis, an often fatal form of pneumonia. The host ameba enables the pathogen's persistence and transmission to human hosts.

THOUGHT QUESTION 20.6 What might happen when an ameba phagocytoses algae?

NOTE: The taxonomy of amebas and slime molds remains problematic, with diverse views as to the number of clades, their relatedness, and their degree of divergence.



M. I. Walker/Photo Researchers, Inc.

Figure 20.27 Amebas with lobe-shaped pseudopods. *Amoeba proteus* moves by extending its pseudopods.

Diverse Kinds of Amebas

Ameba-like cell forms occur in many different species. Some species persist as an ameba throughout all or most of the life cycle. Others can convert to flagellates, particularly when the habitat fills with water, a low-viscosity condition favoring flagellar motility. Still other protist species, such as dinoflagellates, never become fully amebic, but they can extend a pseudopod to engulf prey.

Different kinds of amebas have different kinds of pseudopods. The "classic" ameba (phylum Amoebozoa or Lobosea) has lobe-shaped pseudopods (**Fig. 20.27**). Lobe-shaped pseudopods have the most variable shape. A different form is the sheetlike pseudopod, or **lamellar pseudopod**. Lamellar pseudopods are extended by dinoflagellates. Similar lamellar pseudopods are generated by human white blood cells such as leukocytes. Finally, needlelike pseudopods, or filopodia, are thin extensions reinforced by microtubules. Filopodia are made by the shelled amebas (phylum Cercozoa), such as Foraminifera (spiral shells) and Radiolaria (radial form).

Amebas Move by Cytoplasmic Streaming into Pseudopods

The extension of lobe-shaped and lamellar pseudopods has been studied closely for its relevance to human white blood cells (for more on white blood cells as host defenses, see Chapter 23). The mechanism of pseudopod motility remains poorly understood, but it is known to involve a sol-gel transition between cortical cytoplasm (just beneath the cell surface) and the cytoplasm of the deeper interior (**Fig. 20.28**). The tip of a pseudopod contains a gel of polymerized actin beneath its cell membrane. From the center of the ameba, liquid cytoplasm (sol) containing actin subunits streams forward along microtubular "tracks," powered by ATP hydrolysis. The actin subunits stream into the pseudopod, where they polymerize, forming a gel. The gel region grows, pushing the membrane forward and extending the pseudopod. As the gel is pushed backward, it resolubilizes to continue the cycle.

Ameba Reproduction and Genetics

Amebas can be uninuclear or multinuclear. They are usually haploid and reproduce asexually by nuclear mitosis, without dissolution of the nuclear membrane, followed by fission of the cytoplasm. Some species do have reproductive alternatives, such as cyst formation, gamete fusion and meiosis, and even growth of flagella in a favorable habitat.

THOUGHT QUESTION 20.7 What kind of habitats would favor a flagellated ameba?

Ameba genetics is poorly understood, but the sequence of at least one genome is near completion, that of the intestinal parasite *Entamoeba histolytica*. The strain being sequenced contains 20 Mb of DNA in 14 chromosomes; some of these are linear, whereas others are circular. Closely related strains show considerable variation in organization, suggesting that ameba genomes (like their cytoplasm) undergo extensive rearrangement.

Slime Molds Generate Multicellular or Multinucleate Fruiting Bodies

Some amebas conduct a life cycle in which thousands of individuals aggregate into a complex differentiated fruiting body (**Fig. 20.29A**). Such an organism is called a **slime mold**. Slime molds, as the name implies, were originally classed with fungi because their fruiting bodies superficially resemble fungal reproductive forms. There are two kinds of slime molds: **cellular slime molds**, in which the individual cells remain cellular, and **plasmodial slime molds**, in which the mass of aggregating cells becomes a multinucleate single cell.

David Scharf/Peter Arnold

A well-studied example of a cellular slime mold is *Dictyostelium discoideum*, historically an important model system for multicellular development (**Fig. 20.29**). *D. discoideum* amebas are relatively small, about 10 μm, but large enough to consume bacteria. They can be cocultured on a plate with *Escherichia coli*. As the haploid amebas consume bacteria, they divide asexually until their food runs out. At this point, a few amebas begin to emit the aggregation signal molecule cyclic AMP. An ameba emitting cyclic AMP attracts other amebas nearby, which move toward the center and begin emitting cyclic AMP as well. Successive waves of cyclic AMP continue to attract thousands of amebas to the center, where they pile on top of each other to form a slug as long as 1 mm. The slug then migrates, attracted by light and warmth, to find an appropriate place to form a fruiting body and disperse its spores.

The slug at last differentiates into a fruiting body, a spherical sporangium supported upon a stalk of largely empty cells that emerges from a basal disk. The sporangium then releases spores (also called cysts), which are dispersed on air currents and can remain viable for several years. When a spore detects chemical signals from bacteria, it germinates an ameba to feed on them.

Note that the entire reproductive cycle just described is asexual; the amebas and their differentiated structures remain haploid throughout. *D. discoideum* amebas do have a sexual alternative in which cells of opposite mating type can fuse to form a diploid zygote, then undergo meiosis, restoring haploid amebas.

By contrast, the amebas of a plasmodial slime mold, such as *Physarum polycephalum*, aggregate only following gamete fusion to form diploid cells. The diploids then aggregate and become transformed into **plasmodium**, a giant multinucleate cell that can spread over an area of many square centimeters. Out of the plasmodium arise fruiting bodies whose sporangia undergo meiosis, producing haploid spores. A large plasmodium can occasionally be seen as a yellow mass of slime spreading over decaying wood.

NOTE: Distinguish the term plasmodium (a large multinucleate cell) from the genus *Plasmodium* (an apicomplexan parasite, such as *Plasmodium falciparum*, which causes malaria.)

C. Hemleben/©Cushman Foundation for Foraminiferal Research, Inc.

Figure 20.30 **Filamentous and shelled amebas.** **A.** Shells (tests) of radiolarians (colorized SEM). **B.** A live foraminiferan, *Globigerinella aequilateralis* (darkfield).

Filamentous and Shelled Amebas

A distinct clade of amebas (phylum Cercozoa) form needlelike pseudopods. Most of these amebas are encased by mineral shells called **tests** (**Fig. 20.30A**). A major class of shelled amebas is the **radiolarians**, whose shells are made of silica perforated with numerous holes through which pseudopods appear to radiate in all directions. Many different kinds of radiolarians exist today, and many can be recognized in fossil rock. A second class of shelled amebas is the **foraminiferans** (**Fig. 20.30B**). The foraminiferans, or forams, generate shells of calcium carbonate as chambers laid down in helical succession. Their pseudopods all extend from one opening in the most recent chamber.

Radiolarians and forams grow in marine and aquatic habitats. Their shells make up a substantial part of reef formations, sedimentary rock, and beach sand. Forams, in particular, play a key role in geological surveys as indicators of petroleum deposits.

TO SUMMARIZE:

- **Amebas** have an amorphous form that moves using pseudopods. In different species, pseudopods are lobe-shaped, lamellar, or filamentous (filopodia).
- **Cytoplasmic streaming** through cycles of actin polymerization and depolymerization drives the extension and retraction of pseudopods.
- **Slime molds** show an asexual reproductive cycle in which individual amebas attract each other and aggregate to form a slug. The slug develops into a fruiting body that forms spores.
- **Radiolarians** have silicate shells penetrated by filamentous pseudopods.
- **Foraminiferans** have calcium carbonate shells with helical arrangement of chambers, the most recent of which opens to extend filamentous pseudopods.

20.5 Alveolates: Ciliates, Dinoflagellates, and Apicomplexans

The Alveolata include voracious predators such as the ciliated protists (**Fig. 20.31A**). Alveolates are named for the flattened vacuoles called alveoli within their outer cortex (**Fig. 20.31B**; see also **Fig. 20.7A**). Some alveoli contain plates of stiff material, such as protein, polysaccharide, or minerals. Besides alveoli, most alveolate protists possess other kinds of cortical organelles such as extrusomes for delivery of enzymes or toxins, bands of microtubules for reinforcement, and whiplike cilia or flagella. The alveolate cell form is highly structured, in contrast to the amorphous shape of amebas. Major groups of alveolates include ciliates, dinoflagellates, and apicomplexans.

Ciliates Possess Numerous Cilia for Motility and Prey Capture

A diverse group of alveolates known as Ciliophora, or ciliates, possess large numbers of cilia, short projections containing 9+2 microtubules, whose whiplike action is driven by ATP (for review, see Appendix 2). The cilia

Extrusomes secrete various enzymes or toxins. **C.** Intracellular organelles of a paramecium include the contractile vacuole, digestive vacuoles, and the oral groove for ingestion.

beat in coordinated waves that maximize the efficiency of motility. Cilia serve two functions:

- **Cell propulsion.** Coordinated waves of beating cilia, usually covering the cell surface, propel the cell forward.
- **Acquiring food.** By generating water currents into the mouth of the cell, cilia, usually arranged in a ring around the mouth, bring food into the cell.

Ciliate cell structure. *Paramecium* is one of the most studied ciliates. Paramecia feed on bacteria and in turn are consumed by larger ciliates such as *Didinium* (**Fig. 20.31A**). They can also take up smaller particles through endocytosis by specialized pores in their cortex, called parasomal sacs.

The cell structure of *Paramecium* includes an **oral groove** for uptake of food driven by the beating cilia (**Fig. 20.31C**). Once ingested through the oral groove, a food particle travels within the digestive vacuole in a circuit around the cell. The digestive vacuole ultimately empties into the cytoproct, a specialized vacuole for the discharge of waste outside the cell. Paramecia maintain osmotic balance by means of a **contractile vacuole**, a vacuole that withdraws water from the cytoplasm to shrink it or contracts to expand it. Contractile vacuoles are widespread among protists and algae, but their mode of action has been most studied in paramecia.

Genetics and reproduction. Most ciliates have a complex genetic system involving one or more **micronuclei** and **macronuclei**. The micronucleus contains a diploid set of chromosomes that undergoes meiosis for sexual exchange. For gene expression, however, the micronucleus generates hundreds of copies of its DNA within a macronucleus. This phenomenon has surprising applications for the study of human aging (**Special Topic 20.2**).

The macronucleus is formed by genetic rearrangement and excision of some micronuclear DNA. Only macronuclear genes are transcribed to RNA and translated to protein. When a ciliate reproduces asexually, the micronucleus undergoes mitosis, whereas the macronucleus divides by a different mechanism that is poorly understood. Cell division occurs across the long axis, necessitating generation of a new oral groove for the posterior daughter cell and a new cytoproct for the anterior daughter cell—again, a process poorly understood.

Most ciliates are diploid and never produce haploid gamete cells. Instead, they reproduce sexually

Special Topic 20.2 A Ciliate Model for Human Aging

An unusual model for a molecular process of human aging is seen in the ciliate *Oxytricha fallax*. Like all ciliates, *Oxytricha* cells exchange their micronuclei during sexual reproduction by conjugation (**Fig. 1A**). After transfer, when the new micronuclei form, the chromosomes of the micronucleus are subsequently replicated into a thousand copies, forming a macronucleus to serve gene expression.

As the macronucleus forms, the chromosomes fragment into many pieces. During this process, virtually all noncoding DNA, about 95% of the genome, is eliminated. In *Oxytricha*, the fragmentation is particularly extreme; the genome is cut into tens of thousands of pieces until each cut-down chromosome contains only one to three genes. And all the tens of thousands of cut-down chromosomes must possess new **telomeres**, special end sequences of DNA that protect the chromosome termini. A telomere is a special form of DNA in which the 3′ OH end of the double helix extends beyond the 5′ OH end and doubles back to form base pairs that enable “filling in” of the last portion of the helix.

In multicellular animals, telomeres usually shorten throughout the life of an individual. Telomere shortening is associated with chromosome damage as part of the process of aging. Thus, telomeres are of vital importance to research on human aging.

With its abundant supply of telomeres, the obscure protist *Oxytricha* serves as a key model system for telomere research. The three-dimensional structure of *Oxytricha* telomeres has been determined by George Thomas and colleagues at the University of Missouri, using X-ray crystallography, and by Juli Feigon and colleagues at the University of California, Los Angeles, using nuclear magnetic resonance (NMR) spectroscopy (techniques discussed in Chapter 2). The structure consists of a quadruple helix in which the end of each DNA strand doubles back, and four guanines form base pairs with each other (**Figs. 1B** and **C**). The resulting knot-like structure protects the chromosomal end from degradation by exonucleases. Similar structures have since been observed for human telomeres. The structure of telomeres yields clues to the function of telomerases in maintaining the length of our chromosomes.

Figure 20.32 **Conjugation.** **A.** Two paramecia conjugating (light micrograph). **B.** In conjugation, two paramecia of opposite mating type form a cytoplasmic bridge. The $2n$ micronucleus of each cell undergoes meiosis. Each macronucleus, as well as three out of four meiotic products, disintegrates. The haploid micronuclei undergo mitosis forming two daughter micronuclei. Daughter nuclei from each cell are exchanged across the cytoplasmic bridge, then fuse with their respective counterparts, restoring $2n$ micronuclei. The cells come apart, and each micronucleus generates a new macronucleus.

by exchanging haploid micronuclei. Micronuclei are exchanged through **conjugation**, a process in which two cells of opposite mating type join by a cytoplasmic bridge and exchange nuclear products of meiosis (**Fig. 20.32**). During fusion, the micronucleus of each cell undergoes meiosis to form four haploid nuclei. Three out of four of the haploid nuclei disintegrate, as does the entire macronucleus. The haploid micronuclei then undergo mitosis, and one of each daughter nuclei is exchanged across the cytoplasmic bridge. Each transferred nucleus then fuses with its haploid counterpart, restoring diploidy. The two cells come apart, and each recombined micronucleus generates a new macronucleus.

THOUGHT QUESTION 20.8 Compare and contrast the process of conjugation in ciliates and bacteria (see Chapter 9).

THOUGHT QUESTION 20.9 For ciliates, what are the advantages and limitations of conjugation, as compared with gamete production?

Stalked ciliates. Some ciliates adhere to a substrate and use their cilia primarily to obtain prey (**Fig. 20.33A**). **Stalked ciliates** such as *Stentor* and *Vorticella* possess a ring of cilia surrounding a large mouth. The ciliary beat is specialized to draw large currents of water and whatever prey it carries. Stalked ciliates are commonly found in pond sediment and in wastewater during biological treatment by microbial digestion, where they are attached to flocs of filamentous bacteria.

Another group of stalked ciliates, the **suctorians** (**Fig. 20.33B**), possess cilia for only a short period after a daughter cell is released by the stalked cell. The daughter cell swims by ciliary motion until it finds a good habitat to settle, whereupon its cilia are replaced by knobbed tentacles similar to the filopodia of shelled amebas. Suctorians prey on swimming ciliates such as paramecia.

Dinoflagellates Are Phototrophs and Predators

The dinoflagellates (class Dinophyceae) are a major group of marine phytoplankton, essential to marine food chains. Like ciliates, they are highly motile, but instead of numerous short cilia, dinoflagellates possess just two long flagella, one of which wraps along a crevice encircling the cell (**Fig. 20.34A**). Dinoflagellates are secondary or tertiary algal endosymbionts. They have a chloroplast derived from a red alga, which in some species was later replaced by a heterokont alga, itself a secondary endosymbiont (**Fig. 20.34C**). Some dinoflagellates possess carotenoid pigments that confer a red color. Blooms of red dinoflagellates cause the

famous red tide, which may have inspired the biblical story of the plague in which water turns to blood (**Fig. 20.34B**).

The armor-plated appearance of a dinoflagellate results from its stiff alveolar plates, composed of proteins or calcified polysaccharides (**Fig. 20.34C**). The complex outer cortex includes various extrusomes (organelles that extrude a defensive substance) and endocytic pores, as well as a species-specific pattern of alveolar plates. Dinoflagellates supplement their photosynthesis by predation, extending a lamellar pseudopod to engulf prey (**Fig. 20.34D**). Some dinoflagellates have evolved to lose their chloroplasts altogether, becoming obligate predators or parasites.

Some phototrophic dinoflagellates inhabit other organisms as endosymbionts. Their hosts include shelled amebas, sponges, sea anemones, and most importantly, reef-building corals. Coral endosymbionts, known as **zooxanthellae**, are vital to reef growth. The zooxanthellae are temperature sensitive, and their health is endangered by global warming. Rising temperatures in the ocean lead to coral bleaching (the expulsion of zooxanthellae), after which the coral dies.

Figure 20.35 ***Toxoplasma gondii*: An apicomplexan parasite.** Numerous *T. gondii* parasites infecting myocardium (a cell of heart muscle; stained tissue section, light micrograph).

Apicomplexans Are Specialized Parasites

Apicomplexans form a major group of parasites of humans and other animals. They are characterized by the presence of the **apical complex**, a highly specialized structure that facilitates entry of the parasite into a host cell. An example of an apicomplexan is *Toxoplasma gondii*, a parasite commonly carried by cats and transmissible to humans, where it can harm a developing fetus (**Fig. 20.35**). Like the ciliates and dinoflagellates, apicomplexans possess an elaborate cortex composed of alveoli, pores, and microtubules. But as parasites, apicomplexans have undergone extensive reduc-

The apical complex facilitates invasion, then dissolves as the merozoite transforms into an intracellular form.

tive evolution, losing their flagella or cilia. They possess a unique organelle called the **apicoplast**, derived by extensive genetic reduction from an endosymbiotic chloroplast. No capacity for photosynthesis remains, but the apicoplast provides one essential function in fatty acid metabolism.

The best known apicomplexan is *Plasmodium falciparum*, the main causative agent of **malaria**, the most important parasitic disease of humans worldwide (**Fig. 20.36A**). *P. falciparum* is carried by mosquitoes, which transmit the parasite to humans when the insect's proboscis penetrates the skin. The disease is endemic in areas inhabited by 40% of the world's population; it infects hundreds of millions of people and kills more than a million African children each year.

The transmitted parasites invade the liver, then develop into the **merozoite** form that invades red blood cells (**Fig. 20.36B**). The merozoite first contacts a red blood cell through interaction between its surface proteins on the apical complex and specific host receptors. The apical complex consists of a pair of secretory organelles capped by the "conoid," a ring of microtubules that injects enzymes that aid entry of the parasite. The cone-like tip of the apical complex penetrates the host cell, enabling secretion of lipids and proteins that facilitate invasion. Eventually, the entire merozoite enters the host cell, leaving no traces of the parasite on the host cell surface. Thus, the internalized parasite becomes invisible to the immune system until its progeny burst out.

P. falciparum acquires resistance rapidly and no longer responds to drugs such as quinine that nearly eliminated the disease half a century ago. The life cycle and molecular properties of *P. falciparum* have been studied extensively for clues as to the development of new antibiotics and vaccines. The elaborate life cycle of *P. falciparum* and other parasites involves several common features:

- **Schizogony**, mitotic reproduction of a diploid or haploid form to achieve a large population within a host tissue.
- **Gamogony**, the differentiation of haploid cells into male and female gametes capable of fertilization.
- **Sporogony**, mitotic reproduction and development of the diploid zygote into a spore-like form transmissible to the next host.

In the case of malaria (**Fig. 20.37**⏯), whip-shaped sporozoites injected by the mosquito invade the liver,

where they undergo schizogony in the form of merozoites. The merozoites invade the red blood cells, where they feed on hemoglobin. The red cells burst, liberating progeny merozoites that invade another round of red cells. The bursting of red blood cells also releases cell fragments that trigger the cyclic fevers characteristic of malaria.

Some of the merozoites in the bloodstream undergo meiosis, generating pre-gamete cells, or gamonts. The gamonts multiply and mature (a process called gamogony), then they are acquired by bloodsucking mosquitoes. In the mosquito's midgut, the gamonts develop into female eggs and flagella-like male cells. The male cells fertilize the egg cells, and the resulting zygotes undergo mitosis (sporogony) and differentiate into sporozoites, which enter the salivary gland for transmission to the next human host.

The nuclear genome of *P. falciparum* consists of 24 Mb contained in 14 chromosomes. Sequence annotation and expression studies predict 5,300 protein-encoding ORFs, comparable to the number in a yeast genome. The parasite has lost many genes encoding enzymes and transporters while expanding its repertoire of proteins involved in antigenic diversity. In addition, the parasite contains two smaller nonnuclear genomes: that of its mitochondria and that of the chloroplast-derived apicoplast.

Unique metabolic and transport components emerge from its genome that offer promising targets for drug design. For example, the fatty acid biosynthesis occurring within the apicoplast is targeted by triclosan and other antibiotics. Other promising targets for antimalarial drugs are the unique proteases required to digest hemoglobin within the *P. falciparum* food vacuole.

TO SUMMARIZE:

- **Ciliates are covered with numerous cilia.** Cilia provide motility and help capture prey. Ciliates undergo complex reproductive cycles involving exchange of micronuclei through conjugation.
- **Dinoflagellates are phototrophic predators.** Dinoflagellates are tertiary endosymbiotic algae. Their alveoli contain calcified plates; they have paired flagella, one of which is used for propulsion. Predation occurs by extension of a lamellar pseudopod.
- **Apicomplexans are parasites that penetrate host cells.** The apicoplast is a specialized organ for cell penetration. Apicomplexans such as *Plasmodium falciparum* conduct complex life cycles involving several different cell forms within mammalian and arthropod hosts.

20.6 Trypanosomes, Microsporidia, and Excavates

Several other major groups of protists are known mainly for organisms that are human parasites. These parasites cause some of the most gruesome and debilitating conditions known to humanity; for example, *Leishmania major,* the cause of leishmaniaisis, causes swelling and decay of the extremities and eventually death (**Figs. 20.38A** and **B**). The leishmanias are related to **trypanosomes**, ruffle-shaped cells with a cortical skeleton of microtubules culminating in a long flagellum. *Trypanosoma brucei*, carried by the tsetse fly, causes African sleeping sickness (**Fig. 20.38C**), whereas *T. cruzi*, carried by the bedbug, causes Chagas' disease, a debilitating infection of the internal organs. Chagas' disease is prevalent in South and Central America, and global warming is expected to expand its range north. Like apicomplexans, trypanosomes show genetic evidence of descent from chloroplast-bearing flagellates, in this case Euglenida (a clade distinct from Alveolata). Euglenida includes *Euglena gracilis*, a chloroplast-containing flagellate that is frequently presented to students for microscopic observation.

The rise of AIDS and the growth of elderly and immunocompromised populations have led to the emergence of new opportunistic pathogens. An example is found in Microsporidia, a clade that falls within the Opisthokonta, including animals and fungi (see **Fig. 20.3**). The microsporidian *Encephalitozoon intestinalis* is now a common intestinal pathogen among susceptible populations. Analogous to apicomplexans, the microsporidians possess a specialized invasion complex that enables entry to host cells, typically macrophages.

Excavata, a highly degenerate group of parasites, includes the intestinal parasite *Giardia lamblia*, an organism familiar in North America, Europe, and Russia (**Fig. 20.38D**). Giardia is a frequent nemesis of day-care centers as well as a contaminant of aquatic streams frequented by bears and other wildlife. *Giardia* occasionally contaminates community water supplies and has become endemic in some Russian cities. *Giardia* and other excavates are noted for their anaerobic metabolism and their complete absence of mitochondria, reflecting their absolute dependence on the anaerobic intestinal environment of their hosts.

Concluding Thoughts

The microbial eukaryotes, including fungi, algae, and many kinds of protists, serve many diverse roles in our ecosystems. A survey of protists may leave an impression that most protist clades exist primarily to parasitize humans. However, recent genetic surveys based on DNA sequence analysis of environmental communities suggest the existence of twice as many protist clades in nature as we have studied to date. Most of these unknown clades have no direct connection with humans, yet they may fill crucial niches in the ecosystems on which human existence depends. The remaining chapters in Part 4 emphasize the interconnections among many kinds of microbes that form the foundations of Earth's biosphere.

CHAPTER REVIEW

Review Questions

1. Discuss the evidence for the branching of fungi and animals within one clade, the Opisthokonta, which is distinct from algae and protists.
2. How do primary symbiont algae differ from secondary and tertiary symbiont algae? Compare with respect to cell structure and nutritional options.
3. Compare and contrast the molecular basis of motility in amebas and ciliates. Cite particular species.
4. Compare and contrast the traits of these heterokont protists: kelps, diatoms, and dinoflagellates. Compare with respect to cell structure, colony organization, and nutritional options.
5. Summarize the key traits of fungi. What do fungi have in common with protists, and how do they differ?
6. Outline the life cycles of the major phyla of fungi: Chytridiomycetes, Zygomycetes, Ascomycetes, and Basidiomycetes. Explain their ecological significance.
7. Compare and contrast the traits of green and red algae (Chlorophyta and Rhodophyta, respectively).
8. Outline the life cycle of the slime mold *Dictiostelium discoidium*. Compare and contrast its features with that of fungi that produce fruiting bodies, such as Basidiomycetes.
9. Outline the complex parasitic life cycles of an apicomplexan parasite and a trypanosome. Cite evidence of reductive evolution, as well as of evolution of elaborate specialized structures to facilitate the parasite's life cycle.

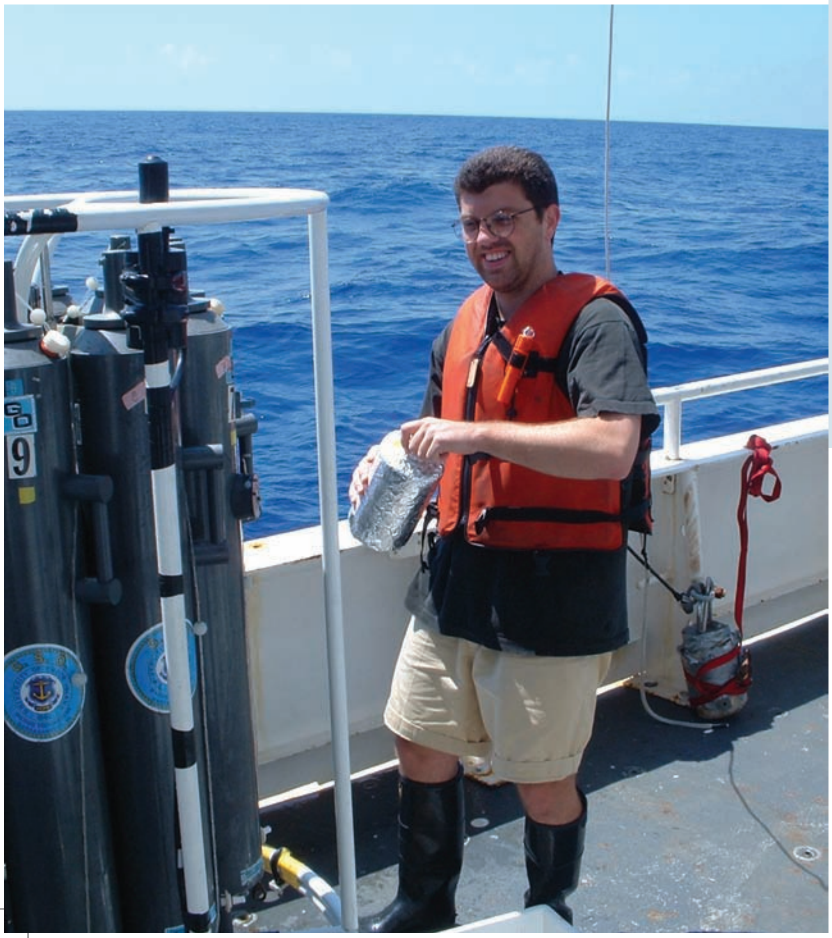
Chapter 21

Microbial Ecology

21.1 Microbes in Ecosystems
21.2 Microbial Symbiosis
21.3 Marine and Aquatic Microbiology
21.4 Soil and Subsurface Microbiology
21.5 Microbial Communities within Plants
21.6 Microbial Communities within Animals

Of all organisms, microbes grow in the widest range of habitats, from Antarctic lakes to the acid drainage of iron mines, as well as the air, water, and soil that surround us. Microbial communities form the foundation of Earth's biosphere, shaping the environments inhabited by plants and animals. In the ocean, vast quantities of microbes produce the biomass that ultimately feeds fish and humans. In forests and fields, microbes are actually the main consumers; they decompose the majority of plant material, generating fertile soil. Through their biochemistry, diverse microbes largely determine the quality of soil, air, and water for human life.

In all ecosystems, microbes associate with animals and plants. Microbes form elaborate symbiotic systems, such as mycorrhizae, underground networks of fungal hyphae that support and connect the roots of plants throughout forest and field. Rhizobia fix nitrogen for legumes, whereas algae photosynthesize for coral reefs. Anaerobes digest complex plant fibers for termites, cattle, even humans. This chapter explores how microbes interact with each other and with their many diverse habitats on Earth.



Erik Zinser, a postdoctoral fellow with Sallie Chisolm at the Massachusetts Institute of Technology, charted the distribution of the tiny cyanobacterium *Prochlorococcus* across the Atlantic Ocean. *Prochlorococcus* is one of Earth's most abundant producers of biomass and of oxygen in our atmosphere. Zinser is now at the University of Tennessee, Knoxville. *Source*: Johnson, et al. 2006. *Science* 311:1737.

The enteric disease cholera causes hundreds of thousands of deaths annually in India, Bangladesh, and other countries. The causative bacterium, *Vibrio cholerae*, inhabits both ocean and freshwater, contaminating the drinking water of millions of people too impoverished to boil it. Microbial ecologist Anwar Huq, from Bangladesh, worked with Rita Colwell, director of the U.S. National Science Foundation, to devise a simple way to decrease the incidence of cholera, based on the ecology of *V. cholerae*. Huq found that *V. cholerae* cells rarely exist in free suspension; rather, they colonize the surfaces of tiny invertebrates called copepods (**Fig. 21.1**). The copepods actually depend on these bacteria to eat through the chitin of their egg cases, releasing their young.

The copepods are much larger than individual bacteria—large enough to be excluded by a simple cloth filter. Most filter materials would be too expensive for villagers, but Huq found an alternative: the sari cloth worn by Bangladeshi women. A study showed that villagers could halve the incidence of cholera by filtering all their water through several layers of folded cloth from old saris. Although the sari cloth could not remove isolated bacterial cells, it removed the copepods that *V. cholerae* inhabited. This case shows how public health can benefit from understanding microbial ecology.

This chapter shows how microbes interact with each other in communities of organisms. Microbial communities critically impact other organisms in all habitats, from oceans to forests (**Fig. 21.2**). Microbes recycle organic material into aquatic and terrestrial ecosystems, providing resources for plants and animals. Our agricultural productivity depends in part on positive and negative effects of microbes in the soil and air. And deep below Earth's surface, microbial communities shape crustal rock.

Following this chapter, Chapter 22 shows how microbial geochemistry shapes the global biosphere as a whole and how microbes in our soil, air, and water determine Earth's environmental quality. As a scientist at the U.S. Department of Energy's Microbial Genome Program observed, "Microbes rule. They operate this planet, we don't."

21.1 Microbes in Ecosystems

"No man is an island," nor is any microbe. All organisms exist within **ecosystems** consisting of populations of species plus their habitat or environment. A **population** is a group of individuals of one species living in a common location. Within an ecosystem, each population of organisms fills a specific **niche**. The niche is a set of traits that defines the conditions for an organism to live and the

organism's relations with other members of the ecosystem. For example, the niche of *Synechococcus*, a cyanobacterium, is that of a free-living filamentous organism that fixes CO_2 into biomass while producing molecular oxygen utilized by swarms of heterotrophic bacilli. The habitat of *Synechococcus* is the upper water layer of the ocean; its biomass provides food for protist predators, which in turn feed invertebrates and fish.

Microbes Fill Unique Niches in Ecosystems

The essential role of microorganisms in all ecosystems was formulated by the Dutch microbiologist Cornelis B. Van Niel (1897–1985). Van Niel was the first to show that bacteria in the soil and water can conduct photosynthesis without producing oxygen, using electron donors such as H_2S. This surprising discovery revealed one of many kinds of metabolism unique to microbes but unknown in plants or animals. Other unique forms of microbial metabolism (discussed in Chapters 13–15) include nitrogen fixation and the degradation of lignin by bacteria and fungi. Moreover, microbial metabolism provides ecosystems with their sole source of key elements, such as sulfur, phosphorus, and iron.

Unique microbial metabolism provides unique roles for microbes in ecosystems. Van Niel expressed this principle in two key postulates of microbial ecology:

- **Every component or product of living cells can be used as a source of carbon or energy by a microorganism found somewhere in the biosphere.** Any cell component, such as sugars and amino acids, or cell product, such as fermentation acids and H_2S, can participate in some kind of energy-yielding reaction. If an energy-yielding reaction exists, some microbe must have evolved to use it.
- **Microbes are found in every environment on Earth.** Every possible habitat for life supports microbes. In fact, the largest part of the biosphere (below Earth's surface) is colonized solely by microbes.

The Van Niel postulates imply an extraordinary variety of microbial species using different energy-yielding functions. But what determines the contribution of each microbe? What a microbe gives to and takes from its ecosystem depends on two things:

- **The microbial genome.** Each genome provides a set of metabolic enzymes available to interconvert molecules. For example, the genomes of pseudomonads encode enzymes for catabolizing complex aromatic molecules, whereas genomes of cyanobacteria encode the apparatus of oxygenic photosynthesis. Microbial genomes share content through mobile genes (acquired by transfer mechanisms, discussed in Chapter 9).
- **Environmental factors.** The environment's physical and chemical factors, such as temperature, nutrient supplies, oxygen availability, and pH, determine the range of metabolic options. For example, if H_2 is available in the presence of O_2, *Rhodopseudomonas palustris* will oxidize hydrogen to water; on the other hand, if O_2 is absent but light is available, *R. palustris* will use anaerobic photosynthesis, splitting H_2S to make sulfur. Each organism's environment includes other organisms in the community. For example, the H_2 oxidized by *R. palustris* is provided by fermenting bacteria.

All organisms depend, directly or indirectly, on the presence of other organisms. Some populations cooperate by reciprocally supplying each other's needs. Cooperation by organisms may be incidental, as in the case of hydrogen-oxidizing bacteria using H_2 from fermenters; or it may involve mutualism, a highly developed partnership in which two species have coevolved to support each other (discussed in Section 21.2).

Carbon Assimilation and Dissimilation: The Food Web

The interactions between microbes and their ecosystems include two common roles of metabolic input and output, often referred to as assimilation and dissimilation, respectively. Most of these metabolic processes were discussed in Chapters 13, 14, and 15, but the ecological viewpoint offers a different perspective.

Assimilation refers to processes by which organisms acquire an element, such as carbon from CO_2, to build into body parts. When the environment lacks organic compounds containing an element such as nitrogen or phosphorus, microbes may assimilate the element from mineral sources. Major forms of assimilation include carbon dioxide fixation and nitrogen fixation. Organisms that produce biomass from inorganic carbon (usually CO_2 or bicarbonate ions) are called **primary producers**. Producers are a key determinant of productivity for other members of the ecosystem.

Dissimilation is the process of breaking down organic nutrients to inorganic minerals such as CO_2 and NO_2^-, usually through oxidation. Microbial dissimilation releases minerals for uptake by plants, and it provides the basis of wastewater treatment (discussed in Chapter 22). On the other hand, microbial dissimilation of an energy-rich nitrogenous fertilizer, such as N_2, causes nitrogen to be lost from the soil.

This chapter covers microbial assimiliation and dissimilation of carbon and nitrogen in association with the plants and animals of an ecosystem. The cycles of other key elements, and their effects on the global biosphere, are explored in Chapter 22.

THOUGHT QUESTION 21.1 From Chapters 13–15, give examples of microbial metabolism that fit patterns of assimilation and dissimilation.

The major interactions among organisms in the biosphere are dominated by the production and transformation of **biomass**, the bodies of living organisms. To obtain energy and materials for biomass, all organisms participate in the **food web** (**Fig. 21.3**). A food web describes the ways in which various organisms consume each other as well as each other's products. Levels of consumption are called **trophic levels**. Each trophic level represents the consumption of biomass of organisms from the previous level, lower in the food web. At each trophic level, the fraction of biomass retained by the consumer is small; most is dissipated as CO_2 to provide energy.

Every food web depends on primary producers for two things:

- **Absorbing energy from outside the ecosystem.** In most cases, the ultimate source of energy is the sun, and the producers are phototrophs.
- **Assimilating minerals into biomass.** The biomass of producers is then passed on to subsequent trophic levels.

The majority of carbon in Earth's biosphere is assimilated by oxygen-producing phototrophs such as cyanobacteria, algae, and plants. Certain important ecosystems are founded on carbon fixation by lithotrophs—for example, the hydrothermal vent communities, in which bacteria oxidize hydrogen sulfide to fix CO_2, capturing both gases as they well up from Earth's crust. The vent communities, however, require oxygen generated by phototrophs from above.

In addition to producers, all ecosystems include **consumers** that acquire nutrients from producers and ultimately dissimilate biomass by respiration, returning carbon back to the atmosphere (**Fig. 21.3A**). Consumers constitute several trophic levels based on their distance from the primary producers. The first level of consumers, generally called **grazers**, directly feed on producers. Grazers usually convert 90% of the carbon back to CO_2 through respiratory metabolism, yielding energy. The next level of consumers, often called **predators**, feed on the grazers, again converting 90% back to atmospheric CO_2. In microbial ecosystems, the trophic relationships are often highly complex, as a given species may act both as producer and consumer.

At each trophic level, some of the organisms die, and their bodies are consumed by **decomposers**, returning carbon and minerals back to the environment for use by producers. Decomposers are invariably microbes (fungi or bacteria). Decomposers have particularly versatile digestive enzymes capable of breaking down complex molecules such as lignin. Without decomposers, carbon and minerals needed by phototrophs would be locked away by ever-increasing mounds of dead biomass. Instead, all biomass is recycled, and all the energy acquired by ecosystems is eventually converted to heat.

Note that in the function of ecosystems, phylogenetic distinctions between bacteria, archaea, and eukaryotes are of less significance than the biological and biochemical consequences of an organism's presence in the community; that is, what does the organism produce or consume? Thus, in this chapter, we place greater emphasis on trophic roles than on phylogenetic distinctions.

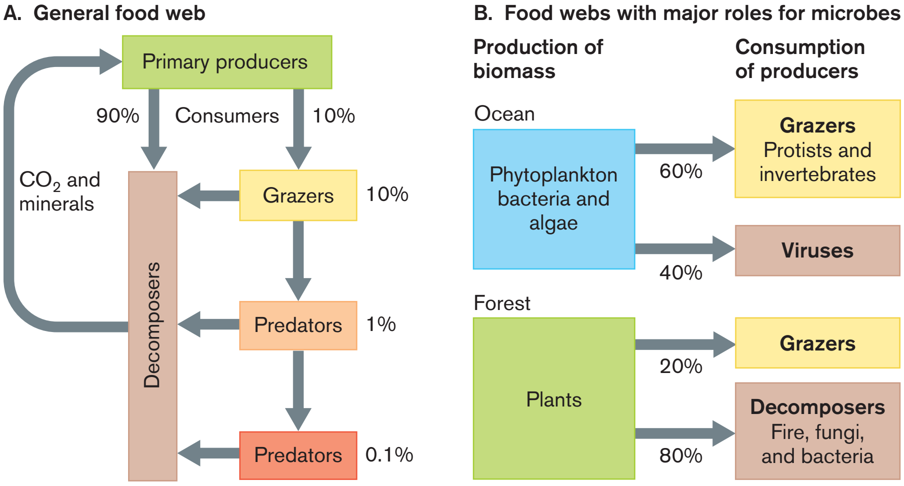

Figure 21.3 Microbes within food webs. A. The general view of a food web includes primary producers that fix CO_2 into biomass, grazers (primary consumers) that feed on primary producers, and predators that consume the grazers and smaller predators. Decomposers consume dead bodies of organisms from every level, recirculating their minerals to the producers. Percentages indicate fraction of original CO_2 converted to biomass at each trophic level. **B.** In different habitats, the relative significance of the various trophic component varies. In marine ecosystems, the primary producers are bacteria, archaea, and algae. About 10–40% of consumption is by viruses, which mineralize both producer and consumer microbes. In a forest, the major producers are trees, much of whose biomass is poorly digested by grazers; 80% of consumption occurs by fungal and bacterial decomposition. In some forests, the major decomposer is fire.

Table 21.1 Aerobic and anaerobic metabolism.

Element	Oxidized by O_2 (lithotrophy)	Reduced by CHO* or H_2 (anaerobic respiration)
Nitrogen	$NH_3 + O_2 \longrightarrow NO_3^-$	$NO_3^- + CHO \longrightarrow N_2$
Manganese	$Mn^{2+} + O_2 \longrightarrow Mn^{4+}$	$Mn^{4+} + CHO \longrightarrow Mn^{2+}$
Iron	$Fe^{2+} + O_2 \longrightarrow Fe^{3+}$	$Fe^{3+} + CHO \longrightarrow Fe^{2+}$
Sulfur	$H_2S + O_2 \longrightarrow SO_4^{2-}$	$SO_4^{2-} + CHO \longrightarrow H_2S$
Carbon	$CH_4 + O_2 \longrightarrow CO_2$	$CO_2 + H_2 \longrightarrow CH_4$

*CHO = organic material.

The relative significance of microbial and multicellular producers and consumers varies considerably among different habitats. A major difference appears between marine and terrestrial ecosystems (**Fig. 21.3B**). In the oceans, most CO_2 fixation and biomass production are performed by the smallest inhabitants, phototrophic bacteria. The major consumers are protists and viruses; in terms of bulk biomass, multicellular organisms barely contribute. In terrestrial ecosystems, by contrast, the major primary producers and fixers of CO_2 are multicellular plants. Plants generate **detritus**, discarded biomass such as leaves and stems, that requires decomposition by fungi and bacteria. These differences between the food webs of ocean and dry land explain why most of the food we harvest from the ocean consists of predators at the higher trophic levels (fish), whereas most food harvested on land consists of producers and first-level consumers (plants and herbivores). Fish depend on a vast invisible food web of microbes, and thus their numbers remain limited despite the seemingly huge volume of ocean. Thus, marine fish populations are especially vulnerable to overharvesting and to any environmental change that disrupts the food chain.

Oxygen and Other Electron Acceptors

The availability of oxygen and other electron acceptors is the most important factor that determines the kind of assimilation and dissimilation occurring in a given environment. Examples of aerobic and anaerobic metabolism are presented in **Table 21.1**. In aerobic environments, microbes use molecular oxygen as an electron acceptor to respire on organic compounds (abbreviated CHO) produced by other organisms (discussed in Chapters 13 and 14). Aerobic respiration on organic compounds is highly dissimilatory in that it tends to break compounds down to CO_2. Microbes also use oxygen to respire on reduced minerals such as NH_3, H_2S, and Fe^{2+} (lithotrophy). Lithotrophy is coupled to CO_2 fixation and is therefore assimilatory metabolism.

In anaerobic environments, such as deep soil, microbes use minerals such as Fe^{3+} and NO_2^- to oxidize organic compounds supplied by other organisms (anaerobic respiration). Other anaerobes use these electron acceptors to oxidize reduced minerals. Anaerobic environments allow much slower rates of assimilation and dissimilation than occurs in the presence of oxygen. The total volume of anaerobic microbial communities, however, far exceeds that of the oxygenated biosphere.

Temperature, Salinity, and pH

Other abiotic factors can profoundly affect the environment for microbes and other members of the food chain, either directly or by impacting other factors. The effects are most significant for **extremophiles**, species that grow in environments considered extreme by human standards (**Table 21.2**; discussed in Chapter 5). Temperature limits

Table 21.2 Extremophiles.

Class of extremophile	Typical environmental conditions for growth
Acidophile	Acidic environments at or below pH 3
Alkaliphile	Alkaline environments at a range of pH 9–14
Barophile	High pressure, usually at ocean floor, above 380 atm
Endoliths	Within rock crystals down to a depth of 3 km
Halophile	High salt, typically above 2 M NaCl
Hyperthermophile	Extreme high temperature, above 80°C
Oligotroph	Low carbon concentration, below 1 ppm
Psychrophile	Low temperature, below 15°C
Thermophile	Moderately high temperature, 50–80°C
Xerophile	Dessication, water activity below 0.8

the rate of metabolism: Higher temperatures, particularly those found in hot springs, enable the fastest growth rates measured (doubling times as short as 10 minutes for some hyperthermophiles). On the other hand, temperature limits the oxygen concentration in water, so hyperthermophiles often use sulfur instead.

High salt concentration limits the growth of microbes adapted to freshwater conditions. On the other hand, many microbial species have adapted to high salinity (they are called halophiles). The haloarchaea, for instance, bloom in population as a body of water shrinks and becomes hypersaline.

Acidity is important geologically because a high concentration of hydrogen ions accelerates the release of reduced minerals from exposed rock. Extreme acidity is often produced by lithotrophic acidophiles (discussed in Chapter 14). The increasing acidity enhances further release of minerals to be oxidized, while excluding acid-sensitive competitors. Other kinds of habitat, such as soda lakes, show extreme alkalinity resulting from high sodium carbonate concentration.

TO SUMMARIZE:

- **Microbial populations fill unique niches in ecosystems.** Every environment on Earth (to depths of 3 km below the surface) contains microbes. Every chemical reaction that may yield free energy can be utilized by some kind of microbe.
- **Microbes fix or assimilate essential elements into biomass**, which recycles within ecosystems. Important elements, such as nitrogen, are fixed solely by prokaryotes.
- **Primary producers fix single-carbon units, usually CO_2.** Microbial primary producers include algae, cyanobacteria, and lithotrophs.
- **In a food web, consumers catabolize the bodies of producers**, generating CO_2 and releasing heat energy. Dissimilation is the process of breaking down nutrients to inorganic minerals such as CO_2 and NO_2^-, usually through oxidation.
- **Microbial activity depends on levels of oxygen, carbon, nitrogen, and other essential elements**, as well as environmental factors such as temperature, salinity, and pH. The largest volume of our biosphere contains anaerobic bacteria and archaea. Beneath Earth's surface, anaerobic forms of metabolism predominate.

21.2 Microbial Symbiosis

Crucial relationships with microbes may occur at a distance; for example, the oxygen gas generated by marine cyanobacteria is breathed by organisms around the globe. Other kinds of interactions, however, require intimate association between microbes or between a microbial population and animals or plants. Intimate association between organisms of different species is called **symbiosis**. Symbiotic associations include a full range of positive through negative relationships (**Table 21.3**).

Mutualism Involves Partner Species That Require Each Other

The most highly developed forms of symbiosis involve partner species that require each other for survival, a phenomenon termed **mutualism**. A highly evolved form of mutualism is exemplified by **lichens** (**Fig. 21.4**). Lichens consist of an intimate symbiosis between a fungus and an alga or cyanobacterium—sometimes both. The highly evolved association usually requires compatible partner species. The alga or bacterium provides photosynthetic nutrition, while the fungus provides minerals and protection. Lichens grow very slowly, but they tolerate extreme dessication.

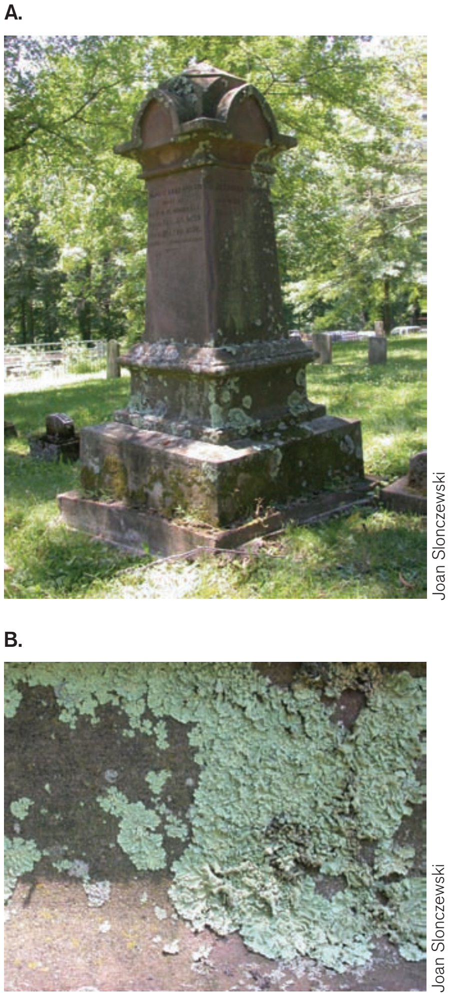

Figure 21.4 Lichens on tombstone. **A.** Tombstone at Kenyon College cemetery encrusted with lichens (pale blue) and mosses (dark green), a nonvascular plant. **B.** Close-up of lichens on tombstone.

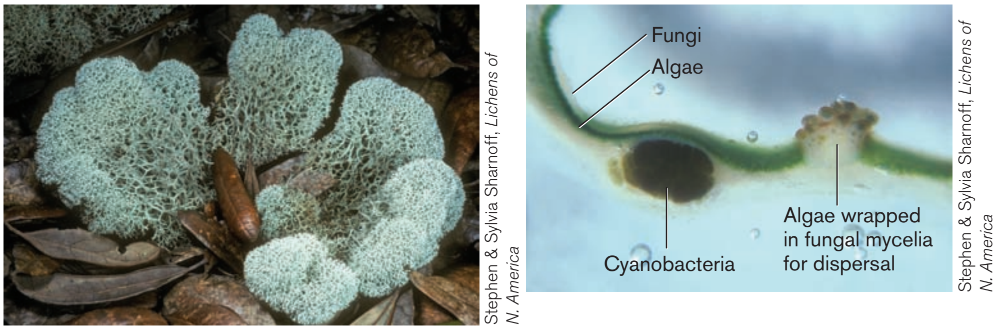
Table 21.3 Types of interactions involving microbial species.

Type of interaction	Effects of interaction	Example
Mutualism	Two organisms grow in an intimate species-specific relationship in which both partner species benefit and may fail to grow independently.	Lichens consist of fungi and algae (in some cases cyanobacteria) growing together in a complex layered structure. Both species only grow in the presence of the other.
Synergism	Both species benefit through growth in proximity, but the partners are easily separated and either partner can grow independently of the other.	Human colonic bacteria produce H_2 and CO_2 as fermentation products, which methanogenic archaea metabolize to methane. The methanogens gain energy, and the bacteria benefit energetically through the steady-state removal of the end products of their metabolism.
Commensalism	One species benefits, while the partner species neither benefits nor is harmed.	In wetlands, *Beggiatoa* bacteria oxidize H_2S for energy. Removal of H_2S from the environment enables growth of other microbes for whom H_2S is toxic. The other microbes are not known to benefit *Beggiatoa*.
Amensalism	One species benefits by harming another. The relationship is nonspecific.	On the human skin, *Staphylococcus epidermidis* and related species produce short-chain fatty acids whose uptake inhibits growth of yeasts and pathogens. The staphylococci benefit by outcompeting inhibited microbes for scarce water and nutrients.
Parasitism	One species (the parasite) benefits at the expense of the other (the host). The relationship is usually obligatory for the parasite.	*Legionella pneumophila*, the cause of legionellosis pneumonia in humans, parasitizes amebas in natural aquatic habitats. Within the human body, *L. pneumophila* parasitizes macrophages.

Lichens show a surprising variety of form. Different species may form a flat crust, branched filaments (**Fig. 21.5A**), or leaflike lobes. A cross section of the leaflike lichen *Lobaria pulminaria* reveals a layer of algae (green) covered by fungal mycelium (white), which probably protects the algae from excessive photodamage (**Fig. 21.5B**). In addition to the algae, this lichen includes patches of cyanobacteria—a three-way mutualism. For dispersal, the lichen forms asexual clumps of algae wrapped in fungal mycelium. The clumps flake off and are carried by wind to new locations.

Other forms of mutualism involve a plant or animal host. A mutualism particularly crucial to ecosystems is that of bacterial nitrogen fixation. Many cyanobacteria fix nitrogen in association with specific plants, similar to the legume symbiosis in which rhizobial bacteria such as *Sinorhizobium* species form intracellular "bacteroids" within plant cells (discussed in Section 21.5). Both the

Figure 21.5 **Lichen form and structure.** **A.** *Cladina evansii*, known as "deer moss," a branch-like lichen, growing on oak leaves and sandy soil in Florida. **B.** Section through lichen (*Lobaria pulminaria*) shows fungal, algal, and bacterial symbionts.



A. "Deer moss" lichen

Stephen & Sylvia Sharnoff, *Lichens of N. America*

B. Lichen cross section

Stephen & Sylvia Sharnoff, *Lichens of N. America* cyanobacteria and their plant hosts are highly evolved to respond to each other chemically and develop the nitrogen-fixing system. The plants provide protection and nutrients from photosynthesis, while receiving fixed nitrogen from the bacteria.

Many animal hosts require endosymbiotic bacteria to digest plant material such as cellulose. Digestive symbiosis is well known in termites, whose bacteria digest wood, and in ruminants such as cattle. Less known is that many primates, such as gorillas, depend on bacterial fermentation. Even humans derive about 15% of their caloric intake from bacterial fermentation.

A particularly complex digestive endosymbiont is *Mixotricha paradoxa* (**Fig. 21.6**), a large ciliate (as long as half a millimeter) that grows in the termite gut. The *Mixotricha* cell contains several kinds of bacterial endosymbionts. Intracellular bacteria digest cellulose from wood consumed by the termite. There are also organelles that appear to be vestigial remnants of another endosymbiont, diminished by reductive evolution. On the protist's surface, four kinds of bacteria are attached. Two of the attached species are spirochetes, one significantly larger than the other. The spirochetes extend from the protist's cell membrane; they are flagellated, and their flagellar motility propels the protist cell. Two other species of "anchor bacteria" are gram-negative rods attached to knobs of the protist surface; their function is unknown. All members of the partnership appear to have evolved an obligate relationship.

Symbiosis May Involve Cooperation or Parasitism

Less intimate cooperation is called **synergism**, in which both species benefit but can grow independently and show less specific cellular communication (**Table 21.3**). For example, human colonic bacteria produce fermentation products that colonic methanogens metabolize to methane. The methanogens gain energy, and the fermenting bacteria benefit energetically through the steady-state removal of their end products. This kind of metabolic cooperation is also known as **syntrophy**, or "feeding together." In other cases, one species derives benefit from another without return; for example, some wetland bacteria derive benefit from *Beggiatoa* because *Beggiatoa* bacteria oxidize H_2S, which inhibits growth of other species. An interaction that benefits one partner only is called **commensalism**. Commensalism is difficult to define in practice since "commensal" microbes often provide a hidden benefit to their host. For example, gut bacteria such as Bacteroides species were considered commensals until it was discovered that their metabolism aids human digestion.

An interaction that harms one partner nonspecifically, without an intimate symbiosis, is called **amensalism**. An example of amensalism is actinomycete production of antimicrobial peptides that kill surrounding bacteria. The dead bacterial components are then catabolized by the actinomycete. Finally, **parasitism** is an intimate relationship in which one member (the parasite) benefits while harming a specific host. Many microbes have evolved specialized relationships as parasites, including intracellular parasitic bacteria such as the rickettsias, which cause diseases such as Rocky Mountain spotted fever.

The distinction between mutualist and parasite is often subtle. Lichens consist of a mutualistic association between fungus and algae; but environmental change can convert the fungus to a parasite. On the other hand, parasitic microbes may coevolve with a host to the point that each depends on the other for optimal health. For example, the incidence of certain allergies and immune disorders appears to correlate with lack of exposure to pathogens and parasites.

TO SUMMARIZE:

- **Symbiosis** is an intimate association between organisms of different species.
- **Mutualism** is a form of symbiosis in which each partner species benefits from the other. The relationship is usually obligatory for growth of one or both partners. Examples of mutualism include lichens (algae or cyanobacteria and fungi) and termite gut communities of cellulose-digesting bacteria and protists.
- **Parasitism** is a form of symbiosis in which one species grows at the expense of another, usually a much larger host organism.

21.3 Marine and Aquatic Microbiology

The oceans cover more than two-thirds of the Earth's surface, reaching depths of several kilometers and forming an immense habitat (**Fig. 21.7**). Marine water is distinguished by its salt concentration, averaging 3.5%. The major ions are Na^+ and Cl^-, with significant levels of sulfate, iodide, and bromide. Marine salt concentration is high enough to prevent growth of many aquatic and terrestrial bacteria such as *E. coli*, although salt-tolerant organisms such as *Vibrio cholerae* grow well over a broad range of salt concentration.

Marine Habitats

Marine waters vary considerably with respect to temperature, pressure, light penetration, and concentration of organic matter. In the open ocean, the water column (known as the **pelagic habitat**) is subdivided into distinct regions (see **Fig. 21.7**):

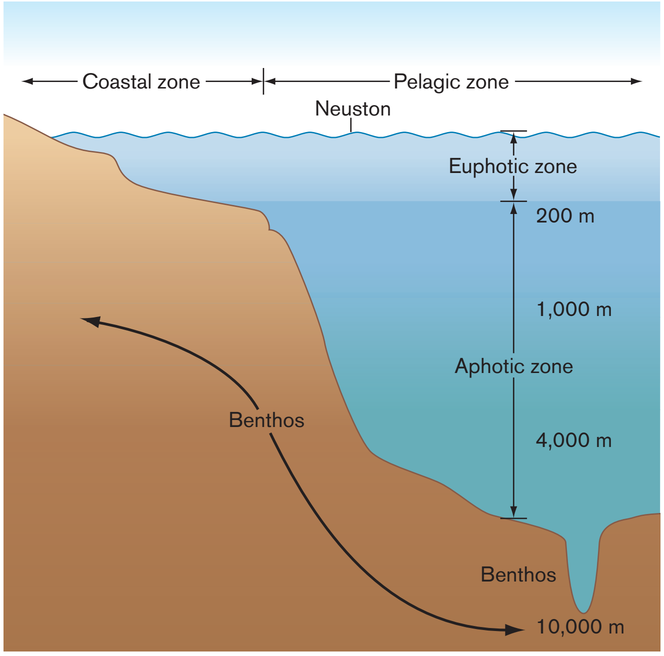

Figure 21.7 Regions of marine habitat. The marine habitat subdivides into several categories. The coastal shelf region is defined as the water extending from the shoreline out to a depth of 200 m. The open ocean includes several depth regions: the neuston, the microscopic interface between water and air; the euphotic zone of light penetration, where phototrophs can grow, down to 100–200 m; the aphotic zone, which supports only heterotrophs and lithotrophs; and the benthos, at the ocean floor.

- **Neuston (about 10 μm).** The **neuston** is the air-water interface. Although extremely thin, the neuston layer contains the highest concentration of microbes. Many algae and protists have evolved so as to "hang" from the layer of surface tension.
- **Euphotic zone (100–200 m).** The **euphotic zone**, or **photic zone**, is the upper part of the water column that receives light for phototrophs. In the open ocean, the euphotic region extends down a couple of hundred meters, whereas at the **coastal shelf** (<200 m to floor), a higher concentration of silt and organisms reduces the photic zone to as little as 1 m.
- **Aphotic zone.** Below the reach of light, in the **aphotic zone**, only heterotrophs and lithotrophs can grow.
- **Benthos.** The **benthos** includes the region where the water column meets the ocean floor, as well as sediment below the surface. Organisms that live in the benthos, such as those of thermal vent communities, are called **benthic organisms**.

Another important determinant of marine habitat is the **thermocline**, a depth at which temperature decreases steeply and water density increases. A thermocline typically exists in an unmixed region. At the thermocline, a population of heterotrophs will peak, feeding on organic matter that settles from above.

Coastal regions show the highest concentration of nutrients and living organisms and the least light penetration. The open ocean is largely oligotrophic (extremely low concentration of nutrients and organisms). The concentration of heterotrophic microorganisms determines the **biochemical oxygen demand** (**BOD**), the amount of oxygen removed from the water by aerobic respiration. The open ocean has such a low concentration of organisms that the BOD is extremely low; therefore, the dissolved oxygen content is high. This explains why enough oxygen reaches the ocean floor to serve lithotrophs growing at hydrogen sulfide thermal vents.

To nineteenth-century microbiologists, the oceans appeared virtually free of bacteria. Trained in the tradition of Robert Koch (discussed in Chapter 1), microbiologists attempted to isolate marine bacteria by plate culture, considered the definitive way to study a microbial species. But the colonies that grew on traditional plate media were extremely few. Then in 1959, the German microbial ecologist Holger Jannasch (1927–1998; **Fig. 21.8A**) showed that many more bacteria could be seen by light microscopy than could be grown on plates. Later, with colleagues at the Woods Hole Oceanographic Institution, Jannasch went on to study life at the ocean floor, using the famous submersible vessel *Alvin* (**Fig. 21.8B**). They documented the bacteria and archaea of biofilms at black smoker thermal vents such as those of Guaymas Basin, in the Gulf of California (**Fig. 21.8C**).

The crew of the *Alvin* discovered entire ecosystems based on symbiotic sulfide-oxidizing bacteria adapted to the enormous pressure under many kilometers of seawater. They made important discoveries about the effect of deep-sea pressure on microbial decomposition. An accident that left the *Alvin* stranded on the ocean floor led to observation of an abandoned sandwich that lasted several months with minimal decomposition. This and similar observations showed that our familiar microbial decomposers grow extremely poorly under deep-sea conditions—a discovery with implications for the fate of human garbage dumped in the open sea.

Because marine bacteria proved difficult to grow in culture, Jannasch's initial observations sparked decades of controversy. How could the organisms be alive if they were not cultured? Other researchers, including Rita Colwell, showed that even nonculturable bacteria could show metabolic activities. These elusive bacteria were described as **viable but nonculturable** (**VBNC**). Viable bacteria can be nonculturable in the laboratory for many reasons, such as lack of unknown complex growth requirements, the presence of inhibitory molecules, or unfavorable environmental factors such as temperature and pressure. We now know that the vast majority of bacteria alive in the biosphere are nonculturable under current laboratory conditions.

Nonculturable bacteria are observed and studied by PCR amplification of their DNA and by epifluorescence microscopy.

THOUGHT QUESTION 21.2 Does "viable but nonculturable" mean that growth is permanently shut down?

Measuring Planktonic Communities

In marine science, the term **plankton** refers to organisms that float passively in water (**Fig. 21.9A**). The term is used loosely, as it includes motile microorganisms. Microbial plankton are known by different prefixes based on their approximate size ranges (**Table 21.4**): **microplankton**, 20–200 μm, consisting of relatively large ciliated protists and algae; **nanoplankton**, 2–20 μm, consisting of smaller algae and flagellated protists as well as filamentous cyanobacteria; and **picoplankton**, 0.3–2 μm, consisting of primarily bacterial phototrophs, heterotrophs, and lithotrophs. The picoplankton include the smallest living cells known. In addition to these different classes of floating cells, marine ecologists refer to marine viruses as **femtoplankton**, the smallest detectable particles capable of reproduction.

Counting and Identifying Marine Plankton

From an ecological perspective, how do we define a planktonic population? This is challenging because not all marine microbes float independently. Many colonize suspended inorganic particles known as **marine snow** (**Fig. 21.9B**). Until recently, the ecological significance of these miniature biofilm-like particles of marine snow was discounted because they appeared so dilute. In fact, perhaps half of all marine bacteria are associated with particulate substrates. As observed by Farooq Azam at the Scripps Institution of Oceanography, "Seawater is an organic matter continuum, a gel of tangled polymers with embedded strings, sheets, and bundles of fibrils and particles, including living organisms, as 'hotspots'." Marine snow adds a new dimension to our view of the oligotrophic marine habitat, in that the ocean as a whole has a low average nutrient concentration, but marine waters include a suspension of concentrated tangles of nutrient-rich substrates.

Population size can be defined in different ways: the number of individual reproductive units, total organic biomass available to consumers, or the rate of productivity or assimiliation of key nutrients such as carbon dioxide. All ways of measuring these quantities present challenges; there is no one right method, but different approaches serve to answer different questions.

Table 21.4 Microbial plankton: size categories.

Size category	Microbial group	Size range (μm)
Microplankton	Eukaryotes	20–200
	Microalgae—phytoplankton	
	Heterotrophs, ciliates—zooplankton	
	Mixotrophs and symbiotic protists	
	Microscopic multicellular plants and invertebrates	
Nanoplankton	Prokaryotes: Cyanobacteria (filamentous)	2–200
	Eukaryotes	2–20
	Nanoalgae	
	Heterotrophs and mixotrophs—flagellates	
Picoplankton	Prokaryotes	
	Bacteria	0.5–1.0
	Phototrophs (phytoplankton)	
	Prochlorophytes	0.5–2.0
	Cyanobacteria (coccoid)	1.0–2.0
	Lithotrophs (oxidize NH_4^+, H_2S, etc.)	0.3–1.0
	Heterotrophs (zooplankton)	0.3–1.0
	Archaea	
	Eukaryotes	
	Picoalgae—phytoflagellates	1.0–2.0
	Heterotrophic protists—zooflagellates	1.0–2.0
Femtoplankton	Viruses	0.01–0.02

Enumeration by epifluorescence microscopy. Marine microbes of all sizes, even viruses, can be counted under the microscope using a DNA-intercalating fluorescent dye (**Fig. 21.10**). Recall that fluorescence enables detection even of particles whose size is below the resolution limit defined by the wavelength of light (discussed in Chapter 2). Epifluorescence microscopy with DNA-binding fluorophores is used to detect planktonic microbes (**Fig. 21.11A**). The fluorescent dye DAPI reveals extremely small bacteria and algae (large spots) and viruses (small spots). For differential detection of specific classes or species of microbe, the fluorescent dye can contain a DNA probe, a short DNA sequence that can hybridize only to DNA of a particular species.

Biomass. The amount of biomass in a population can be determined by standard chemical assays of protein and other forms of organic matter. Net biomass of a population, however, does not indicate productivity within an ecosystem because it misses the amount of carbon cycled through respiration. Marine microbes have an extremely rapid rate of turnover, but what appears to be a small population may nonetheless conduct tremendous rates of carbon fixation into biomass, which is rapidly consumed by the next trophic level.

Incorporation of radiolabeled substrates. The measured amount of biomass does not indicate the rate of biomass production. The rate of production can be estimated based on the cells' incorporation of a radiolabeled substrate. Uptake of $^{14}CO_2$ indicates the rate of carbon fixation—a highly significant property for study of global warming. Uptake of ^{14}C-thymidine measures the rate of DNA synthesis, an indicator of the rate of cell division. These procedures can be conducted in seawater under native conditions, without requiring laboratory cultivation.

A limitation of these methods is that addition of the radiolabeled substrate may raise a nutrient concentration to artificially high levels that distort the naturally occurring rates of activity. In the case of labeled thymidine, another limitation is that not all growing cells incorporate exogenous thymidine into their DNA.

Mapping marine phytoplankton. Marine phytoplankton produce a substantial part of the world's oxygen and consume much of atmospheric CO_2. How do we measure marine phytoplankton and calculate their metabolic contributions? Teams of microbiologists, including undergraduate students, conduct such studies at the Bermuda Biological Station for Research, based in the Sargasso Sea southeast of Bermuda. At the Bermuda station, a long-term study of marine ecology known as the Bermuda Atlantic Time-Series (BATS) measures seasonal and long-term changes in microbial production, populations, and diversity (**Fig. 21.10A**). The BATS study, led by Stephen Giovannoni and Craig Carlson, tracks how marine ecosystems respond to environmental disturbances such as the wind patterns of El Niño and global warming.

The BATS researchers use epifluorescence microscopy to detect and count bacteria, most of which cannot be cultured in the laboratory. The bacteria are stained with DAPI, a DNA-binding fluorescent stain that indicates live organisms with intact DNA (**Fig. 21.11A**). The number of DAPI-stained organisms is counted in samples of seawater from a series of depths (0–300 m). Depth profiles over time further reveal the seasonal dynamics of the microbial community (**Fig. 21.11B**). At Bermuda, the highest populations of bacteria (coded red) are generally found at depths of 40–100 m, peaking during the summer. Overall, the BATS results can help improve our models of productivity of the world's oceans.

In another experiment at the Bermuda station, a group of undergraduates mapped the bacterial community over the depth series and compared it with a profile of ^{14}C-thymidine uptake as an indicator of DNA synthesis (**Fig. 21.12**). The profiles showed that while the bacterial concentration

peaks at about 60 m, the biochemical activity (DNA synthesis) peaks at a shallower depth (about 20 m). This occurs because the photosynthesis is most active near the surface, with greatest light exposure. The phototrophic cells, however, are lysed and degraded rapidly by viruses. Thus, the phototrophs near the surface cycle tremendous amounts of carbon relative to their net biomass.

Metagenomic analysis of microbial DNA. The behavior of marine plankton, such as its interactions with marine animals and its production and consumption of carbon, depends upon its species. The vast majority of microbial species can only be identified based on their DNA. The DNA of marine microbial populations is now characterized by metagenomics, the sequencing of "community DNA." For metagenomic analysis, the DNA is obtained from organisms taken directly from their habitat without culturing.

In 2007 a team led by Craig Venter of the J. Craig Venter Institute sequenced over six billion base pairs of DNA from ocean water samples taken from around the globe. The research team estimated that their sequences identified 25,000 different microbial species per liter of seawater. Their survey revealed many new gene sequences, doubling the number of known protein types for all living organisms. Many protein classes believed to be found in only one domain (bacteria, archaea, or eukaryotes) were discovered in members of another domain. For example, proteorhodopsins, light-driven ion pumps originally found only in halophilic archaea, were found in numerous bacterial species. The bacterial proteorhodopsins have evolved diverse spectral sensitivities; those found in the open ocean are optimized to absorb blue light, whereas those in coastal regions absorb green light.

Planktonic Food Webs

Marine plankton interact with each other as producers and consumers in a food web. A simplified outline of the food web in the open ocean is shown in **Figure 21.13A**. The diagram of a food web is often called a "spaghetti diagram" because so many trophic interactions cross each other in various directions. The phototrophic producers are known as **phytoplankton**. Examples of phytoplankton include tiny *Prochlorococcus*, predominating in the upper photic layer, and *Synechococcus*, in a slightly deeper layer reached by longer wavelengths of light. In addition, there are myriad forms of algae, such as diatoms and dinoflagellates. Our knowledge of planktonic communities is evolving rapidly, as many marine phytoplankton are so small and difficult to study that major new species are discovered every year.

Bacterial phototrophs (picoplankton and nanoplankton) are mainly consumed by protists and by heterotrophic bacteria and archaea. These, in turn, are consumed by larger protists, which feed small invertebrates, which feed larger invertebrates and ultimately vertebrates such as fish. All levels of microbial plankton, however, are subject to intense predation by viruses. The degree of viral predation is difficult to measure, but recent studies indicate that cell lysis by viruses mineralizes (breaks down to CO_2 and minerals) about half of microbial biomass. Virus particles represent a significant sink for carbon and nitrogen. They accelerate the return of minerals to producers and necessitate a larger base of producers to sustain the ecosystem.

THOUGHT QUESTION 21.3 How do viruses select for increased diversity of microbial plankton?

Ocean ecosystems contain a large number of trophic levels, of which the top consumers include fish and humans. Because each trophic level spends 90% of its biomass for energy, ecosystems require a huge lower foundation to sustain the highest-level consumers. This is one reason why fisheries worldwide are now in danger of running out of fish for human consumption: Fish are being harvested faster than the ecosystem can replace them.

Note that actual food webs are far more complex than shown in **Figure 21.13A**. One source of complexity is that many "algal protists" such as chrysophytes (golden algae) and dinoflagellates are actually **mixotrophs**, organisms conducting both photosynthetic and heterotrophic metabolism. Mixotrophs include secondary endosymbiont algae, such as Sargassum weed, as well as protists containing cyanobacterial or algal endosymbionts. A scheme for a food web that includes mixotrophs is shown in **Figure 21.13B**. The scheme is further complicated by the existence of elaborate mutualistic associations between different kinds of protists, algae, and bacteria.

Finally, it must be remembered that the microbial flora includes numerous unique species associated within or adherent to macroscopic organisms, including invertebrates, fish, and marine mammals. An example of a microbe found solely within a specialized animal host is *Epulopiscium fishelsoni*, a highly unusual bacterium that "gives birth" to progeny formed within the parent cell. *E. fishelsoni* grows only within the digestive tract of the Red Sea surgeonfish. Microbial communities within plants and animals are discussed in detail in Sections 21.5 and 21.6.

Figure 21.13 **The pelagic marine food web.** **A.** In the marine water column, the vast majority of carbon transfer occurs among microbes. Arrows lead from organisms consumed and point to their consumers. The primary producers are phototrophic bacteria and algae, with a smaller contribution from lithotrophic bacteria and archaea. Grazers include heterotrophic bacteria and protists. Predators include protist flagellates and ciliates. About 40% of bacterial and protist biomass is degraded by viral lysis. Multicellular organisms cycle a relatively small fraction of biomass. **B.** A more complex view of the marine food web includes mixotrophs, organisms that combine phototrophic and heterotrophic nutrition, and symbiotic associations between protists and phototrophic bacteria or algae.

The Ocean Floor

The ocean floor (benthos) experiences extreme pressure from the water column. Most organisms that live there are pressure-dependent species, known as **barophiles** (discussed in Chapter 5). Barophiles require high pressure for growth, failing to grow when cultured at sea level. In the absence of light, heterotrophic bacteria depend on detritus from above as their carbon source; but by the time any material reaches the benthos, its food value has largely been depleted by prior consumers. Thus, at the benthos, with less food available, microbial decay occurs at a much lower rate than at sea level. The cold temperatures (about 10°C) also limit microbial growth.

The ocean floor provides reduced inorganic minerals such as iron sulfide (FeS) and manganese (Mn^{2+}) that can combine with dissolved oxygen to drive lithotrophy (discussed in Chapter 14). Lithotrophic metabolism by microbes in the sediment generates a permanent voltage potential between the reduced sediment and the oxidizing water. As a result, the entire benthic interface between floor and water acts as a charged battery that can actually generate electricity.

The benthic redox gradient is enhanced dramatically at thermal vents, where volcanic activity causes upwelling of hydrogen sulfide (H_2S), H_2, and carbonates (**Fig. 21.14A**). These minerals are brought up by seawater that seeps through the sediment until it reaches a magma pool, where it becomes superheated and rises to the surface as steam. Sulfate-reducing bacteria reduce sulfate from seawater with H_2 upwelling from the vent fluids, to form H_2S. As the H_2S rises, it is oxidized by sulfur-oxidizing bacteria such as *Thiomicrospira*. The vent waters also support methanogens, and the methane they produce becomes oxidized by methanotrophs.

Figure 21.14 The thermal vent ecosystem. A. At thermal vents, volcanic activity causes upwelling of hydrogen sulfide and carbonates. The high concentrations of sulfides have selected for evolution of invertebrates that feed through mutualistic associations with H_2S-oxidizing bacteria. The H_2S oxidizers fix carbon from the carbonates, generating organic metabolites that feed their animal hosts. **B.** Vent bacteria within the gills of tube worms provide energy from oxidation of hydrogen sulfide. Source: A. Maier, et al. *Environmental Microbiology.*

The high concentrations of sulfides at thermal vents have selected for a remarkable evolution of invertebrate species that feed through mutualistic associations with H_2S-oxidizing bacteria. The H_2S oxidizers fix carbon from the carbonates, generating organic metabolites that feed their animal hosts—species of worms, anemones, and giant clams, all closely related to surface-dwelling species that would be poisoned by H_2S. The tube worm *Riftia* is colored bright red by a pigment carrying H_2S and O_2 in its circulatory fluid (**Fig. 21.14B**). The worm has evolved such a complete dependence on its symbionts that it has lost its own digestive tract.

Freshwater Microbial Communities

Many features of marine habitats also apply to freshwater aquatic systems, such as lakes and rivers. Freshwater habitats, of course, contain much lower salt, usually less than 0.1%. The study of aquatic systems is called limnology. Like the marine water column, the profile of a lake water column is defined by depth, aeration, and temperature (**Fig. 21.15**).

Large, undisturbed lakes are usually **oligotrophic**, with dilute concentrations of nutrients and microbes (**Fig. 21.15A**). The warm upper water layer above the thermocline is called the epilimnion. The epilimnion water is warm, well mixed, and oxygenated relative to the lower layers of water that are isolated from the atmosphere. It supports oxygenic phototrophs such as algae and cyanobacteria. Below the epilimnion lies a thermocline, a steep transition zone to colder, denser water below.

The epilimnion reaches only about 10 m in depth, much shallower than the marine euphotic zone. In a lake, the depth of light penetration varies greatly, depending on the concentration of microbes and particulate matter.

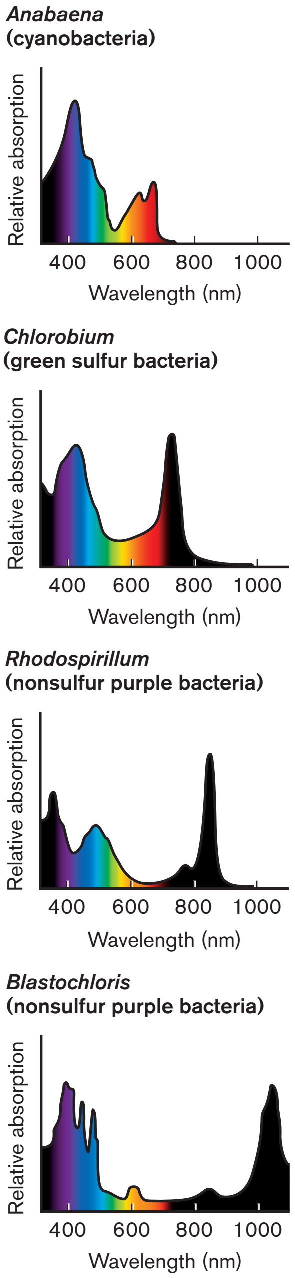
Figure 21.15 Aquatic microbial metabolism in lakes. A. Depth profile of an oligotrophic lake. The oxygenated zone (epilimnion) reaches to the thermocline, below which grow only anaerobes. **B.** Depth profile of a eutrophic lake. The oxygenated epilimnion is much shallower, and microbial concentrations are tenfold higher than in an oligotrophic lake. **C.** Algal bloom due to excess nitrogen from septic systems releasing into the pond.

At the edge of the lake, where the upper layer becomes shallow enough for rooted plants, is the **littoral zone**. In the deeper water, below the epilimnion, lies the hypolimnion, a region that becomes anoxic in lakes that are eutrophic (rich in organic nutrients).

When deeper water is anoxic, it supports only anaerobic microbes. These include a series of anaerobic phototrophs that do not produce O_2. Enough light may penetrate to support anaerobic H_2S-splitting phototrophs such as *Chlorobium* and *Rhodopseudomonas*. Although H_2S photolysis provides less energy than oxygenic H_2O photolysis, these bacteria have evolved in a productive niche by using chlorophyll pigments whose spectrum extends into the infrared (**Fig. 21.16**). Light in the red and infrared portions of the spectrum extends the deepest into the lake column. Light with wavelengths in this range cannot be used by oxygenic phototrophs because the photon energy is insufficient to split water. The less efficient H_2S photolyzers, however, can harness the energy of red and infrared radiation (discussed in Chapter 14). The green and purple phototrophs overlap metabolically with anaerobic heterotrophs and lithotrophs that reduce oxidized minerals. Some bacteria, such as *Rhodospirillum rubrum*, can grow anaerobically with or without light; others grow only by anaerobic catabolism, unassisted by light.

At the bottom of the water column, the water meets the sediment (benthos). In the benthic sediment, gradients develop in which successive electron acceptors become reduced by anaerobic respirers and lithotrophs (**Fig. 21.17**). Electron acceptors that provide the most energy are consumed first; as each in turn is depleted, the electron acceptor with the most energy is consumed next. First, molecular oxygen is used to oxidize organic material and reduced minerals such as NH_4^+. As molecular oxygen falls off, bacteria use nitrate (NO_3^-) from oxidized ammonium ion as an electron acceptor to respire on remaining organic material. As the nitrate is used up, still other bacteria use manganese (Mn^{4+}) as an electron acceptor, followed by iron (Fe^{3+}) and sulfate (SO_4^{2-}). Reduction of sulfate leads to H_2S, which eventually returns to the upper layers supporting anaerobic photolysis. Reduction of CO_2 by H_2 produces methane (CH_4). Methane collects below and sometimes ignites when it escapes to the surface. Methane is of global concern as a potent "greenhouse gas" (discussed in Chapter 22).

NOTE: Certain minerals and organic molecules occur in equilibrium between ionized and un-ionized states over the range of pH typical of most common habitats (pH 4–9). Examples include ammonia (NH_3), which protonates to ammonium ion (NH_4^+), and organic acids such as acetic acid (CH_3COOH), which deprotonates to acetate (CH_3COO^-). In this chapter, we refer to the form most prevalent at pH 7 unless stated otherwise.



Anabaena (cyanobacteria)

Chlorobium (green sulfur bacteria)

Rhodospirillum (nonsulfur purple bacteria)

Blastochloris (nonsulfur purple bacteria)

Figure 21.16 Absorbance spectra of chlorophyll from lake phototrophs. In the upper waters, algae and cyanobacteria absorb primarily blue and red. Below, where red has been absorbed by microorganisms above, anaerobic phototrophs such as *Blastochloris* absorb infrared (wavelengths beyond 750 nm).

Throughout the water column, fungi and protists serve as grazers and predators on algae and bacteria, respectively. They also interact with invertebrates and fish as parasites. Other important consumers are the viruses, which lyse about half of microbial populations in lakes, as they do in the ocean. Viruses serve an important function by limiting the number of microbes and keeping the water clear enough for light to penetrate.

Note that all fish and invertebrates need access to the epilimnion for oxygen. Only anaerobic microbes can

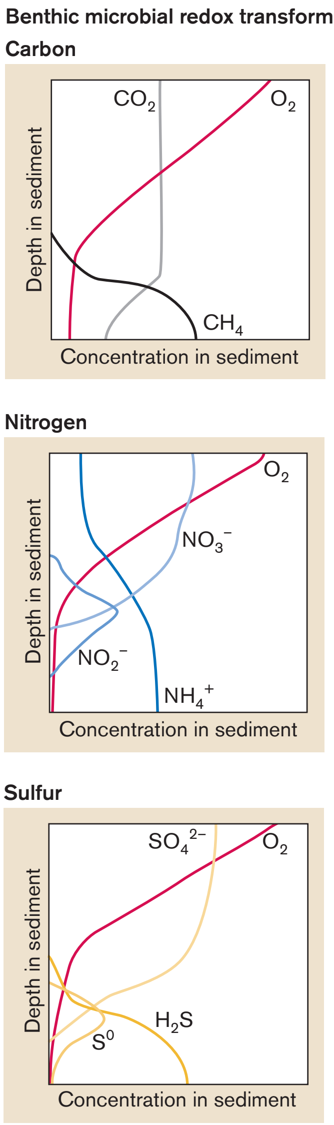


Figure 21.17 **Redox gradients in the benthic sediment.** At the top of the sediment interface with the water column, minerals are first oxidized lithotrophically by O_2; then, as O_2 declines, the oxidized minerals are used as alternative electron acceptors for anaerobic respiration. The nitrate, nitrite, and sulfur concentrations fall as these species are used as alternative electron acceptors for anaerobic respiration.

grow entirely in the anoxic hypolimnion. Thus, problems arise when effluents entering a lake carry high concentrations of nutrients causing overgrowth of phototrophs. Initially, the phototrophs increase the oxygen content of the epilimnion. But, the cell mass of the phototrophs sinks to the bottom, where overgrowth of heterotrophs depletes oxygen, causing **eutrophication** (**Fig. 21.15B**). So the anaerobic zone near the bottom of the lake grows larger, meaning that the boundary between the aerobic and anaerobic zones rises. In a eutrophied lake, fish die off owing to lack of oxygen, which heterotrophic microbes have consumed. Such a lake is said to have a high level of biochemical oxygen demand (BOD).

Common causes of eutrophication include:

- **Phosphates.** Because phosphorus is commonly a **limiting nutrient** (nutrient in shortest supply) for algae, addition of phosphates from detergents and fertilizers can lead to an **algal bloom** in which algae overgrow the water surface. The algae die, and their consumption by heterotrophic bacteria depletes oxygen, suffocating fish.
- **Nitrogen** from sewage effluents can lead to algal blooms by relieving nitrogen limitation.
- **Organic pollutants** from sewage effluents overfeed heterotrophic bacteria, depleting the epilimnion of oxygen.

A **eutrophic lake** is one in which the lower layers have become depleted of oxygen as a result of overgrowth of microbial producers. Thermal stratification may break up, and the lake may mix one to several times per year, thus reoxygenating the entire lake. A permanently eutrophic lake typically supports ten times the microbial concentrations of an oligotrophic lake (see **Figs. 21.15A** and **B**), but shows greatly decreased animal life.

TO SUMMARIZE:

- **The euphotic zone of the ocean** is the upper part of the water column that receives light for phototrophs. Below, in the aphotic zone, only heterotrophs and lithotrophs can grow. The benthos includes the region where the water column meets the ocean floor, as well as sediment below the surface.
- **Plankton are small floating organisms**, including swimming microbes. Phytoplankton are phototrophs such as cyanobacteria and algae. Microbial consumers include protists and viruses. Many marine protists are mixotrophs (producers and consumers in one).
- **Picoplankton** are measured by epifluorescence microscopy. Their biochemical rate of production is measured by uptake of radiolabeled nutrients.
- **New microbial species** are discovered by metagenomic analysis.
- **Benthic microbes are barophiles.** The seafloor supports psychrophiles, whereas hydrothermal vents support thermophiles. Vent microbes include sulfur-oxidizing bacteria, sulfur-reducing bacteria, and methanogens. Bacteria that oxidize H_2S feed symbiotic animals such as tube worms.
- **Aquatic freshwater lakes** exhibit stratified water levels. As depth increases, minerals become increasingly reduced. Anaerobic forms of metabolism predominate, with the more favorable alternative electron acceptors used in turn.
- **Lakes may be eutrophic or oligotrophic.** Eutrophic lakes may show such high biochemical oxygen demand (BOD) that they cannot support vertebrate life.

21.4 Soil and Subsurface Microbiology

In contrast to the ocean, where the base of producers is almost entirely microbial, the major producers of terrestrial ecosystems are macroscopic plants. Plants vary greatly in size and form, from mosses and bryophytes to prairie grasses and forest trees, but all terrestrial plants are rooted in **soil**. Soil is a complex mixture of decaying organic and mineral matter that feeds vast communities of microbes—arguably the most complex microbial ecosystem on our planet. And soil-based agriculture is the major source of food for our planet's human inhabitants. The qualities of a given soil—oxygenated or water saturated, acidic or alkaline, salty or fresh, nutrient-rich or -poor—define what food can be grown and whether the human community will eat or starve.

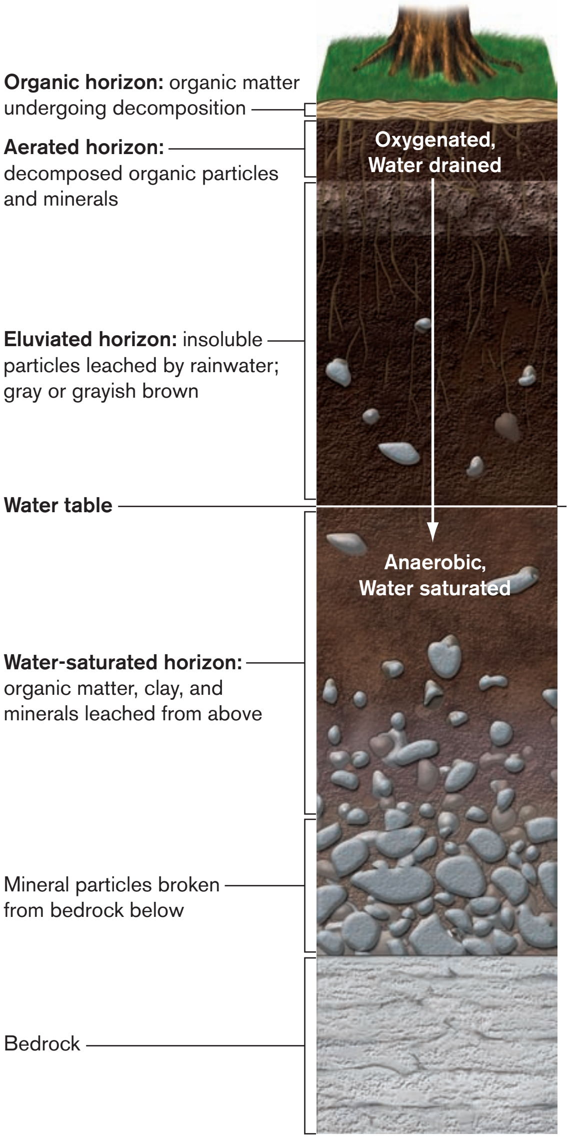
Soil Microbiology

The general structure of soil (**Fig. 21.18**) includes a series of layers called **horizons** that arise as a result of soil-forming factors such as rainfall, temperature variation, wind, and biological activity. Note that the soils of different habitats, such as prairie, forest, and desert, vary greatly as to the depth and quality of each layer.

The surface layer of soil we see is the organic horizon. The organic horizon consists of dark, organic detritus, such as shreds of leaves fallen from plants. The detritus of the organic horizon is in the earliest stages of decomposition by microbes, primarily fungi and bacteria such as actinomycetes. Early-stage decomposition is defined loosely as a state in which the origin of the detritus may be still recognizable.

Beneath the organic horizon lies the lighter colored aerated horizon, in which organic particles in more advanced stages of decomposition combine with minerals from rock at lower levels. In the aerated horizon, the source of the organic particles is no longer recognizable, and decomposers have broken down some of the more difficult-to-digest plant structural components such as lignin. (Lignin is a complex aromatic molecule whose digestion is discussed later in this section.) Such material is often sold by garden stores as peat or topsoil.

In well-drained soil, both the organic and aerated horizons are full of oxygen as well as nutrients liberated by the decomposers and used by plants. In these layers, soil consists of a complex assemblage of organic and inorganic particles (**Fig. 21.19A**). In between soil particles are air spaces that provide access to oxygen. Each particle of soil supports miniature colonies, biofilms, and filaments of bacteria and fungi that interact with each other and with the roots of plants. An interaction of fundamental significance is that of fungi with plants in the symbiotic system known as mycorrhizae (discussed shortly).



Organic horizon: organic matter undergoing decomposition
Aerated horizon: decomposed organic particles and minerals

Water table
Water-saturated horizon: organic matter, clay, and minerals leached from above
Mineral particles broken from bedrock below
Bedrock
Oxygenated, Water drained
Anaerobic, Water saturated

Figure 21.18 The soil profile. Soil forms layers in which decomposing organic material predominates at the top, minerals toward the bottom, at bedrock. The top layers are aerated, providing heterotrophs with access to O_2, whereas the bottom layers are water-saturated and anaerobic.

Below the aerated horizon, the eluviated horizon experiences periods of water saturation from rain. Rainwater leaches (dissolves and removes) some of the organic and mineral nutrients from the upper layers. Below the eluviated horizon lie increasing proportions of minerals and rock fragments broken off from bedrock below. These lower layers experience increasing water saturation, forming the **water table**. Prolonged water saturation generates anoxic conditions. This anoxic, water-saturated region contains mainly lithotrophs and anaerobic heterotrophs.

The soil layers finally end at bedrock, a source of mineral nutrients such as carbonates and iron. Interestingly, bedrock is permeated with microbes. Core samples show

that crustal rock as deep as 3 km down contains **endoliths**, bacteria growing within the very crystals of solid rock (**Fig. 21.19B**). What energy source feeds microbes trapped within rock? For some endoliths, a surprising answer may be the radioactive decay of uranium. Uranium-238 decay generates hydrogen radicals that combine to form hydrogen gas. The hydrogen gas combines with CO_2 from carbonate rock to feed methanogens and other endolithic lithotrophs. Still other endoliths are consumers that feed on the lithotrophs or the organic compounds they produce.

The Soil Food Web

The top horizons of soil feature a food web of extraordinary complexity (**Fig. 21.20**). The major producers are green plants, whose leaves generate detritus and whose root systems serve predators, scavengers, and mutualists. Some carbon is also fixed by lithotrophs oxidizing reduced nitrogen (NH_3), hydrogen sulfide (H_2S), and iron (Fe^{2+}). In well-aerated soil, however, the proportion of carbon fixed by lithotrophs is small.

Plant matter is decomposed by many species of fungi, such as *Mycena* species, and by bacteria such as the actinomycetes. The actinomycetes include *Streptomyces*, a genus famous for the production of antibiotics and for generating chemicals whose odors give soil its characteristic smell (**Fig. 21.21A**). Besides fallen leaves, another source of organic matter from plants is the **rhizosphere**, the region of soil surrounding plant roots. The rhizosphere contains proteins and sugars released by roots, as well as sloughed-off plant cells. These materials feed large numbers of bacteria, which then cycle minerals back to the plant. Bacteria in the rhizosphere may also discourage growth of plant pathogens. Another habitat colonized by bacteria is the surface of fungi, whose filaments are considerably larger than bacterial cells (**Fig. 21.21B**).

At the next trophic level, bacteria feeding on leaf detritus and root exudates are then preyed on by protists and nematodes (**Figs. 21.21C** and **D**). Diverse predators such as nematodes, fungi, and protists exhibit different preferences for bacteria, fungi, or protists as prey. *Vampirella* protists drill holes in fungal hyphae to suck out their nutrients. Parasitic fungi prey on plants or invertebrates; some actually capture and strangle nematodes. Besides predation, there exist many complex forms of mutualism, such as lichens (discussed earlier). Another mutualistic interaction of fungi is that of **mycorrhizae**, fungal infections of plants in which the fungal hyphae extend the root surface area and increase the root's ability to absorb nutrients.

Microbes also cooperate to form complex communities such as microbial mats and biofilms. The microbes ultimately feed invertebrates, which then feed larger invertebrates and vertebrate predators. Some predators, such as earthworms and burrowing animals, enhance the soil quality by turning over the matter, aerating the soil particles and helping to mix the organic matter from above with the mineral particles from below.

Decomposition of Lignin to Humus

A critical role of fungal decomposers (also known as **saprophytes**) is the breakdown of extremely complex structural components of vascular plants such as grass and trees. Trees, in particular, accumulate vast stores of biomass in

forms that are difficult to digest, such as lignin. Fungal and bacterial decomposers possess enzyme systems to degrade lignin and other complex components of plants. Examples of decomposers include white rot fungi (**Fig. 21.22A**) and actinomycete soil bacteria. The prevalence of lignin is one reason that decomposition by fungi plays a much larger role in terrestrial ecosystems than in marine ecosystems.

Lignin is a highly complex and diverse covalent polymer composed of interlinked phenolic groups (benzene rings with OH or related oxygen-bearing side groups; **Fig. 21.22B**). These phenolic polymers can be broken down relatively rapidly to smaller units, some containing only a single phenol or benzoic acid. This first phase of degradation (about 50%) occurs within a year of deposition in the soil. The remaining phenolics, however, may degrade less than 5% per year; and some samples dated by ^{14}C isotope ratios have been shown to last 2,000 years. These phenolic molecules are called **humic material** or **humus**. Because of its slow degradation, humic material provides a steady slow-release supply of nutrients for plant growth. But forests whose rate of microbial decomposition is particularly low—for example, the New Jersey Pine Barrens—ultimately depend on fire to clear the mounting layers of humus.

Lignin is also a major constituent of newsprint and other kinds of paper disposed of by composting or in landfills. Because of the low degradation rate, particularly in anoxic soil, newsprint in landfills can maintain its structure for decades. Archaeology of landfills outside New York City has revealed readable headlines from papers dating to the 1940s.

Microbes Associated with Roots

The presence of plant roots provides yet another level of complexity to soil communities (**Fig. 21.23**). Plant roots influence the surrounding soil by taking up nutrients and by secreting organic substances and molecules that modulate their surroundings. The environment surrounding a plant root can be further subdivided into two categories: the **rhizoplane**, the root surface; and the **rhizosphere**, the region of soil outside the root surface but still influenced by plant exudates (materials secreted by the plant). Particular bacterial species are adapted to these environments. For example, in anaerobic wetland soil, the rhizoplane and rhizosphere of plant roots provide oxygen for methanotrophs that oxidize methane produced by methanogens.

The rhizoplane and rhizosphere also provide the environment for symbiotic fungi that generate mycorrhizae. At least 80% of plants in nature, including 90% of forest trees, require mycorrhizae for growth.

Mycorrhizae: The Fungal Internet

The function and significance of mycorrhizae for plant growth is just beginning to be understood. Mycorrhizae (from *myco*, fungal, and *rhiza* root) consist of fungal mycelia that associate intimately with the roots of plants, extending access to minerals while obtaining in return the energy-rich products of plant photosynthesis. Mycorrhizae were first discovered in the 1880s by German truffle hunters who sought to cultivate the prized delicacy, the fruiting body of an ascomycete (for review of fungi, see Chapter 20). The propagation of truffles was investigated by mycologist A. B. Frank at the Landwirtschaftlichen Hochschule, Berlin. To Frank's surprise, he found that the truffles extended their mycelia far beyond the site of the

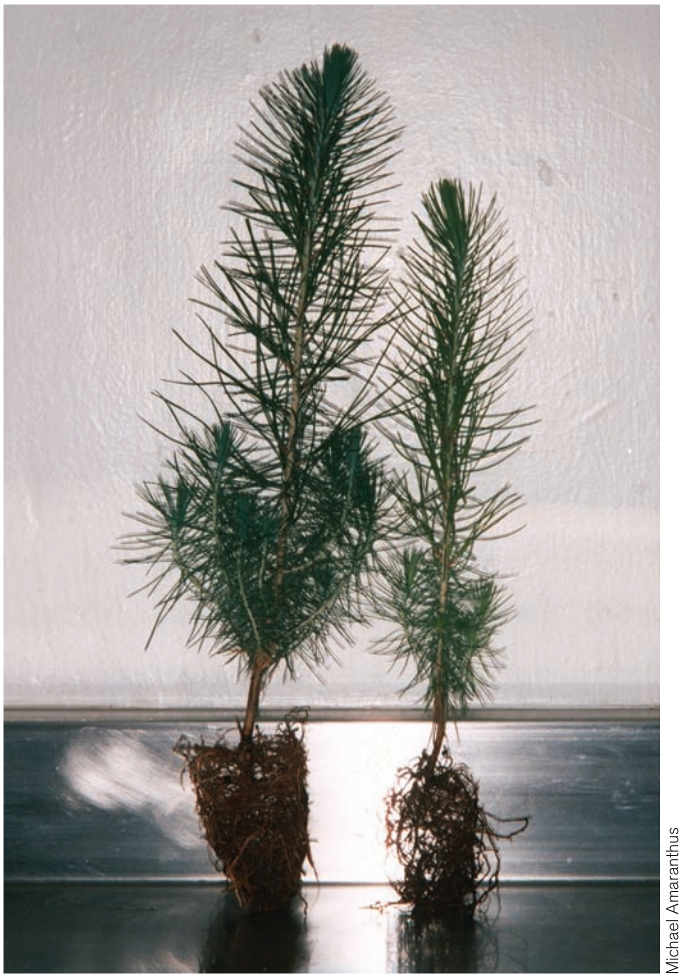
fruiting body, and that the mycelia formed an impenetrable tangle with plant roots. Frank called the tangled mycelia "fungus-root" or mycorrhizae. A century later, we are beginning to appreciate that these mysterious fungal-root tangles offer a vast interconnected network for exchange of nutrients among fungi and many different plants, like an internet connecting countless sites.

Two different kinds of mycorrhizae are observed: ectomycorrhizae and endomycorrhizae. **Ectomycorrhizae** colonize the rhizoplane, the surface of plant rootlets, the most distal part of plant roots (**Fig. 21.24**). The fungal mycelia never penetrate the root; instead, they form a thick mantle surrounding the root, then extend long mycelia away from the root to absorb nutrients. Numerous kinds of fungi form ectomycorrhizae, including ascomycetes, such as truffles, and basidiomycetes, known by their mushrooms, such as stinkhorns. **Endomycorrhizae** form a more intimate association, in which the fungal filaments penetrate plant cells.

A typical "large plant, small plant" experiment demonstrates the impact of mycorrhizae (**Fig. 21.25**). In this experiment, pine seedlings of *Pinus densiflora* were grown with or without inoculation with the ectomycorrhizal fungus *Pisolithus tinctorius*. The seedlings inoculated with the fungus clearly grew faster and larger than those without. Furthermore, analysis of root/shoot ratios shows that plants grown with mycorrhizae invest less of their body mass in roots and more in the aboveground stems and leaves—an important consideration for agriculture, in which the aboveground plant is usually the part harvested.

Unlike the ectomycorrhizae, the endomycorrhizae generate an intimate association in which fungal hyphae penetrate plant cells deep within the cortex (**Fig. 21.26**). The penetrating hyphae form knobbed branches that resemble



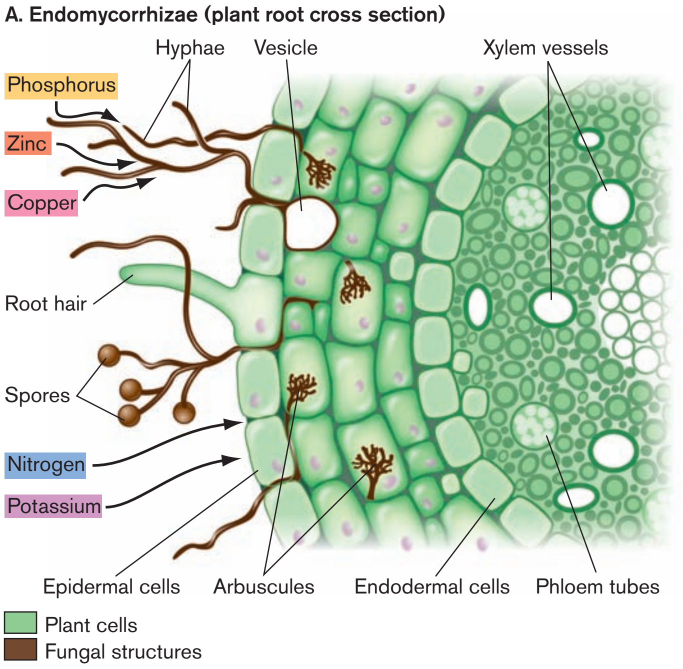
Michael Amaranthus

Figure 21.25 Pine seedlings grown with or without mycorrhizal fungi.

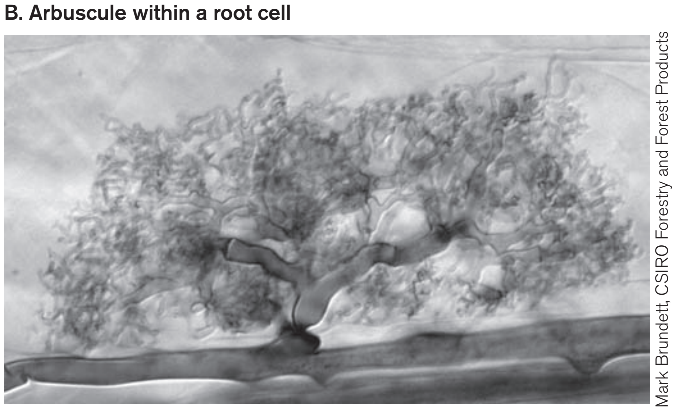
microscopic “trees,” or **arbuscules** within the root cells. Some of the hyphae form specialized vesicles within the plant that store nutrients. Another name for this kind of mycorrhizae is **vesicular-arbuscular mycorrhizae** (**VAM**).

Endomycorrhizae are more specialized than ectomycorrhizae. They comprise a relatively small number of fungal species, such as members of the zygomycete family Glomales, and they show obligate dependence on their host plants. Their presence in nature and their importance in the ecosystem, however, are actually greater. Endomycorrhizal species exist entirely underground (they do not form mushrooms), and they completely lack sexual cycles. They may acquire 25% of the photosynthetic product of their hosts in exchange for tremendous expansion of access to soil resources.

Mycorrhizae greatly enhance the plant’s uptake of water as well as minerals such as nitrogen and phosphorus. In addition, the hyphae sequester toxins, and they actually distribute organic substances from one plant to another. Mycorrhizae may join many different plants, even different species, in a vast nutrient-sharing network.



A. Endomycorrhizae (plant root cross section)



B. Arbuscule within a root cell

Figure 21.26 **Endomycorrhizae: Fungi invade root cells, forming arbuscules.** **A.** Plant root cross section. Endomycorrhizal hyphae penetrate cells deep within the root cortex. **B.** The penetrating hypha forms an arbuscule within a root cell.

The reliance of plants on mycorrhizae may explain why some plants, such as orchids, grow better in nature than in sterilized potting soil, which lacks mycorrhizal fungi.

THOUGHT QUESTION 21.4 Design an experiment to test the hypothesis that the presence of mycorrhizae enhances plant growth in nature.

Wetland Soils

So far, we have considered the interface between ground and water (the benthic sediment beneath oceans and lakes) and the interface between ground and air (aerated soil). An interesting case that combines the two is that of wetlands (**Fig. 21.27A**). A **wetland** is defined as a region of land that undergoes seasonal fluctuations in water level, so that sometimes the land is dry and oxygenated, at other times water saturated and anaerobic. Wetlands provide many crucial functions; for example, the Everglades filter much of the water supply for Florida communities.

Wetland soil that undergoes such periods of anoxic water saturation is known as **hydric soil**. Hydric soil is characterized by "mottles," patterns of color and paleness (**Fig. 21.27B**). The reddish brown portions (for example, surrounding a plant root) result from oxidized iron (Fe^{3+}). The gray-colored "gley" portions indicate loss of iron in its water-soluble reduced form (Fe^{2+}) generated by anaerobic respiration.

Soil becomes anoxic when the rate of oxygen diffusion is too low to support aerobic metabolism. Anaerobic metabolism allows much lower rates of production than metabolism in the presence of oxygen, as anaerobes use oxidants of lower redox potential and limited quantity, such as sulfate and nitrate. Many kinds of anaerobic bacteria inhabit wetlands. For example, denitrifiers (bacteria using nitrate to oxidize organic food) remove nitrate from water before it enters the water table—one of the ways that wetlands protect our water supply.

Figure 21.27 Wetland soil. A. A true wetland experiences periods of water saturation alternating with dry soil. Soil that is water saturated becomes anaerobic because O_2 diffuses slowly through water. **B.** Alternating periods of water saturation and dryness generate an appearance of mottled color in soil. The red-orange colored portions around root holes result from oxidized iron (Fe^{3+}), whereas the gray portions ("gley") indicate loss of iron in its water-soluble reduced form (Fe^{2+}) generated by anaerobic respiration.

The alternative oxidants (electron acceptors) are always in limited supply, so further catabolism occurs by fermentation. Fermentation allows only incomplete breakdown of food molecules, generating a rich and diverse supply of nutrients for a variety of consumers, including aerobic organisms when the water recedes. Thus, despite its lower overall productivity, anaerobic soil contributes to the nutritional diversity of wetland ecosystems. The relatively slow rate of decomposition can lead to accumulation of high levels of organic carbon, particularly rich for plant growth.

The anoxic conditions of wetlands also favor methanogenesis. Methanogenesis is performed solely by archaea (discussed in Chapters 13 and 17). Methanogenesis occurs when fermenting bacteria generate H_2, CO_2, and other one- or two-carbon substrates that methanogens convert to methane. Methane is a more potent greenhouse gas than CO_2, and although the current methane concentration in our atmosphere is low, it is rising exponentially.

In water-filled anaerobic soils, particularly those of rice fields, significant quantities of methane escape to the air through air-conducting channels in the roots of the rice plant. The roots of rice plants, like those of other wetland vascular plants, contain channels for oxygen to reach the roots. These same channels, however, allow methane to escape from anaerobic soil. Fortunately, the rhizosphere of the roots supports methanotrophs that oxidize methane, so research is being done to maximize methanotroph activity. There is some evidence that natural wetlands actually take in more carbon than they put out, whereas disturbed wetlands (wetlands altered by human activity) generate net efflux of CO_2 and CH_4. The role of wetlands in global cycling is discussed further in Chapter 22.

Dry Land: Lichens and Cryptogamic Crust

The opposite of wetlands is the dry, nutrient-poor habitats that support extremely hardy microbial communities such as lichens. Lichens are essential for boreal (northern) forests, where they cover the majority of the ground and serve as food for grazing animals (**Fig. 21.28A**). In winter, lichens are a major food source for caribou, which dig beneath the snow to obtain them (**Fig. 21.28B**). Native populations of North America often use lichens for medicines and to dye cloth (**Fig. 21.28C**). Many lichens are found to contain antibacterial agents.

More southern climates, such as the dry hot deserts of the western United States, host a slow-forming type of soil called **cryptogamic crust** (**Fig. 21.29**).

Biological Soils

Figure 21.29 **Cryptogamic crust.** **A.** Cryptogamic crust interspersed by vegetation, Utah's Capitol Reef National Park. **B.** Close-up view of cryptogamic crust just after rainfall.

(*Crypto* means “hidden,” referring to the hidden nature of this ground cover.) Cryptogamic crust includes a complex, spongy association of lichens, mosses, and nonlichenous algae and fungi. The crust takes many years to grow a centimeter thick and is easily destroyed by bikes or hiking boots—a problem for desert parks such Utah’s Capitol Reef National Park. The crust plays a vital role in desert ecosystems by holding moisture, protecting plant seeds for germination, and preventing erosion.

TO SUMMARIZE:

- **The uppermost horizons of soil** consist of detritus, largely aerated. Below the aerated layers, the eluviated horizon experiences water saturation. Lower layers are anoxic.
- **The soil food web** includes a complex range of microbial producers, consumers, predators, decomposers, and mutualists. Microbial mats and biofilms are complex multispecies communities of bacteria, fungi, and other microbes.
- **Fungi decompose lignin**, a complex aromatic tree component that is challenging to digest. Lignin decomposition forms humus.
- **Fungi form symbiotic associations** with plant roots called mycorrhizae. Mycorrhizae transport soil nutrients among many different kinds of plants.
- **Wetland soils** alternate aerated (dry) with anoxic (water-saturated) conditions. Anoxic wetland soil favors methanogenesis. Wetland soils are among the most productive ecosystems.
- **Dry soils** depend on lichens.

21.5 Microbial Communities within Plants

Specialized habitats for microbes exist within the bodies of plants and animals. Multicellular plants and animals coevolve with the microbes in their environment, and in many cases their microbes can exist nowhere else. The microbial partners may grow as mutualists, commensals, or parasites. A form of bacteria-plant mutualism critical for agriculture is that of nitrogen fixation by rhizobia, a group of alpha proteobacteria related to *E. coli* and other gram-negative species. Major rhizobial genera include *Rhizobium*, *Bradyrhizobium*, and *Sinorhizobium*.

Rhizobia Fix Nitrogen for Legumes

Rhizobia, associated with legumes such as peas and beans, fix more nitrogen than the plants absorb from soil, actually increasing the soil’s nitrogen content. For this reason, farmers often alternate crops such as corn with soybeans to restore nitrogen to the soil. The rhizobial bacteria develop specialized forms within plant cells, called **bacteroids**. Bacteroids lack cell walls and are unable to reproduce; their function is specialized for nitrogen fixation. The rhizobial infection of root hairs induces formation of nodules within which the nitrogen-fixing bacterioids are sequestered (**Fig. 21.30A**).

The initiation, development, and maintenance of the rhizobia-legume symbiosis poses intriguing questions of genetic regulation. How does the association begin? How do host plant and bacterium recognize each other as suitable partners? The legume exudes signal molecules called **flavonoids** into its rhizosphere. Flavonoids resemble steroid hormones such as estrogen and have similar effects on animals; they are also called phytoestrogens. The flavonoids are detected by rhizobial bacteria, which respond by chemotaxis, swimming toward the root surface.

Figure 21.31 **The infection thread.** **A.** Rhizobia are attracted to the legume by chemotaxis toward exuded flavonoids. A bacterium induces an epidermal root hair to curl around it and take it up into a tube of plant cell wall material. The bacteria entering through the plant tube form an infection thread. The thread eventually penetrates cortical cells, where the bacteria lose their cell walls and become nitrogen-fixing bacteroids. **B.** Root hair curling around *Rhizobium*, and the formation of an infection thread (light microscopy). **C.** Infection threads invading the cortex (fluorescence microscopy). Bacteria are labeled with transgenes expressing either DsRed (pink) or green fluorescent protein (green).

THOUGHT QUESTION 21.5 High levels of nitrate or ammonium ion corepress the *nod* genes through NodR. Why?

Within the bacterial cell, the signal molecules induce transcription of genes involved in nodule formation, called *nod* genes (**Fig. 21.30B**). The overall regulatory protein NodD then amplifies its own subsequent expression, subject to limitation by the repressor NodR. This highly sensitive feedback loop leads to coordinated expression of proteins that induce root infection, plant cell proliferation, and nodule development. One of the functions of the *nod* genes is to synthesize Nod factors, molecules composed of chitin with lipid attachments. Nod factors communicate with the host plant and help establish species specificity between bacterium and host.

The entry of the bacteria into the host involves a fascinating interplay between bacterial and plant cells, whose mechanism remains largely unknown (**Fig. 21.31A**). First, a bacterium is attracted by flavonoids to the surface of a root hair extended by a root epidermal cell. The presence of the bacterium somehow induces the root hair to curl around it and ultimately surround the bacterium with plant cell envelope. The bacterium then induces growth of a tube poking into the plant cell. The tube growth is directed by the plant nucleus, which migrates toward the plant cortex. As the tube grows, bacteria proliferate, forming a column of cells that projects down the tube. This column of cells is known as the **infection thread**. The infection thread can be visualized by light microscopy (**Fig. 21.31B**).

As the infection thread develops, signals from the bacteria induce the cortical cells (below the epidermis) to prepare to receive the bacteria. The bacteria induce further tube formation into the cortical cells and continue penetration as they grow. The penetration of the infection thread into the cortex appears strikingly in fluorescence micrographs (**Fig. 21.31C**) in which the bacteria are engineered to express a fluorescent protein.

The cortical cells invaded by bacteria are induced to proliferate in an organized manner, forming nodules. Within the nodules, most of the infecting bacteria differentiate into wall-less bacteroids that will fix nitrogen (**Fig. 21.32A**). A few bacteria fail to differentiate; their fate is unclear. The bacteroids remain sequestered within a sac of plant-derived membrane known as the **symbiosome**. The symbiosome membrane contains special transporters that mediate the exchange of nutrients between the bacteroid and its host cell, sustaining bacteroid metabolism while preventing harm to the host.

From the plant cytoplasm, the bacteroid receives catabolites such as malate, which enter the TCA cycle and donate electrons for respiration. The oxygen for respiration comes from the plant's photosynthesis (**Fig. 21.33**). About a fifth of the plant's photosynthesis is required to fix nitrogen. As discussed in Chapter 15, nitrogen is fixed by the nitrogenase enzyme into ammonium ions:

$$N_2 + 8H + 2H^+ \longrightarrow 2NH_4^+ + H_2$$

The reaction requires expenditure of 8 NADPH or NADH plus 16 ATP, which are generated by respiration. But respiration requires oxygen, which poisons nitrogenase. Thus, oxygen needs to be delivered to the bacteroid only as needed, and in an amount just enough to run respiration. Excess oxygen is sequestered by **leghemoglobin**, an iron-bearing plant protein related to blood hemoglobin. Leghemoglobin in plant cytoplasm colors the nodule pink (**Fig. 21.32B**).

Overall, the nitrogen fixation symbiosis is kept in balance by several regulatory mechanisms. The presence of ammonium or nitrate ions inhibits symbiosis and nitrogen fixation. The bacteroids cannot synthesize their own amino acids; instead, they must provide ammonium to the plant cytoplasm for assimilation into amino acids, some of which cycle back to the bacteroid. But what is known of regulation is dwarfed by the unanswered questions. How is the infection thread formed? How does the plant allow infection while preventing uncontrolled growth of bacteria? What determines how much of plant products of photosynthesis are harvested by the bacteria? Why is hydrogen gas released, and how can this loss of potential energy be prevented? What limits the host specificity of rhizobia to legumes, and can it be extended to other crop plants, such as corn? Research on these questions is critical for agriculture.

Bacteroid-containing cells form nodules. **B.** Within a sectioned nodule, the pink color indicates leghemoglobin.

THOUGHT QUESTION 21.6 One unanswered question is, how do symbiotic rhizobia reproduce? Why do bacteroids develop if they cannot proliferate?

Plant Pathogens

We have seen how many bacteria and fungi interact positively with plants, but many other species act as pathogens. In any environment, pathogens are always outnumbered by the vast community of neutral or helpful microbes. Nevertheless, when a pathogen does colonize a plant, its growth can have effects ranging from minimal to devastating (**Fig. 21.34**). A relatively harmless plant virus was associated with a famous historical phenomenon, the tulip craze in the Netherlands in the sixteenth century. The virus caused streaking of tulip petals, a pattern much admired by tulip fanciers. Other viruses, however, can cause devastating blights and epidemics. (For more on viruses, see Chapters 6 and 11.)

A pathogenic relative of rhizobia is the bacterium *Agrobacterium tumefasciens*, whose DNA transforms plant cells to form crown gall tumors (**Fig. 21.34B**). *A. tumefasciens* has an unusually broad host range, and its natural genetic transformation system has been applied widely for commercial plant engineering (discussed in Chapter 16). The tumors remain largely confined and have relatively little effect on plant growth. Other bacterial pathogens, particularly species of *Erwinia* and *Xanthomonas*, severely damage plants.

Figure 21.33 Energy and oxygen regulation during nitrogen fixation. The bacteroid receives photosynthetic products from the plant, such as malate, and oxygen to generate ATP for nitrogen fixation. The amount of oxygen is regulated closely by leghemoglobin. The bacteroid provides nitrogen (fixed as ammonium ion) to the plant cell.

Figure 21.34 Plant diseases range from innocuous to devastating. **A.** Striped tulips result from a virus. **B.** Crown gall tumor on rose stem caused by *Agrobacterium tumefaciens*. **C.** White oak leaf spotted by anthracnose fungus. **D.** Elm tree wilted by Dutch elm disease, caused by the fungus *Ophiostoma novo-ulmi*.

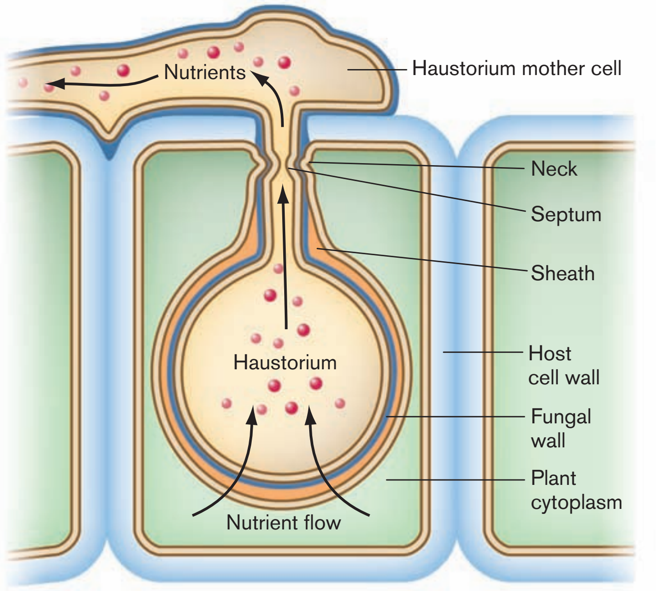

Figure 21.35 A fungal pathogen inserts haustoria into plant cells. The haustorium is surrounded by an invagination of the plant's cell membrane. Plant nutrients such as sucrose flow into the haustorium and are transferred out to the fungal mycelia.

The most common plant pathogens are fungi. Fungus diseases such as anthracnose (**Fig. 21.34C**) cause substantial losses in agriculture, affecting cucumbers, tomatoes, and other vegetables. Dutch elm disease, which has wiped out nearly all the native elms of the United States (**Fig. 21.34D**), is caused by the fungus *Ophiostoma novo-ulmi*. The fungus is carried by bark beetles, which bore into the xylem, damaging the plant's transport vessels and allowing access to fungal spores.

Some fungal pathogens generate specialized structures to acquire nutrients from plants. As a hypha grows across the plant epidermis, its tip can penetrate the plant cell wall, followed by ingrowth of a bulbous extension called a **haustorium** (**Fig. 21.35**). The haustorium never penetrates the plant cell membrane, thus avoiding leakage and loss of plant cytoplasm. Instead, it causes the membrane to invaginate, while expanding into the volume of the plant cell. The haustorium takes up nutrients such as sucrose, generated by adjacent chloroplasts. Depending on the species of fungus, haustorial parasitism can lead to mild growth retardation or it can rapidly kill the plant.

THOUGHT QUESTION 21.7 Compare and contrast the processes of plant infection by rhizobia and by fungal haustoria.

TO SUMMARIZE:

- **Rhizobia induce legume roots** to nodulate for nitrogen fixation. The bacteria enter the root as invasion threads. Some of the bacteria enter root cells and develop into nitrogen-fixing bacteroids.
- **Bacteroids** gain energy from plant cell respiration but must remain anaerobic. The anaerobic state is protected by the oxygen-binding protein leghemoglobin.
- **Plant pathogens** include bacteria, fungi, and viruses. Some pathogens only mildly affect the plant, whereas others cause devastation.
- **Fungi invade plants using haustoria.** The haustoria grow into the plant cell by penetrating the cell wall and invaginating the cell membrane to avoid leakage of cytoplasm.

21.6 Microbial Communities within Animals

Animals, like plants, associate with communities of bacteria on their surfaces or within certain internal organs. Many bacteria have beneficial effects, such as enhancing digestion or generating protective substances in the skin. A relatively small proportion of animal-associated microbes cause disease. We discuss here just a few examples of particular significance for ecology and veterinary science. Human microflora are discussed in Chapter 23. Pathogenesis and disease in humans are discussed in Chapters 25 and 26.

Zooxanthellae in Corals and Sea Anemones

Many invertebrate animals acquire endosymbiotic algae, most commonly dinoflagellates. These endosymbionts are called **zooxanthellae**. The algae receive protection from predators, while the animal receives photosynthetic products. Examples include hydras, anemones, clams, and corals (**Fig. 21.36A**). Coral zooxanthellae are extremely important to the biosphere because healthy coral is responsible for reef formation and much of the biological productivity of coastal shelf ecosystems. The slight rise in temperature that has occurred from global warming has already caused severe problems with **coral bleaching**, in which the algal symbionts die or are expelled. The coral turns white and soon dies unless its symbionts return.

The most common algal partners are members of the dinoflagellate genus *Symbiodinium* (**Fig. 21.36B**). A given coral or anemone may harbor several different species of *Symbiodinium*, which show different preferences for light or shade and different tolerances for temperature change. Studies of coral bleaching due to temperature increase suggest that corals containing diverse species of symbionts are more likely to survive, because one of their species may happen to be resistant to a rise in temperature.

Sponge Communities

Animals often harbor extremely diverse communities of microbes whose specific contributions are poorly understood—for example, bacteria associated with marine sponges (**Fig. 21.37**). In 2001, Russell Hill and colleagues at the University of Maryland, Baltimore, characterized the bacterial species associated with the sponge *Rhopaloeides odorabile,* which grows off the Australian Great Barrier Reef. Using 16S rDNA probes, they identified novel species of delta-proteobacteria, planctomycetes, flavibacteria, green sulfur and nonsulfur bacteria, as well as deep-branching isolates of no known major clade. Most interesting, they discovered a novel actinomycete that produces antimicrobial substances. Hill hypothesizes that the sponge harbors these bacteria to defend it from pathogens, which rapidly consume sponges that lack their own microbial community. Sponge bacteria, therefore, may offer a wealth of previously unknown antibiotics.

Digestive Communities

Some of the most complex and nutritionally important communities of microbes are those found within animal digestive systems. Digestive chambers, such as the stomach and intestines, often support thousands of species of bacteria, protists, and archaea unique to the animal. Among insects, termites harbor thousands of unique cellulolytic species, including spirochetes and multipartner symbiotic organisms such as *Mixotricha*. The human colon contains numerous fermenters and methanogens, some of which feed on intestinal mucus, whereas others digest complex plant fibers, providing up to 15% of our caloric intake. On the other hand, the extremely acidic human stomach supports a very different community, including unique acid-tolerant spirilla such as *Helicobacter pylori*, a cause of gastric ulcers.

The most extensively studied digestive communities are those of ruminant animals, such as cattle, sheep, llamas, and caribou. Throughout most of human civilization, ruminants have provided protein-rich food, textile fibers, and mechanical work. A historical reference is the biblical injunction to consume an animal that "is cleft-footed and chews the cud"—that is, "ruminates," or redigests its food in the fermentation chamber known as the **rumen** (**Figs. 21.38A** and **B**).

The microbial community of the rumen enables herbivores to acquire nutrition from complex plant fibers that the animal could not otherwise digest. From a genomic standpoint, such an arrangement makes evolutionary sense. If the animal had to digest all the diverse polysaccharide chains encountered in nature, its own genome would have to encode a wide array of different enzyme systems. Instead, the ruminant relies on diverse microbial species to conduct various kinds of digestion. Organisms that partly digest a substrate (for instance, converting sugars to lactate) provide a substrate that others can further metabolize. This process is known as syntrophy. Microbial fermentation under the anaerobic conditions of the rumen generates short-chain fatty acids that are absorbed by the ruminant intestinal lining and digested to completion through the animal's respiration.

THOUGHT QUESTION 21.8 Why does ruminant fermentation leave food value for the animal host? How is the animal able to obtain nourishment from waste products that the microbes could not use?

The most intensively studied ruminants are cattle. The bovine stomach has four chambers. The rumen initially digests the feed, then passes it to the reticulum. The reticulum breaks the feed into smaller pieces and traps indigestible objects, such as stones or nails. After initial digestion, feed is regurgitated for rechewing, then returned to the rumen, by far the largest of the chambers.

In the rumen, feed is reduced to small particles and fermented slowly by thousands of species of microbes. The partially digested feed passes to the omasum, which absorbs water and short-chain acids produced by fermentation. The abomasum then decreases pH and secretes enzymes to digest proteins before sending its contents to the colon for further nutrient absorption and waste excretion.

While rumen digestion has been studied since the 1830s, major advances in understanding rumen fermentation were first achieved in 1966 by Robert Hungate (1906–2004) at the University of California, Davis, who pioneered techniques of anaerobic microbiology. An example of Hungate's methods still in use today is that of obtaining anaerobic cultures from fistulated cattle—that is, cattle in which an artificial connection is made between the rumen and the animal's exterior (**Special Topic 21.1**). The full diversity of ruminal flora was revealed by James Russell and colleagues at Cornell Veterinary School (**Fig. 21.38C**), whose rRNA studies showed hundreds of isolates from all three microbial domains—archaea, prokaryotes, and eukaryotes—including several major groups within each domain. Different species fill different niches in ruminal metabolism (**Fig. 21.39**).

Figure 21.39 **Ruminal metabolism.** *Source*: Based on Russell and Rychlik. 2001. *Science* 292:1119.

In nature, the most important role for ruminants is that of breaking down cellulose and complex plant fibers such as lignins. Cattle grown on relatively poor forage (that is, forage high in complex plant content) show a high proportion of ruminal fungi, the chytridiomycetes (discussed in Chapter 20). Chytridiomycete mycelia appear on ruminal food particles, and their motile zoospores—formerly mistaken for protists—swim through rumen fluid. On the other hand, cattle fed a high cellulose diet, such as hay, grow faster and show cellulolytic bacteria such as *Ruminococcus albus* and *Fibrobacter flavefaciens*.

Metabolism of cellulolytic bacteria requires the presence of small amounts of branched-chain fatty acids. The branched-chain acids turn out to be produced by amino acid fermenters such as *Megasphaera elsdenii* and *Peptostreptococcus anaerobius*. However, too much degradation of amino acids can lead to overproduction of ammonia, poisoning the animal; thus, the protein content of cattle feed must be limited.

Another problem with ruminal fermentation is the frequent production of H_2 and CO_2. Hydrogen production is hard to avoid because the quantity of electron donors (reduced food molecules) greatly exceeds that of the available electron acceptors. The hydrogen and CO_2 from fermentation support methanogens, wasting valuable carbon from feed and contributing a substantial part of global methane emissions. So much methane is formed by the rumen that a cannula inserted into the rumen liberates enough of the gas to light a flame.

THOUGHT QUESTION 21.9 How do you think cattle feed might be altered or supplemented to decrease methane production?

Another concern with modern cattle rearing is the shift in feed from hay to grain, whose higher content of starch leads to more rapid digestion and faster growth of the animal. Unfortunately, rapid starch digestion favors fermenters such as *Prevotella* species and *E. coli*, which generate higher acid levels and gases, leading to "starch bloat." Furthermore, rumen acidity selects for acid-resistant pathogens such as the *E. coli* strain O157:H7. Pathogenic *E. coli* contaminates meat and produce in North America and is now a leading cause of serious illness in young people.

Special Topic 21.1 A Veterinary Experiment: The Fistulated Cow

Ruminal ecology is vital to maximize dairy production and minimize contamination by deadly pathogens such as *E. coli* O157:H7. The rumen is observed by a simple surgical operation to form a **fistula**, a connecting hole between the rumen and the exterior of the animal (**Figs. 1A** and **B**). The presence of the fistula, which can be capped and reopened at will, causes the animal no harm and ensures it several years of comfortable existence beyond the usual life of dairy cattle. The fistula can be used to insert experimental feed materials, such as grain or nitrogen supplements, and it can be used to test parameters of rumen fluid, such as pH and microbial content. Study of fistulated cattle is a common exercise for students of veterinary medicine.

An experiment using the fistula is shown in **Figure 2**. In the experiment shown, James Russell and colleagues tested the hypothesis that increasing proportions of grain in cattle feed result in increased acid production and favor the appearance of acid-resistant bacterial species such as *E. coli*. The top part of the figure shows the pH of ruminal fluid (obtained through the fistula) as well as fluid from the colon. As feed includes higher proportions of grain (horizontal axis), the pH of the rumen declines, as does that of the colon. As pH declines, the number of *E. coli* bacteria increases greatly, in part because they are more acid resistant than other species.

These results suggest that the high-grain content in modern cattle feed has contributed to the emergence of pathogenic strains of *E. coli*. One response among consumers has been a renewed interest in hay-fed or free-range cattle. On the other hand, it is likely that fiber-rich diets produce even more methane than grain-rich diets supplemented with antimethanogen agents. Further research on rumen flora will be needed to optimize cattle production while minimizing the growth of pathogens and methanogens.

TO SUMMARIZE:

- **Animals harbor microbial communities.** Microbes populate the skin, where they provide protection from pathogens. Other species grow in the animal's digestive system, where they enhance nutrition.
- **Corals and sea anemones harbor zooxanthellae.** Zooxanthellae are algae that provide products of photosynthesis in exchange for a protected habitat.
- **The rumen of ruminant animals is a complex microbial digestive chamber.** Rumen microbes, including bacteria, protists, and fungi, digest complex plant materials. The microbial digestion generates short-chain fatty acids that are absorbed by the intestinal lining.

Concluding Thoughts

In this chapter, we have seen how microbes colonize a vast array of habitats ranging from the deserts and oceans to the roots of plants and the digestive tracts of animals. Microbes are found in the upper layers of our planet's atmosphere, down to the deepest rock strata we can reach. Wherever found, microbes both respond to and modify the environment that surrounds them. While this chapter has focused on food webs in local habitats, Chapter 22 takes a global perspective of microbial ecology and its roles in the cycling of essential elements, such as nitrogen and iron, in Earth's biosphere.

CHAPTER REVIEW

Review Questions

1. What unique functions do microbes perform in ecosystems?
2. Explain the difference between carbon assimilation and dissimilation.
3. What kinds of microbial metabolism are favored in aerated environments? In anoxic environments?
4. What are examples of microbial producers in ecosystems? Include phototrophs as well as lithotrophs. Can a microbe be both a producer and a consumer? Explain.
5. Explain the microbial relationships in various forms of symbiosis, including mutualism, commensalism, and parasitism. Outline an example of each, detailing the contributions of each partner.
6. Compare and contrast the marine food web with the soil food web. What kinds of organisms are the producers and consumers? How many trophic levels are typically found?
7. Explain the role of biofilms in marine and soil habitats. Are these habitats typically uniform or patchy?
8. Compare and contrast the roles of microbes in photic and aphotic marine communities.
9. Compare and contrast the microbial activities in aerated and waterlogged soil.
10. Explain the different methods of quantifying microbial communities, including the advantages and limitations of each.
11. Explain how anaerobic microbial metabolism can enrich soil for plant cultivation.
12. What are mycorrhizae, and how are they important for plant growth?
13. Explain how bacterial mutualists fix nitrogen for plants.

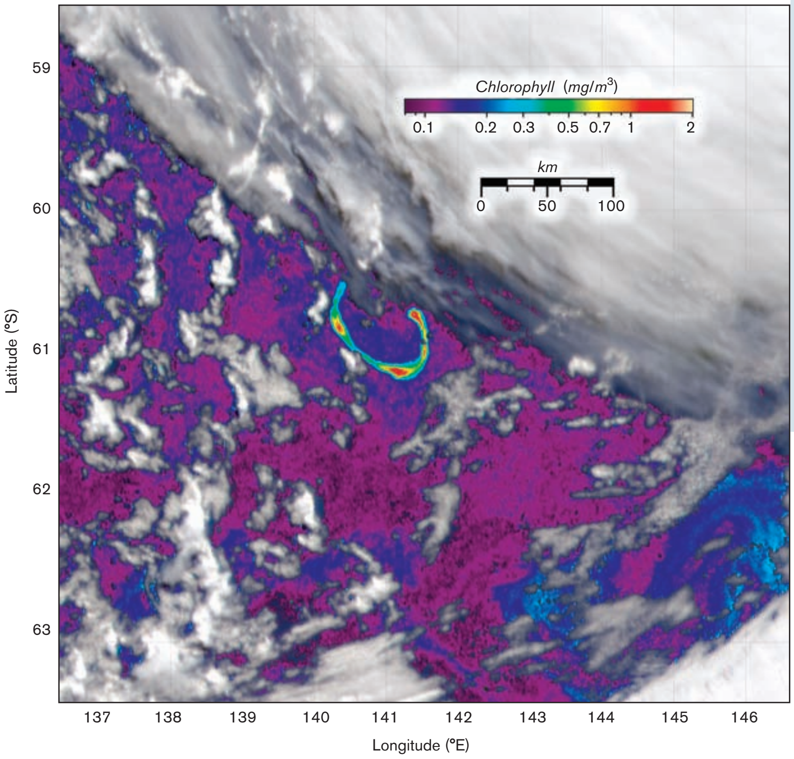
Chapter 22

Microbes and the Global Environment

22.1 Biogeochemical Cycles
22.2 The Carbon Cycle
22.3 The Hydrologic Cycle and Wastewater Treatment
22.4 The Nitrogen Cycle
22.5 Sulfur, Phosphorus, and Metals
22.6 Astrobiology

Microbes throughout the biosphere recycle carbon, nitrogen, sulfur, and other elements essential for all life. Through their biochemical transformations, both helpful and harmful, diverse microbial activities largely determine the quality of soil, air, and water for human life. Today, all of these geochemical cycles are altered profoundly by human activity. The burning of fossil fuels, which were generated millions of years ago by subterranean microbes, releases quantities of carbon dioxide too great to be absorbed by marine bacteria and algae. Growing rice production increases the release of methane by methanogens that thrive in submerged rice paddies. Both carbon dioxide and methane are "greenhouse gases" that lead to global warming. Will we humans learn to manage the perturbations of our own biosphere, from pollution to global warming?

From local wastewater treatment to the control of greenhouse gases, microbes are our hidden partners on Earth. And Earth's microbial cycles lead us to wonder whether biospheres exist on other worlds. Our neighbor planet Mars shows tantalizing hints of water and the possibility of hidden microbial life.



Satellite image of chlorophyll concentration in the waters of the Southern Ocean, due to phytoplankton bloom following an iron enrichment experiment. Green through orange color indicates overgrowth of phytoplankton where iron was added. Iron limits phytoplankton productivity in much of the world's ocean waters. Thus, iron controls algal blooms, which affect the carbon cycle and may influence global warming. Photo provided by Norman Kuring, NASA.
Source: Philip W. Boyd, et al. 2007. *Science* 315:612.

Two billion years ago, ancient cyanobacteria acquired the ability to photolyze water and produce molecular oxygen. Oxygen is a powerful oxidant, lethal to most life in that anoxic era, when all living organisms were anaerobic microbes. Massive extinctions must have occurred until a lucky few species evolved mechanisms of antioxidant protection. Since then microbes have shaped our biosphere by generating oxygen, by fixing gaseous nitrogen and returning it to the atmosphere, and by fixing and producing carbon dioxide. These and countless other microbial processes not only have made the Earth's atmosphere what it is but continue to play a crucial role in its homeostasis.

During the past century, key aspects of global biospheric chemistry have been perturbed by human technology. Already 15% of the nitrogen in the biosphere comes from anthropogenic (human-generated) sources. And increases in atmospheric CO_2 and CH_4, important greenhouse gases, correlate with the rise of the industrial age (**Fig. 22.1**). These gases are produced by the biosphere by bacteria, fungi, and protists, as well as by human technology. Human burning of petroleum releases CO_2 from the product of ancient bacterial cells. Much of global carbon dioxide is fixed by phototrophic prokaryotes and algae as well as land plants. But the added CO_2 production by human industry has outpaced the rate of CO_2 fixation.

Can we adapt to our changing biosphere, just as microbes respond and adapt to environmental change? Concern over the effect of increasing greenhouse gases on global climate change led the United Nations, meeting in Kyoto in 1997, to adopt the Kyoto Protocol for reduction of industrial emissions of CO_2, CH_4, and other gases that contribute to global warming. Over 160 nations adopted the protocol, although the United States declined, contending that it posed a disproportionate economic burden on developed nations. Will the human-induced global warming cause mass extinctions of a majority of Earth's species—as did the rise of ancient cyanobacteria? Or can we use our knowledge of microbial ecology to channel microbial activities into recovering the balance—for example, by increasing microbial CO_2 fixation?

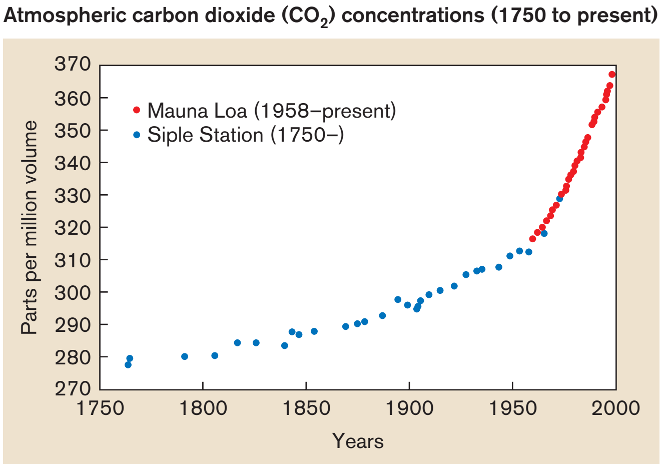


Figure 22.1 Global carbon dioxide levels. Atmospheric CO_2 levels since 1750 reveal the increase of this greenhouse gas accompanying the rise in industrial consumption of fossil fuels. Microbial CO_2 fixation helps limit CO_2 increase in the atmosphere. *Source:* World Resources Institute.

Throughout most of this book, we present microbial biochemistry in the context of growth of individual organisms. In this chapter, we show how the collective metabolic activities of microbial populations contribute to global cycles of elements throughout Earth's biosphere. We consider the ways that we humans enlist microbes to manage our environment. Finally, our awareness of global microbiology has renewed our quest for life beyond Earth.

22.1 Biogeochemical Cycles

Microbes possess exceptional abilities to interconvert molecules. Nearly any kind of molecule can be metabolized by some species somewhere if the reaction provides energy or a useful nutrient. But even microbes face the limits of the actual elements themselves: No microbe, nor any living creature, can convert one element to another. Living organisms conduct chemical reactions, not nuclear reactions—although microbes that live deep underground may obtain chemical energy from hydrogen ions generated by uranium decay.

Microbes Cycle Essential Elements through Their Environment

Because organisms on Earth cannot create their own elements, they need to get them from their environment. While small amounts of matter enter the biosphere from outer space, and gases continually escape the planet, the rate of these changes is tiny compared to the rates of living processes. So organisms acquire their elements either from nonliving components of their environment, such as by fixing atmospheric CO_2, or from other organisms, by grazing, predation, or decomposition. Furthermore, all organisms recycle their components back to the biosphere. The partners in this recycling include **abiotic** entities such as air, water, and minerals, as well as **biotic** entities such as predators and decomposers. Collectively, the metabolic interactions of microbial communitites with the biotic and abiotic components of their ecosystems are known as **biogeochemistry** or **geomicrobiology**.

Which elements need to be recycled and made available for life? In most organisms, six elements predomi-

All others	0.3

nate: carbon, oxygen, nitrogen, hydrogen, phosphorus, and sulfur (discussed in Chapter 4). **Table 22.1** summarizes the elemental composition typical of gram-negative bacteria. In other microbes, elemental proportions vary with species and growth conditions. Some species include inorganic components such as the silicate shells of diatoms or the sulfur granules of phototrophic bacteria. All of these elements flow in **biogeochemical cycles** of nutrients throughout the biotic and abiotic components of the biosphere. The environmental levels of key elements can limit biological productivity. For example, the concentration of iron limits the marine populations of phytoplankton, which are dependent on iron supplied by wind currents. Other elements, such as zinc and copper, are **micronutrients**, nutrients required in still smaller amounts. Micronutrients, too, must be cycled, although their flux is challenging to measure.

Sources and Sinks of Essential Elements

Biogeochemical cycles include both biological components (such as phototrophs that consume CO_2 and heterotrophs that produce CO_2) and geological components (such as volcanoes that produce CO_2 and oceans that absorb CO_2). The major parts of the biosphere containing significant amounts of an element needed for life are called reservoirs of that element (**Table 22.2**). Each reservoir acts both as a source of that element for living organisms and as a sink to which the element returns. For example, the ocean is an important reservoir for carbon (CO_2 in equilibrium with HCO_3^-, bicarbonate ion). The ocean's carbon cycles rapidly; thus, the ocean serves as both a source and a sink for carbon.

As elements cycle from sources to sinks, microbial metabolism generates a series of redox changes. The major oxidation states of carbon, nitrogen, and sulfur

Table 22.2 Global reservoirs of carbon, nitrogen, and sulfur.[a]

Reservoir	Carbon	Rate of cycling	Nitrogen	Rate of cycling	Sulfur	Rate of cycling

Table 22.3 Oxidation states of cycled compounds.

Oxidation state	Carbon		Nitrogen		Sulfur	
−4	CH_4	Methane				
−3			NH_3, NH_4^+	Ammonia, ammonium ion		
−2	CH_3OH, $(CH_2)_n$	Methanol, hydrocarbon	$H_2N\text{-}NH_2$	Hydrazine	H_2S, S^{2-}	Sulfides
−1			NH_2OH	Hydroxylamine		
0	$(CH_2O)_n$	Carbohydrate	N_2	Nitrogen	S^0	Elemental sulfur
+1			N_2O	Nitrous oxide		
+2	HCOOH	Formic acid	NO	Nitric oxide	$S_2O_3^{2-}$	Thiosulfate
+3			HNO_2, NO_2^-	Nitrous acid, nitrite ion		
+4	CO_2, HCO_3^-	Carbon dioxide, bicarbonate ion	NO_2	Nitrogen dioxide	SO_3^{2-}	Sulfite
+5			HNO_3, NO_3^-	Nitric acid, nitrate ion		
+6					H_2SO_4, SO_4^{2-}	Sulfuric acid, sulfate ion

are summarized in **Table 22.3**. Biospheric carbon can be found as CH_4 generated by methanogens (completely reduced, −4), as CO_2 produced by respiration and fermentation (completely oxidized, +4), or as one of various intermediate states of oxidation. Nitrogen is excreted by many organisms in its most reduced form, ammonia (NH_3), which is protonated to ammonium ion (NH_4^+). Ammonium is oxidized by lithotrophic bacteria through several stages to nitrite (NO_2^-) and nitrate (NO_3^-), which serve as terminal electron acceptors for anaerobic respiration. Sulfides (H_2S, HS^-) serve as electron donors for respiration and sulfur phototrophy, whereas oxidized forms, such as sulfite (SO_3^{2-}) and sulfate (SO_4^{2-}), serve in anaerobic respiration.

THOUGHT QUESTION 22.1 Why is oxidation state critical for the acquisition, usability, and potential toxicity of cycled compounds? Cite examples based on your study of microbial metabolism.

How do we study microbial cycling on a global scale? How do we figure out whether ecosystems are net sources or sinks of CO_2? Does microbial activity enhance or limit availability of nitrogen? Rates of flux of elements in the biosphere are very difficult to measure, yet the questions have enormous political and economic implications.

To measure environmental carbon, nitrogen, and other elements, various methods are used. These methods fall under the following categories:

- **Chemical and spectroscopic analysis.** Bulk quantities of CO_2, nitrates, and other chemicals can be determined by sophisticated chemical instrumentation. Atmospheric CO_2 is measured by infrared absorption spectroscopy, applied to samples from towers such as those of the NASA FLUXNET study (**Fig. 22.2**). Gas chromatography is used to separate and quantitate various gases, including oxygen, nitrogen, sulfur dioxide, and carbon monoxide. Mass spectroscopy detects extremely small quantities of different molecules, even distinguishing different isotopes of elements.
- **Radioisotope incorporation.** The influx and efflux of CO_2 can be measured by the uptake of ^{14}C-labeled substrates in a small, controlled model ecosystem called a **mesocosm**. Alternatively, CO_2 flux can be measured with radioisotope tracers in the field using a field chamber.
- **Stable isotope ratios.** Some enzyme reactions show a preference for one isotope over another, such as ^{14}N versus ^{15}N. For example, denitrifiers (bacteria that metabolize nitrate) strongly prefer the ^{14}N isotope, leaving behind nitrate enriched in ^{15}N. The $^{14}N/^{15}N$ ratio is measured using mass spectroscopy. Measuring nitrogen isotope ratios can indicate whether denitrifiers could have conducted metabolism in the sample.

TO SUMMARIZE:

- **Microbes cycle essential elements in the biosphere.** Many key cycling reactions are performed only by bacteria and archaea.
- **Elements cycle between organisms and abiotic sources and sinks.** The most accessible source of carbon and nitrogen is the atmosphere. The Earth's crust stores large amounts of key elements, but their availability to organisms is limited.
- **Environmental flux of elements is measured through biochemistry.** Methods include infrared and mass spectroscopy, gas chromatography, radioisotope incorporation, and the measurement of isotope ratios.

22.2 The Carbon Cycle

The foundation of all food webs involves influx and efflux of carbon. The major reservoirs of carbon are shown in Table 22.2. In theory, carbonate rock forms the largest reservoir of carbon. But Earth's crust is the source least accessible to the biosphere as a whole. Crustal rock yields carbon only to organisms at the surface and to subsurface microbes that grow extremely slowly. The carbon reservoir that cycles most rapidly is that of the atmosphere, a source of CO_2 for photosynthesis and lithotrophy. The atmosphere also acts as a sink for CO_2 produced by heterotrophy and by geological outgassing from volcanoes.

The atmospheric reservoir is much smaller than other sources, such as the oceans, crustal rock, and fossil fuels. For this reason, the industrial burning of fossil fuels has perturbed the balance between atmospheric CO_2 and other reservoirs, such as the ocean. The ocean actually absorbs a good part of the extra CO_2, converting it to carbonates. In addition, marine phototrophs trap a substantial amount of carbon in biomass, which is then consumed by protists and sinks to lower layers. But despite these buffering effects of the ocean, atmospheric CO_2 continues to increase at a rate of about 1% per year. The CO_2 traps solar radiation as heat, a process known as the **greenhouse effect**. CO_2 is one of several greenhouse gases contributing to global warming, the overall rise in temperature of our biosphere over the past hundred years.

Note, however, that the fact that CO_2 is a greenhouse gas does not make it inherently "bad" for the environment. In fact, if heterotrophic production of CO_2 were to cease altogether, phototrophs would run out of CO_2 in roughly 300 years despite the vast quantities of carbon present in the ocean and crust. Thus, both CO_2 fixers and heterotrophs need each other.

Carbon Cycles Depend on Oxygen

The global cycle of carbon in the biosphere is closely linked to the cycles of oxygen and hydrogen, elements to which most carbon is bonded (**Fig. 22.3A**). Overall, carbon cycles between carbon dioxide (CO_2) and various reduced forms of carbon, including biomass (living material). Note that the results of carbon cycling differ greatly, depending on the presence of molecular oxygen.

Aerobic carbon cycling. Aerated ecosystems, such as the photic zone of oceans and the oxygenated surface of terrestrial habitats, are dominated by the photosynthetic fixation of CO_2 into biomass, designated by the shorthand [CH_2O]. Phototrophs include bacteria and protists, as well as plants. Aerobic CO_2 fixation is accompanied by production of O_2. The O_2 is then used by heterotrophs (such as bacteria, protists, and animals) to convert [CH_2O] back to CO_2. In the presence of light, a net excess of O_2 is produced; in the ocean's photic zone, the rate of photosynthesis exceeds the rate of respiration (**Fig. 22.3B**).

Fossil fuels
Anaerobiosis plus heat and pressure produce fossil fuels.
Anaerobic
B.
Photic zone: Rate of photosynthesis exceeds rate of respiration.

Figure 22.3 The carbon cycle: aerobic and anaerobic. **A.** Aerobic and anaerobic conversions of carbon. Blue = reduction of carbon; red = oxidation of carbon; black = fermentation; $[CH_2O]$ = organic biomass. In an aerobic environment, photosynthesis generates molecular oxygen (O_2), which enables the most efficient metabolism by heterotrophs and lithotrophs. In an anaerobic environment, photosynthesis generates only oxidized minerals, which support limited anaerobic respiration. Fermentation generates organic carbon products as well as CO_2 and H_2. In the absence of oxygen, methanogens convert carbon dioxide (CO_2) and molecular hydrogen (H_2) to methane (CH_4), one of the most potent greenhouse gases. **B.** The aerated upper water layer of a pond or ocean. The layer of water in which enough light penetrates to power more photosynthesis than heterotrophy is called the photic zone.

Biomass is also produced through lithotrophy—the oxidation of hydrogen, hydrogen sulfide, ferrous iron (Fe^{2+}) and other reduced minerals, and even carbon monoxide. Lithotrophy is especially prominent in soil and in weathered areas of crustal rock. Lithotrophy is performed solely by bacteria and archaea, essential microbial partners in these ecosystems.

Anaerobic carbon cycling. Anoxic environments support lower rates of biomass production than do oxygen-rich environments, as they depend on oxidants of lower redox potential and limited quantity such as Fe^{3+}. Anaerobic conversion of CO_2 to biomass is mainly done by bacteria and archaea. Vast permanently anaerobic habitats extend several kilometers below Earth's surface, encompassing greater volume than the rest of the biosphere put together. In these habitats, endolithic bacteria inhabit the interstices of rock crystals (discussed in Chapter 21).

In soil and water, anaerobic metabolism includes fermentation of organic carbon sources, as well as respiration and lithotrophy with alternative electron acceptors such as nitrate, ferric iron (Fe^{3+}), and sulfate. Anaerobic decomposition by microbes is one stage in the formation of fossil fuels such as oil and natural gas (primarily methane). In soil, anoxic conditions (extremely low in O_2) favor incomplete breakdown of organic material. This characteristic of anaerobic soil actually enriches ecosystems, particularly those of wetlands, which undergo periodic cycles of aeration and hydration. The partly decomposed matter becomes available for further decomposition with oxygen. Unfortunately, anoxic environments near the surface also favor production of methane from the H_2, CO_2, and other fermentation products of anaerobes.

The Global Carbon Balance

The global balance of biological CO_2 fixation and release largely determines the atmospheric level of CO_2. Since the beginning of the industrial age, however, the release of CO_2 has accelerated significantly. The major part of this increase comes from the combustion of **fossil fuels**, which adds about 6×10^{15} g of carbon annually to the atmosphere. Fossil fuels are the product of microbial anaerobic digestion of plant and animal remains, reduced to hydrocarbons by the pressure and heat of Earth's crust. When burned as fuel, carbon that had accumulated over millions of years is rapidly returned to the atmosphere as CO_2. Some of the CO_2 flux is compensated by increased CO_2 fixation and ocean absorption, but there remains a net flux of 4×10^{15} g of carbon annually.

Another factor in the increase of atmospheric CO_2 is deforestation, which adds about 2×10^{15} g carbon annually to the atmosphere, or approximately a third as much as burning fossil fuels. As forests are cut, CO_2 is released through wood burning and microbial decay. The role of microbes in CO_2 release, as compared to wood burning, is challenging to measure. One study focused on carbon flux in the forests of Amazonia, the Amazon river watershed. The Amazon watershed may account for as much as 10% of global carbon flux from deforestation. In this study, researchers mapped various processes of carbon uptake and efflux throughout the region (**Fig. 22.4**). Processes that generate CO_2 include burning of trees (red line) and microbial decay of cut trees (blue line). Removal of CO_2 from the atmosphere occurs by regrowth of trees (green line). Since 1978, the major contribution to total net carbon efflux has been microbial decomposition of felled trees. Thus, more CO_2 has been released by tree cutting and microbial decay than by burning.

The contribution of ocean ecosystems to carbon flux is even more difficult to measure. New molecular genetic surveys of the upper ocean are revealing previously unrecognized communities of microbial phototrophs, such as submicroscopic cyanobacteria. In the deep ocean, similar studies reveal major new groups of lithotrophic producers, such as anaerobic ammonia oxidizers ("anammox" bacteria). A key question is the fate of the benthic methane hydrates accumulated through methanogenesis. At present, bacteria are believed to oxidize most of the methane released; but a sudden release from methane hydrates could alter the carbon balance and accelerate global warming.

Studies of carbon and oxygen flux based on isotope ratios suggest a much greater level of biological production than earlier estimates. It now appears that the ocean's microbial communities may be responsible for more than half of the global biological uptake of carbon from the atmosphere. This kind of data is crucial for predicting the global effects of changes in atmospheric CO_2.

From a political standpoint, ecosystems such as forests that act as **carbon sinks** by fixing carbon into stable biomass are considered desirable because they lessen the rate of CO_2 input into the atmosphere. Ecosystems that act as sources of carbon dioxide may be viewed with disfavor because they contribute to global warming. But what if CO_2-generating ecosystems provide other environmental benefits? For example, wetlands are among Earth's most productive ecosystems, supporting vast amounts of plant and animal life, but they may also release significant amounts of CO_2 and methane (see **Special Topic 22.1**).

Carbon flux out of Amazonian forest

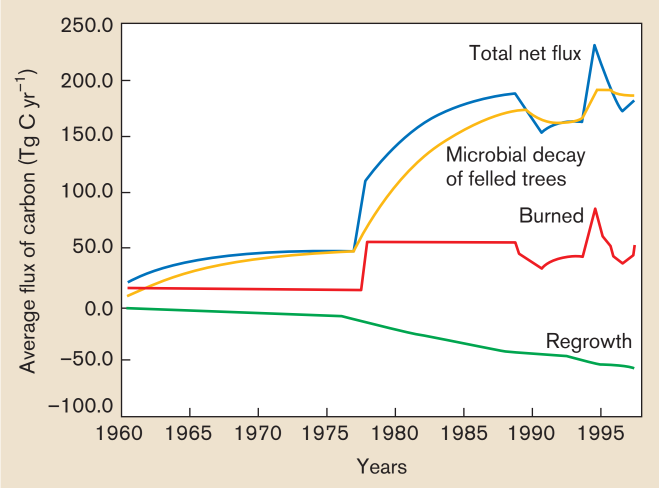

Figure 22.4 Carbon flux from Amazonian forest during 1962–1998. Carbon flux (CO_2 efflux to the atmosphere and uptake by forests) was measured from the Brazilian Amazon forest watershed. Total net carbon flux (blue line) includes contributions from microbial decay (yellow line), burning of trees (red line), and regrowth of trees (green line). Tg C yr^{-1} = teragrams of carbon per year (1 Tg = 10^{12} g). *Source:* Based on R. A. Houghton, et al. 2000. *Nature* 403:301.

TO SUMMARIZE:

- **The most accessible reservoir for carbon is the atmosphere (CO_2).** Atmospheric carbon is severely perturbed by the burning of fossil fuels.
- **Cyanobacteria and other phytoplankton cycle much of the CO_2 in the biosphere.** Oxygen produced by phototrophs is used by heterotrophs and lithotrophs.
- **Carbon cycling is linked to the cycling of hydrogen and oxygen.**
- **Anaerobic environments cycle carbon through bacteria and archaea.** Bacteria conduct fermentation and anaerobic respiration. Methanogens produce methane, much of which is oxidized by methanotrophs.
- **Microbial decomposition returns CO_2 to the atmosphere.** Microbial decomposition is a major contributor to the accelerated CO_2 flux associated with deforestation.

Special Topic 22.1 Wetlands: Disappearing Microbial Ecosystems

Ecologist Siobhan Fennessy (**Fig. 1**) studies wetland ecosystems in Ohio—more than 90% of which have already been destroyed or substantially disturbed by human development. Fennessy and her undergraduate students at Kenyon College compare disturbed and undisturbed wetlands to investigate species diversity and the role that wetlands play in carbon and nitrogen cycling. Much of the carbon and nitrogen is cycled by anaerobic bacteria and archaea such as methanogens.

Student John Tisdale addressed the relationship between nitrogen loading and carbon efflux from a wetland (**Fig. 2**). Excess nitrogen loading into wetlands results from industrial and agricultural runoff of nitrogenous fertilizers. Does this influx of nitrogen to a nitrogen-limited ecosystem affect the rate of carbon flux? Tisdale applied ammonium nitrate fertilizer to wetland soil cores in growth chambers, then measured CO_2 efflux (**Fig. 3**). He found that ammonium nitrate addition was associated with increased CO_2 efflux, presumably caused by the increased respiration by heterotrophs. Moreover, addition of CO_2 together with nitrate had a synergistic effect, augmenting the fertilizer-induced efflux of CO_2. Elevated atmospheric CO_2 is known to increase carbon assimilation by plants, causing an increase in fine root growth and mycorrhizal association. This suggests the possibility of a positive feedback in the carbon cycle: higher CO_2 availability increases plant growth, which leads to higher rates of CO_2 output from the soil, further increasing atmospheric concentrations. Soil carbon flux is one of the largest fluxes in the global carbon cycle, so even small changes in soil flux can lead to substantial carbon inputs to the atmosphere. Thus, the rise in greenhouse gases may lead to significant changes in carbon dynamics.

Today's land developers are required to replace lost wetlands with "created wetlands." But are natural wetlands replaceable? Student Dan Gustafson addressed the survival of mycorrhizae (symbiotic fungal extensions of plant roots) in the anaerobic soil of well-established wetlands. Mycorrhizae are important for productivity of natural ecosystems as well as human agriculture. Gustafson proposed that mycorrhizae require oxygen provided by the oxygenated rhizosphere surrounding the roots of wetland plants. This hypothesis was tested by cutting off the oxygen moving down through the root channels. Oxygen levels were measured by determining soil redox potentials, which decrease when oxygen is depleted. In low oxygen, mycorrhizae failed to grow. Thus, the experiment showed that the mycorrhizae indeed require oxygen provided by the plant roots, even in anaerobic soil. Subsequent field studies showed that "created" wetlands fail to support as much mycorrhizae as natural wetlands do. This delicate mutualism between fungus and plant requires a long-established wetland habitat, a system that could take many decades to form in a "created wetland."

22.3 The Hydrologic Cycle and Wastewater Treatment

The fate and distribution of complex carbon compounds is largely a function of the **hydrologic cycle**, the cyclic exchange of water between atmospheric water vapor and Earth's ecosystems (**Fig. 22.5A**). A vast reservoir of water is supplied by the ocean. In the hydrologic cycle, water precipitates as rain, which is drawn by gravity into groundwater, rivers, lakes, and, ultimately, the ocean. All along this route, of course, evaporation returns water to the air. Human communities interact with the hydrologic cycle by drawing water for drinking and other purposes, and by returning wastewater. Wastewater requires cleansing of organic contaminants, including key forms of treatment by microbes.

Biochemical Oxygen Demand

A major problem in aquatic ecosystems is organic contamination. Water passing through the ground and aquatic ecosystems carries organic carbon material from humus, sewage, and fertilizer runoff. A sudden influx of rich carbon substrates accelerates respiration by aquatic microbes. Microbial respiration then competes with that of fish, invertebrates, and amphibians for the limited supply of oxygen dissolved in water, raising the **biochemical oxygen demand (BOD)**, also called the biological oxygen demand (BOD). The higher the concentration of organic substances, the higher the BOD arising from microbial oxygen consumption.

High BOD can cause a massive die-off of fish and other aquatic animals. Thus, a routine part of monitoring the health of lakes and streams is the measurement of BOD. BOD is measured by observing the rate of oxygen uptake in a water sample by a defined set of heterotrophic bacteria (**Fig. 22.5B**). Oxygen uptake is observed in a BOD meter (**Fig. 22.5C**), which detects dissolved oxygen in water. The rate of decrease of dissolved oxygen measured by the BOD meter is approximately proportional to the amount of dissolved organic matter available for respiration.

A. Hydrologic cycle

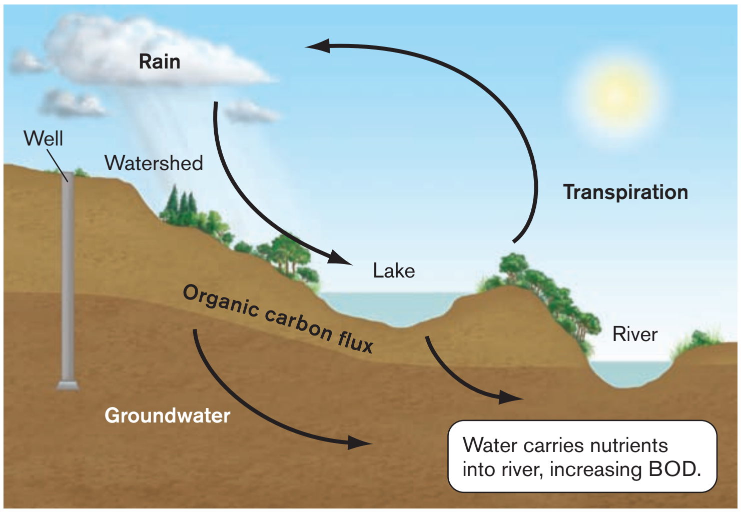

Figure 22.5 The hydrologic cycle interacts with the carbon cycle. A. The hydrologic cycle carries bacteria and organic carbon into groundwater and aquatic systems. **B.** Bottled water samples are measured for dissolved oxygen over time; the rate of decrease of dissolved oxygen indicates biological oxygen demand (BOD). The rate of decrease of dissolved oxygen in water samples is approximately proportional to the concentration of organic matter available for respiration. **C.** A microprocessor-controlled Biox-1010 BOD analyzer measures rate of respiration. Water samples are mixed with a concentrated microbial biomass, and a dissolved-oxygen sensor measures small rates of oxygen decrease over time.

Endress & Hauser, Inc.

Until recently, BOD was considered a local issue, affecting the health of lakes and rivers in a community. Today, however, large regions of ocean have become **dead zones**, or **zones of hypoxia**, devoid of most fishes and invertebrates. A well-known dead zone is a region in the Gulf of Mexico off the coast of Louisiana where the Mississippi River releases about 40% of the U.S. drainage to the sea (**Fig. 22.6**). Over its long, meandering course, which includes inputs from the Ohio and Missouri rivers, the Mississippi builds up high levels of organic pollutants, as well as nitrates from agricultural fertilizer. When these nitrogen-rich substances flow rapidly out to the Gulf in the spring, they lift the nitrogen limitation on algal growth and feed massive algal blooms. The algae then crash, and their sedimenting bodies are consumed by heterotrophic bacteria. The heterotrophs use up the available oxygen, causing **hypoxia**. Hypoxia kills off the fish, shellfish, and crustaceans over a region equivalent in size to the state of New Jersey.

Dead zones now occur along the coasts of industrial and developing countries throughout the world, including, for example, India and Australia. Dead zones contribute to the crash of fisheries worldwide, removing a critical food resource for human populations. Plans to clean up dead zones face daunting costs. For example, in 2000, the Mississippi River/Gulf of Mexico Watershed Nutrient Task Force agreed on a plan to restore 30% of the Gulf dead zone by the year 2015, at a cost of $1 billion per year.

The only way to avoid such dead zones is if all the communities throughout the river drainage areas treat their wastes to eliminate nitrogenous wastes before disposal. There are two common approaches to community wastewater treatment, both of which involve microbial partners: wastewater treatment plants and wetland filtration. Both approaches depend on microbes to remove organic carbon and nitrogen from water before it returns to aquatic systems and ultimately the ocean.

Wastewater Treatment by Microbial Communities

In industrialized nations, all municipal communities use some form of **wastewater treatment** (**Fig. 22.7**). The purpose of wastewater treatment is to decrease the BOD and the level of human pathogens before water is returned to the local rivers.

Figure 22.7 Wastewater treatment plant. **A.** In a typical municipal treatment plant, wastewater undergoes primary treatment (filtering and settling), secondary treatment (microbial decomposition), and tertiary treatment (chlorination or other chemical treatments). **B.** Aeration basin for secondary treatment.

The wastewater treatment plant is the final destination for all household and industrial liquid wastes passing through the municipal sewage system. A typical plant includes the following stages of treatment:

- **Preliminary treatment** consists of screens that remove solid debris, such as sticks, dead animals, and feminine hygiene items.
- **Primary treatment** includes fine screens and sedimentation tanks that remove insoluble particles. The particles eventually are recombined with the solid products of wastewater treatment (known as **sludge**). The sludge ultimately is used for fertilizer or landfill.
- **Secondary treatment** consists primarily of microbial ecosystems that decompose the soluble organic content of wastewater. The microbes generate particulate flocs of biofilm. The flocs are sedimented as sludge, also known as activated sludge owing to their microbial activity.
- **Tertiary (advanced) treatment** includes chemical applications such as chlorination to eliminate pathogens.

The microbial ecosystems of secondary treatment require continual aeration to maximize breakdown of molecules to carbon dioxide and nitrates. The microbes typically include bacilli such as *Zooglia*, *Flavobacterium*, and *Pseudomonas*, as well as filamentous species such as *Nocardia* (**Fig. 22.8A**). Optimal treatment depends on the ratio of filamentous to single-celled bacteria: enough filaments to hold together the flocs for sedimentation, but not so many as to trap air and cause flocs to float and foam, preventing sedimentation.

Besides bacteria, the ecosystem of activated sludge includes filamentous methanogens (discussed in Chapter 19), which metabolize short-chain molecules such as acetate within the anaerobic interior of flocs. Thus, wastewater treatment generates methane, often in quantities sufficient for recovery as fuel.

In addition, the bacteria are preyed upon by protists such as stalked ciliates (**Fig. 22.8B**), swimming ciliates, and amebas, as well as invertebrates such as rotifers and nematodes. The predators serve a valuable function of limiting the planktonic population of bacteria, enabling the bulk of the biomass to be removed by sedimentation.

THOUGHT QUESTION 22.2 What would happen if wastewater treatment lacked microbial predators? Why would the result be harmful?

Wastewater treatment plants are remarkably effective at converting human wastes to ecologically safe water and ultimately human drinking water. The plants are, however, impractical for purifying the runoff from large agricultural operations. For large-scale alternatives to treatment plants, communities and agricultural operations are looking to **wetland restoration**. Much of our current water supplies are already filtered and purified by natural wetlands, such as the Florida Everglades (**Fig. 22.9A**). Wetlands act to remove nitrogen through the action of denitrifying bacteria. In wetlands, rainwater and river water trickle slowly through vast stretches of soil, where microbial conversion acts as the foundation of a macroscopic ecosystem including trees and vertebrates. Thus, much of the carbon and nitrogen is fixed into valuable biomass. In the Everglade wetlands, the remaining water filters slowly through limestone into underground aquifers, which ultimately provide water through wells to human communities.

Some agricultural operations are building artificial wetlands to replace treatment plants. **Figure 22.9B** shows a hog farm where a series of terraced wetlands was built to drain liquified manure. The wetlands were found to produce fewer odors and to remove organics more efficiently and at a lower cost than traditional filtration plants.

TO SUMMARIZE:

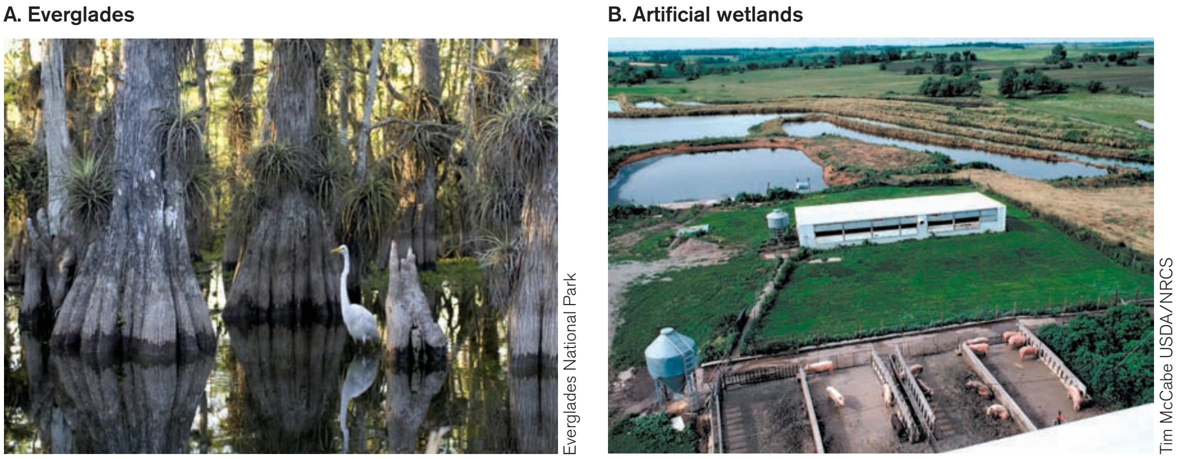
- **The hydrological cycle is the cyclic exchange of water between the atmosphere and the biosphere.** Water precipitates as rain, which enters the ground and ultimately flows to the oceans. Along the way, water evaporates, returning to the atmosphere.
- **Water carries organic carbon that generates biochemical oxygen demand (BOD).** High BOD accelerates heterotrophic respiration and depletes oxygen needed by fish.
- **Wastewater treatment cuts down BOD.** Secondary treatment involves microbial communities that decompose the soluble organic content.
- **Wetlands filter water naturally.** Wetland filtration helps purify groundwater entering aquifers.

22.4 The Nitrogen Cycle

Besides carbon, oxygen, and hydrogen, another major element that cycles largely by microbial conversion is nitrogen (**Fig. 22.10**). The nitrogen cycle is notable in two respects:

- **Many oxidation states.** A larger number of oxidation states exist for biological nitrogen than for any other major biological element (see **Table 22.3**). Conversion between these oxidation states requires metabolic processes such as N_2 fixation, lithotrophy, and anaerobic respiration.
- **Dependence on prokaryotes.** Many steps of the nitrogen cycle require prokaryotes—that is, bacteria and archaea. Without bacteria and archaea, the nitrogen cycle would not exist.

THOUGHT QUESTION 22.3 How many kinds of biomolecules can you recall that contain nitrogen? What are the usual oxidation states for nitrogen?



A. Everglades

B. Artificial wetlands

Sources of Nitrogen

Where is nitrogen found on Earth? A significant amount of nitrogen is found in Earth's crust, in the form of ammonium salts in rock (see **Table 22.2**). This form is largely inaccessible to microbes. The major accessible source of nitrogen is the atmosphere, of which dinitrogen gas (N_2) constitutes 79%. However, N_2 is a highly stable molecule that requires enormous input of reducing energy before assimilation is possible (see Chapter 14). Thus, for many natural ecosystems, and most forms of agriculture, nitrogen is the limiting nutrient for primary productivity.

Until recently in Earth's history, nitrogen was fixed entirely by nitrogen-fixing bacteria and archaea. In the twentieth century, however, the Haber process (see Chapter 14) was invented for artificial nitrogen fixation to generate fertilizers for agriculture. The process was devised by German chemist Fritz Haber, who won the 1918 Nobel Prize in Chemistry. Today, the Haber process for producing fertilizers accounts for more than half of nitrogen fixation in the entire biosphere, while other human activities contribute substantially to oxidized forms of nitrogen such as nitrous oxide (NO_2), a potent greenhouse gas. The nitrogen cycle is the most perturbed of the major biogeochemical cycles.

The "Nitrogen Triangle"

The numerous oxidation states available for microbial metabolism of nitrogen generate a complex cycle of conversions. One way to organize the complexity is to envision a "nitrogen triangle" whose corners include three key forms: atmospheric $\mathbf{N_2}$; the reduced forms $\mathbf{NH_3}$ and $\mathbf{NH_4^+}$; and the oxidized forms $\mathbf{NO_2^-}$ and $\mathbf{NO_3^-}$ (**Fig. 22.11A**). At the base of the triangle, both reduced and oxidized forms of nitrogen are assimilated into biomass.

Figure 22.11 The nitrogen cycle: fixation, nitrification, denitrification. A. The "nitrogen triangle" involves nitrogen fixation and assimilation, reductive dissimilation of nitrate (denitrification; blue), and oxidation (nitrification; red). Denitrification includes production of the potent greenhouse gas nitrous oxide (N_2O). Assimilation into biomass is often reductive; virtually all nitrogen in biomolecules is highly reduced. Oxidation of ammonia generates nitrites and nitrates, whose runoff can pollute water supplies. **B.** *Nitrobacter winogradskyi* oxidizes nitrite to nitrate (TEM). Folded layers of membrane contain the electron transport complexes.

We shall consider in turn the three "legs" of the nitrogen triangle:

- **N_2 fixation** to ammonium (NH_4^+), a form assimilated into biomass by microbes and plants.
- **Nitrification** or oxidation of ammonia to nitrite (NO_2^-) and nitrate (NO_3^-), which are also assimilated by microbes and plants.
- **Denitrification** of NO_2^- and NO_3^- back to N_2 (or, in carbon-rich habitats, reduction to NH_3).

Nitrogen fixation. The main avenue for entry of nitrogen into the biosphere is **nitrogen fixation**—specifically, fixation of dinitrogen, or nitrogen gas (N_2) into NH_3, protonated to NH_4^+. Ammonium ion is rapidly assimilated by bacteria and plants, typically through combination with Krebs cycle intermediates to form key amino acids such as glutamate (discussed in Chapter 14). The ability to assimilate NH_4^+ into nitrogenous organic molecules is found in virtually all primary producers.

Fixation of nitrogen requires enormous energy because the triple bond of N_2 is exceptionally stable. Breaking the triple bond to generate ammonia requires a series of reduction steps involving high input of energy:

$$\overset{\text{Dinitrogen}}{N{\equiv}N} \xrightarrow[2H^+ + 2e^-]{} HN{=}NH \xrightarrow[2H^+ + 2e^-]{} H_2N{-}NH_2 \xrightarrow[2H^+ + 2e^-]{} \overset{\text{Ammonia}}{2NH_3} \underset{2H^+}{\rightleftharpoons} \overset{\text{Ammonium}}{2NH_4^+}$$

All the intermediate reactions of nitrogen fixation are tightly coupled, so the intermediate compounds rarely become available for other uses. The final product, ammonia, exists in ionic equilibrium with ammonium ion:

$$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^-$$

Fixation of nitrogen is catalyzed by the enzyme nitrogenase (discussed in Chapter 15). The highly reductive reactions of nitrogenase require exclusion of oxygen; yet they also require tremendous input of energy, usually provided by aerobic metabolism. Therefore, nitrogen-fixing bacteria generally separate anaerobic nitrogen fixation from aerobic metabolism by one of several mechanisms, such as the heterocysts of cyanobacteria (discussed in Chapter 14).

Given the energy expense and the need to exclude oxygen, many species of bacteria as well as all eukaryotes have lost the nitrogen fixation pathway by degenerative evolution. But all ecosystems, both marine and terrestrial, include some species of bacteria and archaea that fix N_2 into ammonia. Nitrogen-fixing bacteria in the soil include obligate anaerobes, such as *Clostridium* species, and facultative gram-negative enteric species of *Klebsiella*, *Salmonella*, and *Escherichia* (though not the commonly studied laboratory strains of *E. coli*), as well as obligate respirers such as *Pseudomonas*. In ocean and in freshwater systems, cyanobacteria are the major nitrogen fixers. After fixation, all these organisms assimilate the reduced nitrogen into essential components of their cells. Within an ecosystem, nitrogen fixers ultimately make the reduced nitrogen available for assimilation by nonfixing microbes and plants, either directly through symbiotic association (such as that of rhizobia and legumes) or indirectly through predation (marine cyanobacteria) and decomposition (soil bacteria).

If nitrogen fixation is ubiquitous in soil and water, then why is nitrogen limiting? Nitrogen fixation is extremely energy intensive; thus, the rate of fixation usually fails to meet the potential demand of other members of the ecosystem. The one exception is legume symbiosis with rhizobia, which provide ample nitrogen for their hosts.

In agriculture, symbiotic nitrogen fixation by rhizobial bacteria increases the yield of crops such as soybeans (**Fig. 22.12A**). Soybeans can derive as much as 50% of their nitrogen from microbial symbionts. To enhance colonization by nitrogen fixers, farmers apply molecules called isoflavonoids, which mimic the natural plant-derived attractants for rhizobia.

Nitrification. Free ammonia in soil or water is quickly oxidized for energy by **nitrifiers**, bacterial species that possess enzymes for oxidation of ammonia to nitrite (NO_2^-), or of nitrite to nitrate (NO_3^-). This process is called **nitrification**. Nitrification of ammonia is a form of lithotrophy, an energy generation pathway involving oxidation of minerals. The nitrification pathway generates the red leg of the triangle in Figure 22.11A. The pathway of nitrification includes:

$$\begin{array}{ccccccc} \text{Ammonia} & & & & \text{Nitrite} & & \text{Nitrate} \\ NH_3 & \xrightarrow{} & NH_2OH & \xrightarrow{} & NO_2^- & \xrightarrow{} & NO_3^- \\ & + \tfrac{1}{2}O_2 & & + O_2 & & + \tfrac{1}{2}O_2 & \end{array}$$

The pathway includes two separate energy generation mechanisms, utilized by different species: (1) ammonia through NH_2OH to nitrite, and (2) nitrite to nitrate. Typically, soil contains both kinds of microbes living together, a collaboration ensuring complete conversion to nitrate. Nitrifying genera include *Nitrosomonas*, which oxidizes ammonia to nitrite, and *Nitrobacter* (**Fig. 22.11B**) and *Nitrospira*, which oxidize nitrite to nitrate.

THOUGHT QUESTION 22.4 In the laboratory, which kind of bacteria would likely grow on artificial medium including NH_2OH as the energy source: *Nitrosomonas* or *Nitrobacter*?

A. Soybeans grow with symbiotic rhizobia

©Thomas Hovland/Alamy

B. Nitrate contamination of groundwater

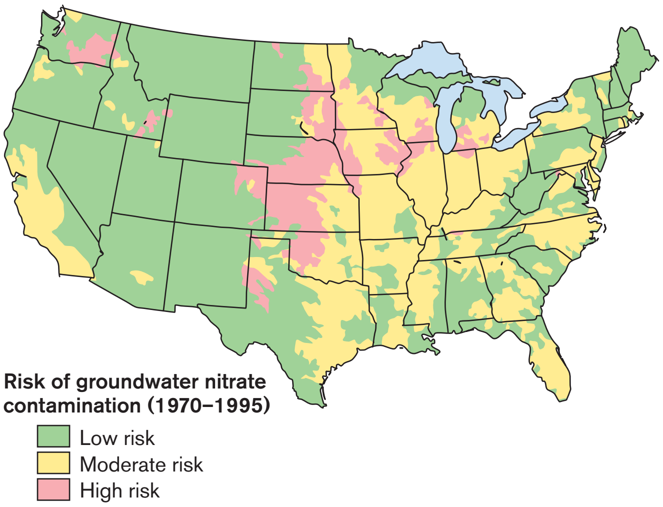

Figure 22.12 Agricultural benefits and consequences of microbial nitrogen metabolism. A. Soybean field in Maine. Rhizobial nitrogen fixation enhances growth of soybeans and other major crops. **B.** Nitrate in drinking water is especially prevalent in agricultural regions of the United States. Ammonification of fertilizer, followed by nitrification, generates nitrate and nitrite. Nitrate and nitrite runoff from oxidized nitrogenous fertilizers pollutes streams and groundwater.

When nitrate is produced in the soil, it is assimilated by plants and bacteria nearly as quickly as ammonium ion, although extra energy is needed to reduce nitrate to NH_4^+ for incorporation into biomass. Nitrate assimilation to biomass is called **assimilatory nitrate reduction**. In agriculture, intensive fertilization generates a large excess of ammonia resulting from **ammonification**, the conversion of organic nitrogen to ammonia. Ammonia is oxidized rapidly by lithotrophic bacteria (nitrifiers). The excess ammonia leads to a buildup of nitrites and nitrates via nitrification faster than they can be assimilated. The nitrites and nitrates are highly soluble in water, and they readily diffuse into aquatic systems. Nitrate influx into lakes leads to eutrophication as the nitrogen limit is lifted and algal blooms cause a rise in BOD. Nitrate influx also causes formation of toxic nitrosamines.

Consumption of nitrate in drinking water can lead to methemoglobinemia, a blood disorder in which hemoglobin is inactivated. Methemoglobinemia occurs in infants whose stomachs are not yet acidic enough to inhibit growth of bacteria that convert nitrate to nitrite. Nitrite oxidizes the iron in hemoglobin, eliminating its capacity to carry oxygen. The failure to carry oxygen leads to a bluish appearance, one cause of "blue baby syndrome." Nitrite-induced blue baby syndrome is a problem in intensively cultivated agricultural regions, such as Kansas and Nebraska (**Fig. 22.12B**).

Recently, another role was discovered for nitrite: as an electron donor for photosynthesis. Certain gammaproteobacteria, related to *Thiocapsa*, can use light energy to oxidize nitrite to nitrate. The extent of nitrogen-based photosynthesis in global nitrogen cycles is unknown.

Denitrification. The blue leg of the triangle in **Figure 22.11A** is generated by reduction of nitrate and nitrite through a series of decreased oxidation states back to atmospheric nitrogen:

$$\begin{array}{ccccccccc} \text{Nitrate} & & \text{Nitrite} & & \text{Nitric oxide} & & \text{Nitrous oxide} & & \text{Dinitrogen} \\ 2NO_3^- & \xrightarrow[4H^+ + e^-]{} & 2NO_2^- & \xrightarrow[2H^+ + 2e^-]{} & 2NO & \xrightarrow[2H^+ + 2e^-]{} & N_2O & \xrightarrow[2H^+ + 2e^-]{} & N_2 \end{array}$$

This process of denitrification, also known as **dissimilatory nitrate reduction**, is performed primarily by anaerobic respirers. (In contrast, assimilatory nitrate reduction incorporates the nitrogen into biomass.) Anaerobic respirers conduct electron transport using an oxidized form of nitrogen as an alternative electron acceptor in the absence of O_2 (discussed in Chapter 14). Many bacterial species in soil and water can respire using one or more of the oxidized nitrogen intermediates. Nitrate respiration is, however, repressed in the presence of oxygen, a more favorable electron acceptor; therefore, it is limited to anoxic habitats.

In undisturbed environments, the products of nitrate respiration rarely build up to significant levels. Heavy fertilization, however, causes buildup of excess nitrate and so increases the environmental rate of denitrification. During this process, some of the nitrogen escapes as nitrous oxide gas (N_2O). A highly potent greenhouse gas, N_2O generates 200 times the warming effect of CO_2; thus, relatively small amounts of N_2O can make a disproportionate contribution to global warming. Furthermore, N_2O in the upper atmosphere reacts catalytically with ozone, depleting the ozone layer. Thus, the atmospheric effects of bacterial denitrification are a serious concern in agricultural and waste treatment processes.

Nitrous oxide also builds up in marine dead zones. A recent study by Syed Wajih Naqvi and colleagues at the National Institute of Oceanography (Goa, India) investigated denitrification in the zone of hypoxia off the Indian coast (**Fig. 22.13A**). Under anoxic conditions, nitrate is used for anaerobic respiration. The study revealed unexpectedly high levels of N_2O production at a series of stations within the zone. In an experiment, introduction of nitrate into water samples from the dead zone led quickly to production of nitrite and N_2O (**Fig. 22.13B**), a process almost certainly caused by denitrifying bacteria. Thus, denitrifying bacteria in polluted ocean waters may contribute significantly to global warming.

Dissimilatory nitrate reduction to ammonia. Most environmental nitrate and nitrite are reduced via N_2O as described previously. Certain conditions, however, favor the alternate route of dissimilatory nitrate reduction to ammonia (DNRA) (see **Fig. 22.11A**). Nitrate reduction to ammonia is a form of anaerobic lithotrophy or hydrogenotrophy, in which nitrate serves as an electron acceptor and hydrogen gas (H_2) is the electron donor:

$$NO_3^- + 4H_2 + H^+ \longrightarrow NH_3 + 3H_2O$$

Bacteria reduce nitrate to ammonia mainly in anaerobic environments rich in organic carbon and H_2 generated by fermentation, but low in reduced nitrogen, such as sewage sludge and stagnant water. Another carbon-rich habitat favoring this pathway is the rumen, the digestive tract of cattle, goats, and other ruminant animals (see Chapter 21). Ruminants consume grasses whose cellulose requires digestion by microbial endosymbionts. They also depend on their microbial endosymbionts to assimilate nitrate into ammonia and synthesize amino acids.

THOUGHT QUESTION 22.5 The nitrogen cycle has to be linked with the carbon cycle, since both contribute to biomass. How might the carbon cycle of an ecosystem be affected by increased input of nitrogen?

TO SUMMARIZE:

- **Nitrogen in ecosystems is found in a wide range of oxidation states.** Interconversion of most of these states requires prokaryotes.
- **The main source and sink of nitrogen is the atmosphere.** Nitrogen gas is fixed into ammonium ion by some bacteria and archaea. Denitrifying bacteria reduce NO_3^- successively back to N_2 and return it to the atmosphere.
- **Nitrogen fixation is conducted by symbiotic bacteria in association with specific plants.** Legume-associated nitrogen fixation is critical for agriculture.
- **Most NH_4^+ in the soil and water is oxidized to nitrate.** Nitrifying bacteria gain energy through lithotrophy.
- **Nitrate can be reduced to ammonia under anoxic conditions.** Especially in the deep ocean, NO_3^- may be reduced by hydrogen gas to ammonia.

22.5 Sulfur, Phosphorus, and Metals

Besides carbon and nitrogen, many other elements participate in biochemical cycles that have important consequences for the biosphere as well as for human environments. Sulfur undergoes a "triangle" of redox conversions analogous to that of nitrogen. Phosphorus, unlike other biological elements, is generally assimilated in the oxidized state, and phosphate is often a limiting nutrient for plants. Iron cycles in complex interactions with sulfur and phosphate. Beyond these macronutrients, many toxic metals in the environment, such as mercury and arsenic, are either bioactivated or detoxified by microbes.

The Sulfur Cycle

Sulfur is a major component of biomass, including proteins and cofactors. Like carbon and nitrogen, sulfur can be assimilated in either mineral or organic form. At the same time, assimilation competes with dissimilation. Reduced and oxidized forms of sulfur (comparable to those of nitrogen; see **Table 22.3**) offer electron donors and acceptors for dissimilatory reactions that generate energy. Reduced forms of sulfur, such as H_2S, can also participate in photolysis in reactions analogous to those of H_2O. Oxidized forms, such as sulfate, serve as anaerobic electron acceptors. As with nitrogen, most of these redox reactions are performed solely by bacteria and archaea. The biochemistry of sulfur cycling has important environmental consequences, such as the corrosion of concrete and iron.

Where is sulfur found? A remarkably large source of sulfur is marine sulfate (see **Table 22.2**). In the ocean, sulfate is the second most common anion after chloride. Marine sulfate turns over slowly and constitutes an essentially limitless supply. Sulfur is similarly plentiful in freshwater sediments. Thus, sulfur is rarely a limiting nutrient.

While the amount of sulfur in ocean water is relatively large compared to that of nitrogen or carbon, the amount in the atmosphere, mainly sulfur dioxide, is small. Nevertheless, these small amounts of sulfur compounds generate toxic effects as well as acidic pollution. Thus, both biochemical and industrial sources of atmospheric sulfur are of concern.

Competing assimilatory and dissimilatory sulfur reactions in the biosphere form a "sulfur triangle" between H_2S, S^0, and SO_4^{2-} (**Fig. 22.14A**). The oxidation and reduction pathways are analogous to those of nitrogen. Sulfur pathways include further options of anaerobic phototrophy. In an aquatic system, H_2S arises from spring waters welling up from the sediment and from decomposition of detritus. In decomposition, anaerobic respirers such as *Desulfovibrio* species convert sulfate to sulfur, then to H_2S. As H_2S rises to the oxygenated surface water, it is readily oxidized by sulfur bacteria such as *Thiobacillus* species (**Figs. 22.14B** and **C**). Microbial sulfur oxidation is helpful for environments because it removes H_2S, which is highly toxic to most nonsulfur bacteria and plants. Because of the toxicity of H_2S, autotrophs more readily assimilate SO_4^{2-} into biomass, despite the extra energy needed to reduce SO_4^{2-}.

Figure 22.14 **The sulfur cycle.** **A.** The "sulfur triangle." In the presence of oxygen, H_2S is oxidized to sulfur dioxide, then sulfate. Anaerobically, H_2S may be photolyzed to sulfur. Sulfate serves as an electron acceptor for anaerobic respiration, or it may be assimilated into biomass, organic molecules with reduced sulfur groups (RSH). Elemental sulfur may be oxidized to sulfate by lithotrophs. **B.** In springs containing H_2S, white sulfur bacteria (H_2S oxidizers) form microbial mats. **C.** Close-up of white sulfur bacteria. Within their filaments are intracellular sulfur granules formed by oxidation of H_2S to S^0.

An alternate route for H_2S oxidation, if light is available, is photolysis by anaerobic phototrophs such as *Rhodopseudomonas* species. Some phototrophic bacteria further oxidize the S^0 generated to sulfate. In some sulfur-rich lakes, such as the Russian Lake Sernoye, underground springs pump so much H_2S that most of the sulfur is photolytically converted to S^0, which forms up to 5% of the sediment. This elemental sulfur can be mined commercially.

In thermal vent ecosystems, several sulfur-based reactions drive metabolism. For example, thermal vent archaea such as *Pyrodictium* species use sulfur to oxidize hydrogen gas to H_2S:

$$H_2 + S^0 \longrightarrow H_2S$$

This form of sulfur-based hydrogenotrophy is enhanced by the vent conditions of extreme pressure and temperature (100°C), conditions under which elemental sulfur exists in a molten state more accessible to microbes than solid sulfur.

Decomposition of biomass generates various organic sulfur compounds, many of which are volatile. Odors of certain microbial sulfur products contribute to the smell of rotting eggs, but others enhance the taste of cheeses (discussed in Chapter 16). In marine environments, algae excrete substantial quantities of dimethyl sulfide, which escapes to the atmosphere, providing part of the characteristic "smell of the sea." Dimethyl sulfide is believed to be the major biogenic source of atmospheric sulfur. Dimethyl sulfide and other organic sulfur compounds in the atmosphere are subject to photochemical oxidation to SO_2 and SO_4^{2-}, a nonbiogenic process.

Sulfur is metabolized underground by bacteria beneath deposits of fossil fuels such as oil and coal (**Fig. 22.15A**). Oil and coal contain sulfur in the form of

Figure 22.15 **Consequences of the sulfur cycle.** **A.** Oil- or coal-bearing geological strata provide rich electron donors for sulfate-reducing bacteria (sulfate respirers). Eventually, various forms of sulfur contaminate the oil or coal, which, when burned as fuel, generate first SO_2 and ultimately sulfuric acid (acid rain). **B.** In a sewer pipe, sulfate-reducing bacteria (sulfate respirers) generate H_2S. Sulfur-oxidizing bacteria then oxidize H_2S to sulfate in the form of sulfuric acid. The sulfuric acid reacts with calcium hydroxide in the concrete, thus corroding the interior surface of the pipe.

SO_4^{2-} and provide a carbon source for sulfate respirers (bacteria that respire using sulfate as a terminal electron acceptor). The products of sulfate respiration include S^0 and organic sulfur. When the fuel is burned, these forms of sulfur cause severe pollution. Before burning, however, the S^0 and organic sulfur can be oxidized by sulfur-oxidizing bacteria. Fuel processors are now turning to sulfur-oxidizing microbes for experimental use in "desulfuration," the removal of sulfur from coal.

A habitat that exhibits the entire range of sulfur oxidation states is that of a sewage pipe. In a concrete sewer pipe, the alternation between anaerobic and oxygenated sulfur biochemistry generates severe corrosion (**Fig. 22.15B**). The microbial decomposition of sewage yields large quantities of toxic H_2S, which then volatilize to high levels that endanger sewer workers. The H_2S is then oxidized to sulfuric acid by *Thiobacillus ferrooxidans,* a bacterium that colonizes the surface of the concrete. The sulfuric acid (H_2SO_4) decreases the pH at the concrete surface to pH 2. In the concrete surface, sulfuric acid converts calcium hydroxide to soluble calcium sulfate. Over several years, this corrosion can cut the thickness of a sewer pipe by half.

Sulfur metabolism shows important connections with metabolism of metals. Many sulfur-oxidizing bacteria, such as *Thiobacillus ferrooxidans,* oxidize iron as well (discussed shortly).

THOUGHT QUESTION 22.6 Compare and contrast the cycling of nitrogen and sulfur. How are the cycles similar? How are they different?

The Phosphate Cycle

Phosphorus is a macronutrient required for assimilation into organic biomass. Phosphate is a fundamental component of nucleic acids, phospholipids, and phosphorylated proteins. Unlike sulfur and nitrogen, which are found in several different oxidation states, phosphorus is cycled almost entirely in the fully oxidized state of phosphate (**Fig. 22.16**). The absence of fully reduced phosphorus in ecosystems may be due to the fact that reduced phosphorus (phosphine, PH_3) undergoes spontaneous combustion in the presence of oxygen. Nevertheless, some anaerobic decomposers may use phosphate as a terminal electron acceptor, reducing it to phosphine. In marshes and graveyards, where extensive decomposition occurs, phosphine has been observed emanating from the ground, where it ignites with a green glow. Microbial respiration might be responsible for such "ghostly" apparitions.

Although phosphate is abundant in Earth's crust, its availability in ecosystems is limited by its tendency to precipitate with calcium, magnesium, and iron ions. Thus, dissolved phosphate in water and soil is often a limiting

The small amount of soluble phosphate is taken up by plants and bacteria, then passed on to consumers. Decomposers return phosphate to the environment.

nutrient for productivity. In natural ecosystems, whatever phosphate is available is taken up rapidly by bacteria and phytoplankton, then consumed by grazers and predators and dispersed by decomposers at each level. The importance of phosphate limitation in the oceans was underscored by the Sargasso Sea collection of genomes sequenced by Craig Venter and colleagues (discussed in Chapter 21). In the genomes they assembled, they found a large number of genes encoding diverse systems of phosphate acquisition.

In agriculture, phosphate is often added as a fertilizer. Phosphate fertilizer is obtained by treating calcium phosphate rock with sulfuric acid, producing calcium sulfate (gypsum) and phosphoric acid. Excess phosphate from fertilizer or industry may drain into streams and lakes where phosphorus is the limiting element. The sudden influx of phosphate causes an algal bloom. The overgrowth of algae leads to overgrowth of heterotrophs, depletion of oxygen, and destruction of the food chain.

THOUGHT QUESTION 22.7 Compare and contrast the cycling of nitrogen and phosphorus. How are the cycles similar? How are they different?

The Iron Cycle

Iron is one of a large number of micronutrients, elements that form a negligible part of biomass but are essential for growth of organisms. Nearly all organisms require iron, which acts as a cofactor for enzymes and is an essential component of oxygen carrier molecules such as hemoglobin. Other common micronutrients required for enzymes and cofactors are zinc, copper, and selenium.

While iron is a major component of Earth's crust, its availability to organisms is limited by its extremely low solubility in the oxidized form. In microbial biochemistry, the oxidized form, ferric ion (Fe^{3+}), interconverts with the reduced form, ferrous ion (Fe^{2+}). In the presence of oxygen, iron metal (Fe^0) "rusts" and is therefore available to organisms mainly as Fe^{3+}. Ferric ion is especially insoluble at high pH, precipitating as ferric hydroxide [$Fe(OH)_3$] or ferric phosphate ($FePO_4$) (**Fig. 22.17A**).

In iron mines, where pyrite (FeS_2) is exposed to air, spontaneous oxidation produces sulfuric acid:

$$2FeS_2 + 7O_2 + 2H_2O + 4H^+ \longrightarrow 2Fe^{2+} + 4H_2SO_4$$

This reaction drives the growth of lithotrophs such as *Thiobacillus ferrooxidans*, which greatly increases the rate of sulfuric acid production, leading to acid mine drainage. Where a source of concentrated reduced iron from acid mine drainage enters an aquatic system, it is oxidized by lithotrophs to ferric hydroxide, forming an orange precipitate, seen in home plumbing (**Fig. 22.17B**). Iron mine drainage causes severe pollution of streams (**Fig. 22.18**).

In anoxic habitats, such as benthic sediment, Fe^{3+} is largely reduced to Fe^{2+} by anaerobic respiration. Reduction leads to loss of the reddish color, generating gray-colored sediment, as in wetland soil (discussed in Chapter 21). The reduction of Fe^{3+} to Fe^{2+} is one of the enriching contributions of anaerobic sediment in aquatic wetlands and coastal estuaries, because reduced iron is more available to plants and bacteria. Oxidized iron, in aerobic soils, can only be taken up by bacteria. Bacteria synthesize special iron uptake systems, including molecules called **siderophores** that bind ferric ion outside the cell (discussed in Chapter 4). Bacterial iron then becomes available to consumers in the ecosystem.

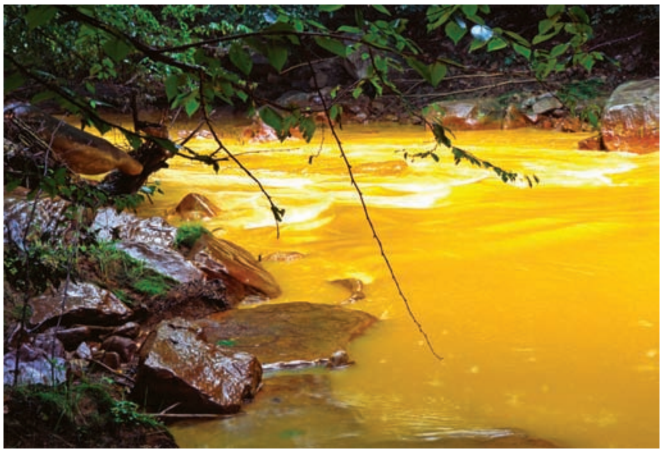
Figure 22.17 **The iron cycle.** **A.** Ferric ion (oxidized iron, Fe^{3+}) precipitates with hydroxide or phosphate. Only bacteria can assimilate Fe^{3+}, which is then passed on to consumers. In anaerobic sediment, bacterial respiration converts Fe^{3+} to Fe^{2+}, a more soluble form of iron available to plants. **B.** Home plumbing shows signs of lithotrophic oxidation of Fe^{2+} to Fe^{3+}, which forms an orange precipitate.



Thomas R. Fletcher/Alamy

Figure 22.18 **Mine drainage enters a stream.** Lithotrophic oxidation of reduced iron yields the orange material polluting this stream in Preston County, West Virginia.

Iron cycling often connects with sulfur in ways that can prove unfortunate for human engineering. The most serious problem is anaerobic corrosion of iron. Iron corrosion occurs spontaneously in the presence of oxygen. In anoxic environments, however, little spontaneous corrosion occurs. Instead, iron is corroded by sulfate-reducing bacteria (**Fig. 22.19**). Bacteria such as *Desulfovibrio* and *Desulfobacterium* can grow on the iron surface, forming an anaerobic biofilm. Within the biofilm, iron is oxidized to Fe^{2+}, and sulfate dissolved in the water is reduced to ferrous sulfide:

$$4Fe + SO_4^{2-} + 4H_2O \longrightarrow FeS + 3Fe^{2+} + 8OH^-$$

The FeS flakes away, exposing more iron to react with water, resulting in cyclic corrosion.

In oceans, iron is limiting because the benthos is so distant that its iron is largely inaccessible. The main

source of marine iron is eolian (wind-borne) dust from dry land. Most of the wind-borne iron is particulate, oxidized, and unavailable to eukaryotic phytoplankton (algae). Thus, bacteria that acquire and reduce ferric ion provide the main entry of iron into the ecosystem. This may explain why so many marine algae are mixotrophs: Although their photosynthesis can fix plenty of carbon for biomass, they must consume bacteria as a source of iron.

Iron limitation in the ocean affects other cycles, particularly those of nitrogen and phosphate. Evidence suggests that in the North Pacific, lack of iron limits the growth of nitrogen fixers, thus setting the limit for nitrogen assimilation into biomass. In the North Atlantic, on the other hand, iron is more available, so nitrogen fixation is not limited; instead, phosphate becomes limiting.

The role of iron limitation has led to speculation that we could remove excess CO_2 from the atmosphere by fertilizing the ocean with iron, accelerating growth of marine phytoplankton. An experiment to demonstrate the feasibility of iron fertilization was conducted by members of the Planktos Foundation, a private organization supported by Canadian rock star Neil Young. In this experiment, a large quantity of iron-rich ore was dumped in marine waters off the Hawaiian Islands. Sure enough, a substantial algal bloom followed. Calculations showed that the algal bloom was large enough to fix significant CO_2.

THOUGHT QUESTION 22.8 Do you think that iron fertilization would succeed in maintaining lowered atmospheric CO_2? What consequences might you predict for widespread iron fertilization?

Table 22.4 Microbial metabolism of metals.

Metal	Major conversions	Microbial genera (examples)	Effects on environment
Manganese, Mn	$Mn^{2+} \longrightarrow Mn^{4+}$ $Mn^{4+} \longrightarrow Mn^{2+}$	*Hyphomicrobium*, *Arthrobacter*, *Bacillus*, *Geobacter*, *Pseudomonas*	Mn is a trace element required for enzymes Anaerobic respiration in sediment
Mercury, Hg	$Hg^{2+} \longrightarrow Hg^0$	*Thiobacillus*	Hg^0 volatilizes; little harm
	$Hg^{2+} \longrightarrow (CH_3)Hg^+$	*Desulfovibrio*	$(CH_3)Hg^+$ is a severe neurotoxin; ingested through contaminated fish
	$(CH_3)_2Hg^+ \longrightarrow (CH_3)_2Hg$		$(CH_3)_2Hg$ volatilizes; poisonous but does not accumulate
Arsenic, As	$AsO_2^- \longrightarrow AsO_4^{3-}$	*Alcaligenes*, *Pseudomonas*	AsO_2^- (arsenite) and AsO_4^{3-} (arsenate) both poison cell metabolism
	$AsO_4^{3-} \longrightarrow AsO_2^-$	*Bacillus*, *Chrysiogenes*, *Pyrobaculum*	Arsenate as terminal e^- acceptor
	$AsO_4^{3-} \longrightarrow (CH_3)_3As$	*Candida* (a fungus), *Scopulariopsis* (a fungus)	Methylarsines poison; inhalation of moldy wallpaper with arsenic pigment
Chromium, Cr	$CrO_4^{2-} \longrightarrow Cr^{3+}$	*Aeromonas*, *Arthrobacter*, *Desulfovibrio*	CrO_4^{2-} [Cr(VI)] is mutagenic and carcinogenic; as e^- acceptor, reduced to Cr^{3+} [Cr(III)], less toxic
Vanadium, V	$VO_3^- \longrightarrow VO(OH)$	*Veillonella*, *Desulfovibrio*, *Clostridium*	V is a trace element for some nitrogenases and invertebrate blood pigments VO_3^- (vanadate) is oxidized as an e^- donor
Selenium, Se	$Se^0 \longrightarrow SeO_3^{2-}$	*Bacillus*, *Micrococcus*	Se is a human trace element, but toxic at higher doses
Uranium, U	$UO_2^{2+} \longrightarrow UO_2$	*Veillonella*, *Shewanella*, *Geobacter*	UO_2^{2+} [U(VI)] is highly soluble; microbes reduce as e^- acceptor to uranium dioxide, UO_2 [U(IV)], insoluble; used for cleanup of radioactive uranium contamination

The iron fertilization experiment was highly controversial, as ecologists pointed out numerous unforeseen consequences of such an attempt. While iron fertilization is unlikely to prove feasible, other means of positive engagement with the biosphere need to be considered to counteract the increasingly negative impacts of human civilization on biogeochemical cycles. Our view of Earth's biosphere increasingly is moving toward **environmental management**—the concept that wilderness as such no longer exists, only a biosphere to be managed for better or worse. Microbes will have many roles as partners in environmental management.

Other Metals in the Environment

Another concern for environmental management is that of toxic metals such as mercury and arsenic. Besides iron, numerous trace metals interact with bacterial species as either electron donors or acceptors (**Table 22.4**). Bacterial conversion of metals can either produce toxic species or remove toxic metals from ecosystems. For example, chromium-6 [Cr(VI)] is an extremely toxic pollutant that can be reduced by soil bacteria to the much less toxic Cr(III).

Mercury contamination. A well-known case of metal toxicity mediated by bacteria is that of mercury (**Fig. 22.20**). Mercury is found in small quantities in nature, but human production of pesticides puts out 10,000 metric tons annually, in addition to 3,000 metric tons released by the burning of fossil fuels. Elemental mercury (Hg^0) has limited toxicity; but in the environment, mercury is methylated by bacteria, forming methylmercury, $(CH_3)Hg^+$, which is highly toxic. When bacteria containing methylmercury are consumed by grazers and predators, the mercury concentration increases as a proportion of biomass until it may reach levels toxic to animals such as fish and shellfish. When these animals are consumed by humans, we may experience extreme toxicity, particularly neurological effects.

Note that methylation of mercury is just one of the reactions bacteria may conduct. Anaerobic respirers may reduce Hg^{2+}, while others may demethylate methylmercury to the less toxic Hg^{2+}. Addition of a second methyl group produces the extremely toxic and volatile compound dimethylmercury $[(CH_3)_2Hg]$ that dissipates initially, but can be taken up by organisms.

Figure 22.20 Mercury conversions include microbial metabolism.
A. Mercury methylated by bacteria is accumulated by consumers across the food web, including, ultimately, humans who eat contaminated fish or shellfish.
B. Various reactions of mercury are mediated by bacteria. Bacteria may modify the metal through lithotrophy or use it to oxidize H_2S. Methylation of ionic mercury (Hg^{2+}) is a common response, probably to detoxify it for the bacterium. Unfortunately, methylmercury (CH_3Hg^+) is the most hazardous form for consumers because it sticks within sediment and dissolves in membrane lipids. Addition of a second methyl group forms dimethylmercury $[(CH_3)_2Hg]$, a volatile, highly toxic compound.

Uranium contamination. Increasingly, bacteria are being harnessed for metal removal and detoxification technologies. An example is the use of microbes to reduce radioactive uranium to an insoluble form, which is easier to remove from contaminated water or soil, such as that of abandoned uranium mines (**Fig. 22.21**). A strain of *Desulfovibrio desulfuricans* reduces U(VI) to U(IV), an insoluble form. *Desulfovibrio* is better known for anaerobic H_2S generation associated with corrosion of sewer pipes and oil wells (discussed earlier). For metal removal, however, the organism can use U(VI) oxide for anaerobic respiration, with an electron donor such as acetate or sugar. By pumping acetate or crude sugars such as molasses into contaminated soil, U(VI) is reduced to insoluble U(IV), which is immobilized in the soil and prevented from migrating further into the water table.

Kevin Moloney/The New York Times/Redux

Figure 22.21 Bacteria remove uranium contamination. **A.** *Desulfovibrio desulfuricans* reduces U(VI) with an organic electron donor (cell length, 1–2 μm; SEM). Because the resulting U(IV) is insoluble, bacterial reduction can remove uranium from contaminated wastewater. **B.** A uranium mine in Moab, Utah, is 200 times more radioactive than the public exposure limit. Such sites may someday be decontaminated by bacteria.

TO SUMMARIZE:

- **A major source of sulfur is marine sulfate.**
- **Oxidized and reduced forms of sulfur are cycled in ecosystems.** Sulfate and sulfite serve as electron acceptors for respiration. Hydrogen sulfide serves as an electron donor. Sulfur cycling participates in acid mine drainage and pipe erosion.
- **Phosphorus cycles primarily in the fully oxidized form (phosphate).** Phosphate limits growth of algae in some aquatic and marine systems.
- **Iron cycles in oxidized and reduced forms.** Oxidized iron (Fe^{3+}) serves as a terminal electron acceptor in anaerobic soil and water. Reduced iron (Fe^{2+}) from rock is oxidized through weathering or mining. Bacterial lithotrophy accelerates iron oxidation, leading to acidification.
- **Metal toxins such as mercury and uranium can be metabolized by bacteria.** Bacterial metabolism may increase toxicity (as in the case of mercury), or it may convert the metal to an oxidation state with changed solubility, enhancing decontamination.

22.6 Astrobiology

As we come to appreciate the ubiquitous contributions of microbes to shaping our planet, in all its diverse habitats, increasingly we wonder whether microbes exist on worlds beyond Earth. Is Earth unique in supporting life; or have living cells evolved as well on Mars or Venus or on Jupiter's planet-sized moons? **Astrobiology** is the study of life in the universe, including its origin and possible existence outside Earth. The discovery of life beyond Earth would arguably be the most significant advance in science since a human set foot on the moon.

If the same physical and chemical laws govern the universe everywhere, then it is hard to suppose that only one of the billions of stars would have a planet supporting life. On the other hand, we have no idea of the number of planets and/or planetary histories that are or were capable of developing and sustaining a biosphere. As Isaac Asimov said, "There are two possibilities. Maybe we're alone. Maybe we're not. Both are equally frightening."

If life exists elsewhere, is it built on the same fundamental elements as ours? Many lines of evidence suggest that the biochemistry of life elsewhere would resemble that of Earth. Terrestrial life is founded on macroelements in the first two rows of the periodic table, including carbon, nitrogen, oxygen, phosphorus, and sulfur (see **Table 22.1**). The valence numbers of these elements from the middle of the periodic table enable them to form complex molecular structures with strong covalent bonds. The same fundamental molecules that appear in early-Earth simulation experiments, such as adenine and glycine, also appear in meteorites. Thus, we suspect that the fundamental building blocks for biochemistry are universal. On the other hand, if life could indeed be founded on some other basis, how would we recognize it?

If life is found on other planets, it will almost certainly include microbes. In fact, a case can be made that the majority of biospheres in our galaxy would consist entirely of microbial life, since microbes inhabit a wider range of conditions than multicellular plants and animals. Even on Earth itself, the largest bulk of our biosphere—including deep sediments and rock strata—consists of microbial ecosystems.

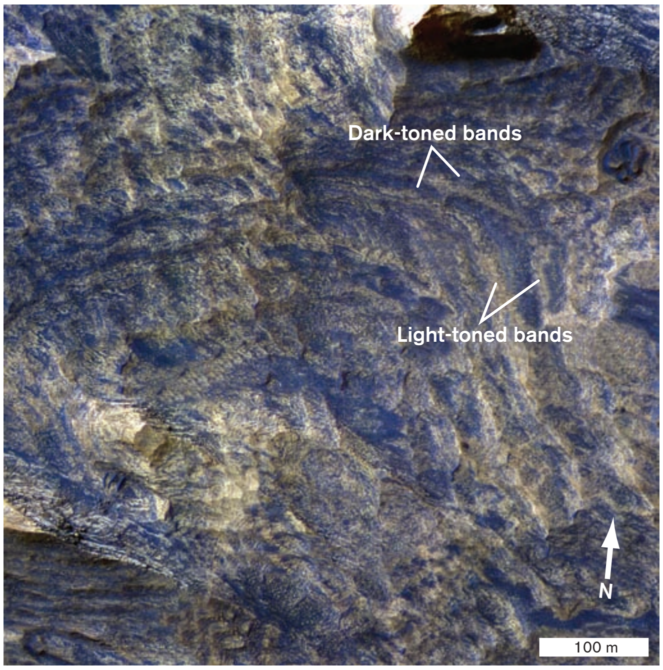
Did Mars Once Support a Biosphere?

For several reasons, the most studied candidate for extraterrestrial life has been the planet Mars.

- **Geology.** Of all the solar planets, Mars seems the most similar to Earth in its topography; indeed, some areas of Mars remarkably resemble desertscapes on Earth. Martian rock contains the fundamental elements needed for life.
- **Day and year length.** Mars has a day length similar to that of Earth, and a year only twice as long as ours.
- **Temperature.** The average temperature on Mars is 220 K (–53°C), too cold for most biochemistry on Earth, but its temperature rises above freezing at the equator. By contrast, the torrid heat of Venus (460°C) would exclude stable macromolecules.
- **Atmosphere.** The overall atmospheric pressure on Mars, 6 mbar, is barely a hundredth that of Earth (1,013 mbar) and lacks molecular oxygen. Thus, aerobes could not grow. But the Martian atmosphere does include carbon dioxide, actually at 20 times the CO_2 content on Earth, so there would be plenty for photoautotrophic production of biomass.
- **Water.** No liquid water exists at the Martian surface, but evidence supports the existence of water in the past. Liquid water may yet exist deep underground, supporting life-forms similar to the endoliths of Earth's crustal rock.

The existence of liquid water is a key question because on Earth, wherever liquid water exists, even brine (concentrated salt) at –20°C, there we find microbial life. Evidence for liquid water, past or present, was a priority for NASA's highly successful Mars Rover mission of 2004. The rovers obtained several types of mineral deposits that on Earth are formed only through crystallization from water, such as jarosite, a form of iron sulfate hydroxide. Another mineral found was smooth spherical deposits of hematite (Fe_2O_3, iron oxide) about 2 mm in diameter, nicknamed "blueberries." Again, these minerals are believed to arise only out of water solution.

Other evidence for water on Mars comes from geological formations surveyed by the Mars Reconnaissance Orbiter in 2007. The Orbiter mapped sedimentary deposits in one of Mars's deepest canyons, Candor Chasma (**Fig. 22.22**). The layered patterns are best explained by a model involving fluid flow, such as the flow of water.



NASA/JPL/U. of Arizona

Figure 22.22 Evidence of past water on Mars. Sedimentary deposits in one of Mars's deepest canyons, Candor Chasma, mapped by the Mars Reconnaissance Orbiter in 2007. The layered patterns are best explained by a model involving fluid flow, such as the flow of water. *Source*: From C. H. Okubo and Alfred S. McEwen. 2007. *Science* 315:983.

If life once existed on Mars, what became of it? Two main possibilities are considered:

- **Life developed and existed until the planet froze.** Under this scenario, life originated much as it did on Earth, during a time of heavy bombardment from space and outgassing of nitrogen and carbon dioxide. Unfortunately, however, life failed to generate sufficient atmosphere for a greenhouse effect to sustain temperate conditions. No oxygenic organisms produced molecular oxygen and an ozone layer.
- **Life developed and still exists underground.** In the absence of an ozone layer, the Martian surface is sterilized by cosmic radiation. Nevertheless, microbes may yet exist deep underground, similar to the endolithic prokaryotes on Earth. Endoliths metabolize within interstitial water and are protected from cosmic radiation.

Do Biosignatures Indicate Life?

If microbes do exist on Mars, they should be detectable. But the detection of unknown life, even on Earth, remains a challenge. The advent of PCR sequence detection of species based on ribosomal genes has revealed thousands of unknown species, most of which cannot be grown or recognized by other methods. Other species may well be missed if their rRNA sequences fail to amplify with our probes. On Mars, assuming life evolved independently of Earth life-forms, we would have no way to define sequence probes for detection.

Instead, researchers try to define **biosignatures**, chemical and physical signs that could only have been created by life. Most of the proposed biosignatures are based on types of evidence for life on Earth, either as fossils of ancient life (discussed in Chapter 17) or signs of current life in extreme habitats. Proposed biosignatures include the following:

- **Microfossils.** The mineralization of microbial cells leads to formation of structures that can be visualized under a microcope. The cell fossils must be sufficiently distinct to establish that no abiotic process could have formed them.
- **Isotope ratios.** Certain biochemical reactions preferentially use one isotope of an atom over another; for example, rubisco, the key enzyme of carbon dioxide fixation, uses ^{12}C in preference to ^{13}C. Thus, photosynthetic use of ^{12}C can decrease the ratio of $^{12}C/^{13}C$ in subsequent carbonate deposits. Isotope ratios of nitrogen, oxygen, and sulfur are also used as biosignatures.
- **Mineral deposits.** Certain mineral formations are only observed to be caused by microbial activity. For example, insoluble manganese oxides such as Mn_2O_3 are almost always the result of microbial oxidation of reduced manganese. Reduced manganese ions are very stable, and their abiotic oxidation rate is extremely slow.
- **Metabolic activity.** Samples of soil can be incubated with radioactive tracer substances such as $^{14}CO_2$ and tested for metabolic conversion or incorporation into biomass. It must be established that the conversion could not have occurred abiotically and that no organisms from Earth were present.

Various kinds of evidence for life on Mars have been reported, such as possible microfossils within a Martian meteorite that landed in Antarctica. Metabolic activity was tested in samples obtained by the NASA Viking Lander in 1975. As of this writing, however, no evidence has proved conclusive for active or past living microorganisms on Mars.

Could Mars Be Terraformed to Support Earth Life?

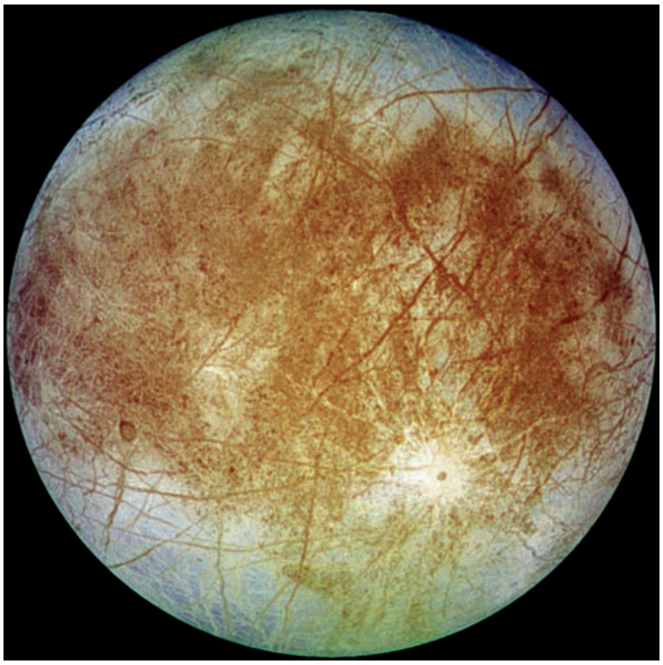
If no life exists—or if it exists only in the form of microbes deep underground—should we consider human intervention, or **terraforming**, to make Mars habitable for life from Earth? Scenarios for terraforming, long explored in science fiction, are now receiving serious thought among space scientists. Terraforming Mars would require increasing the temperature and air pressure. The temperature of the atmosphere might be increased by release of greenhouse gases. In addition, sufficient carbon dioxide and nitrogen gases must be made available from the Mars surface rock. In principle, microbes from Earth could be seeded to grow and generate an atmosphere containing nitrogen, oxygen, and CO_2.

In favor of terraforming, it is argued that Mars offers enormous natural resources of potential benefit for humanity, especially as terrestrial resources are used up. Human settlements on Mars would be a major step forward for space exploration. On the other hand, it is argued that the planet Mars is a natural monument, a place with its own right to exist as such. It should be allowed to remain in its natural state for future generations to appreciate. As a practical matter, terraforming remains unfeasible for the near future. For example, the amount of chlorofluorocarbons calculated to raise Martian temperature is 100 times greater than our global capacity to produce such substances.

Does Europa Have an Ocean?

Farther out in the solar system, surprising candidates for microbial life are the moons of Jupiter. In 2000, the Galileo space probe passed several of Jupiter's moons, including Ganymede, Callisto, and Europa (**Fig. 22.23**). While their distance from the sun results in extreme cold, these bodies receive extra heat from friction generated by tidal forces from the giant planet Jupiter. In the case of Europa, the tidal forces have been calculated to provide enough heat to liquefy water without boiling it off. Furthermore, measurement of Europa's magnetic field suggests that its composition includes a dense iron core surrounded by 15% water. Most of the water must be locked in ice, but tidal heating could melt enough water for an underlying ocean of brine. On Earth, similar brine lakes beneath the ice of Antarctica harbor halophilic archaea that grow at –20°C.

If such oceans do exist, how could they support life without photosynthesis? Photosynthesis is impossible at Jupiter's distance from the sun. However, an alternative source of chemical energy might be the influx of charged particles accelerated in Jupiter's magnetic field. Charged particles entering Europa's ice can react with water to form hydrogen peroxide (H_2O_2). The H_2O_2 then breaks down, releasing molecular oxygen. Oxygen reaching the brine layer below could combine with electron donors from crustal vents and power metabolism. Alternatively, molecular hydrogen (H_2) could be generated from water ionized by decay of radioisotopes. A similar source of H_2



NASA/DRL

NASA

Figure 22.24 A stellar nursery. Nebula RCW-49, in the Milky Way, contains more than 300 newborn stars, from which NASA's Spitzer Space Telescope detected spectroscopic signals of common organic constituents of life (infrared photograph).

for life has been proposed to occur on Earth in rock strata several kilometers below the surface, where it may support lithotrophs. The hydrogen could then combine with oxygen gas or other oxidants to power life. These schemes are highly speculative—but tantalizing enough to encourage further NASA missions to take a closer look at Europa and its sister moons.

Does Life Exist on Planets of Distant Stars?

The past decade of astronomy has seen an extraordinary growth in our knowledge of solar systems beyond our own. Now that we know so many other stars possess planets, we can only wonder whether they, too, possess biospheres of life-forms we would recognize.

Figure 22.24 shows an infrared photograph through the Spitzer Telescope of nebula RCW-49, a gaseous cloud full of newborn stars. Recall from Chapter 17 that as stars form, they take up dust of supernovae that includes all the elements needed to form biomolecules. Spectroscopic observation of RCW-49 reveals stars surrounded by disks coalescing into planets. The planetary disks contain icy particles full of organic molecules such as methanol, glycine, and ethylene glycol, a reduced form of sugar. Could there be biospheres in the making?

TO SUMMARIZE:

- **Astrobiology is the study of life in the universe including possible habitats outside Earth.**
- **The search for extraterrestrial life is based on methods similar to those used to seek early life on Earth.** Methods include chemical and physical biosignatures, isotope ratios, microfossils, and metabolic activity.
- **Mars is the planet whose geology most closely resembles that of Earth.** Geological features strongly support the past existence of flowing water, a prerequisite for microbial life.
- **Jupiter's moon Europa is proposed as another possible site for life.** Europa is bathed in a sea of brine similar to terrestrial habitats for halophiles.

Concluding Thoughts

Our observations of distant molecules, as well as our analysis of meteorites (discussed in Chapter 17), suggest that the biomolecules of Earth fit into a universal pattern of interstellar chemistry. Whether life exists elsewhere or we are alone, we must remember that our Earth is the only place we know of at this time that can support humans and the forms of life we require for our own survival. The function of our entire biosphere depends on our microbial partners to cycle key elements and acquire energy to drive the food web. For the first time in history, human technology now rivals the ability of microbes to alter fundamental cycles of biogeochemistry. But to manage and moderate our alterations—for our own survival and that of the biosphere—our fate still depends on the microbes.

CHAPTER REVIEW

Review Questions

1. Explain the major sources and sinks of carbon, nitrogen, and sulfur. Which sources recycle rapidly, and why?
2. Explain how the carbon cycle differs in oxygenated and anoxic environments.
3. Explain two different chemical methods of measuring the environmental levels of carbon and nitrogen.
4. Outline the hydrological cycle. Explain the role of biochemical oxygen demand (BOD) in water quality and how it may be perturbed by human pollution.
5. Outline the function of a wastewater treatment plant. Include the phases of primary, secondary, and tertiary treatment. Explain the roles of microbes in these phases of water treatment.
6. Outline the main transformations of the nitrogen cycle. Which reactions are carried out only by microbes?
7. Outline the main transformations of the sulfur cycle. Which features are comparable to the nitrogen cycle, and which are unique to the sulfur cycle?
8. For the iron cycle, explain aerobic and anaerobic processes of microbial transformation. Explain how microbial iron transformation may be linked to sulfur transformation.
9. Explain how bacteria may convert metals to toxic forms. Alternatively, explain how bacteria may detoxify metal-polluted sediment.
10. Offer several arguments for and against the existence of life on planets beyond Earth.

Clifford Houston, professor of microbiology and immunology and associate vice president for educational outreach at the University of Texas Medical Branch at Galveston.

AN INTERVIEW WITH

CLIFFORD W. HOUSTON: AN AQUATIC BACTERIUM CAUSES FATAL WOUND INFECTIONS

Clifford W. Houston has taught medical microbiology for over two decades at the University of Texas Medical Branch (UTMB). Houston developed assays to detect toxins from group A streptococci and from *Salmonella* species. He showed how *Aeromonas* bacteria acquired from waterways can fatally infect wounds in humans. A leader in microbial education, he developed innovative outreach programs for UTMB, chaired the Education Board of the American Society for Microbiology (ASM), and was elected president of ASM in 2006. As deputy associate administrator for education at the National Aeronautics and Space Administration (NASA) in 2003, he addressed the medical challenges faced by astronauts and funded programs to inspire the next generation of explorers.

When did you first become interested in science?

I am a native of Oklahoma City, Oklahoma, and the first member of my family to attend college. My parents always encouraged me to obtain as much education as possible. My interest in science began when I did my first science fair project in elementary school. My teacher was very encouraging and gave me confidence that I could do the project. When I was in junior high school, I transformed the basement of my parents' home into a research laboratory.

How did you decide to make a career in microbiology?

My first undergraduate course in microbiology had a significant impact on my life. I was inspired so much by the subject that I immediately changed my undergraduate major from biology to microbiology. It was my good fortune to have the opportunity to conduct my predoctoral studies in the laboratory of Joseph J. Ferretti, whose expertise is streptococcal genetics. In Ferretti's laboratory, I worked on the kinetics and regulation of type A streptococcal exotoxin during the growth of *Streptococcus pyogenes*. This work resulted in one of my first publications in *Infection and Immunity*. Ferretti's mentorship sustained my career interest in determining the role that bacterial toxins play in the pathogenesis of disease. I acquired my expertise in working with gram-negative bacteria from Johnny Peterson as a postdoctoral fellow in his laboratory. As a faculty member, I was honored to have Ashok Chopra as a postdoctoral fellow, who conducted much of our work on *Aeromonas*.

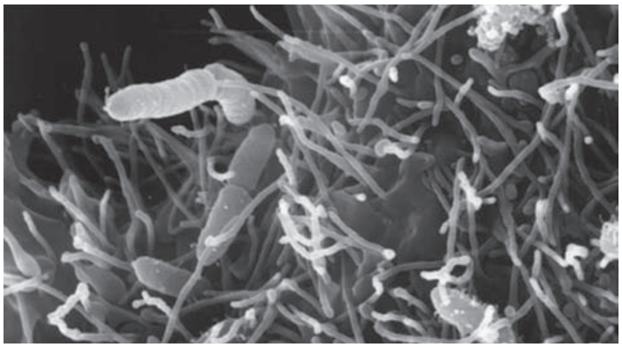
You developed sensitive assays for detection of toxins from group A streptococci and from *Salmonella*. What are the special challenges of assay development for pathogens?

During the mid to late 1970s, I modified the enzyme-linked immunosorbent assay (ELISA) to detect bacterial toxins that play a role in the pathogenesis of disease. The major challenges in developing this type of assay are sensitivity and specificity. I succeeded in developing an extremely sensitive assay (capable of detecting nanogram quantities), as well as an assay specific enough to avoid a high frequency of false positive reactions. The ability to detect these toxins can be used to link a pathogen to causation of human disease.

How did you choose to study *Aeromonas hydrophila*?

We were surveying the cultural filtrates of a variety of bacterial isolates in the laboratory employing an ELISA toxin assay using cholera antitoxin. To our surprise, the *Aeromonas* cultural filtrates tested positive in the ELISA, which meant that some antigen in the cultural filtrate cross-reacts with the cholera toxin.

Aeromonas is associated with wound infections and causes gastroenteritis. We found that a cytotoxic enterotoxin related to cholera toxin is associated with tissue damage in cell cultures and rabbit skin testing, as well as fluid accumulation in rabbit intestinal loops. We also showed that *Aeromonas* with mutations in the cytotoxic enterotoxin gene has diminished virulence.



Courtesy of Clifford W. Houston

***Aeromonas* sp. bacteria adhering to human epithelial cells. (Cell length, 2–4 µm.)**

Is *Aeromonas* an opportunistic pathogen? Why are opportunistic pathogens a growing topic of concern for research and for public health?

Some species of *Aeromonas* may be pathogens, while others may be opportunists. Opportunistic microorganisms are capable of causing disease only when the conditions are favorable to the bacteria, such as when the host's immune system has been weakened as a result of stress, radiation treatment, chemotherapy, or viral diseases. Opportunistic pathogens are a growing concern because they may live in the host for years, waiting for the opportunity to cause disease.

How does a patient contract illness from *Aeromonas*?

Aeromonas hydrophila originally was thought to infect only cold-blooded animals, such as frogs, snakes, and fish. However, there are many isolated cases of *Aeromonas* infections reported in the literature resulting from individuals whose skin has been cut, abraded, and/or punctured coming in contact with water contaminated with *Aeromonas* species. One case involved a motorcycle accident on the side of a highway in which the rider received a compound fracture in one of his legs and decided to put his injured leg into nearby pond water, which unfortunately contained *Aeromonas* species. From the pond, the microorganism entered his bloodstream, and the motorcyclist died in a hospital 48 hours later.

It is possible to acquire an *Aeromonas* infection from infected fish. For example, people have been infected by contaminated fish hooks or by handling infected fish when their hands that have cuts or abrasions. In addition, humans can get gastroenteritis by ingestion of *Aeromonas*-contaminated food.

What are your goals as an educator in microbiology?

My major goal is to expose young precollege and college students to the field of microbiology and to direct more students toward careers in the biomedical sciences. My Educational Outreach Office offers a summer research program for high school students. The students work in the laboratory of research faculty at the University of Texas Medical Branch. The students work 40 hours per week for seven weeks during the summer, get paid a stipend, and present a poster on their work at the end of the program. More than 95% of these students go on to college.

How did microbiology fit into your work at NASA?

I served on a team of NASA experts whose task was to plan the details on returning to the moon and on to Mars. Microbiology will play an important role in our plans because NASA must be careful not to contaminate the moon or Mars with microorganisms from Earth, and vice versa. We are concerned with the impact of long-term space travel on the astronauts' immune system and their susceptibility to infection. Also, there is concern about the impact of long-term exposure to UV light in causing mutations in harmless bacteria that make them virulent or antibiotic resistant.

Do you think the astronauts will find extraterrestrial microorganisms?

Recent data indicate that there may be water on Mars, which suggests the possibility that life may exist on the planet. Water will be examined for microorganisms as a first sign of life on the planet. Plans for isolation and containment have been discussed to prevent transporting Earth microorganisms to another planet because mutations might occur during the journey and the microorganisms could become more virulent. We also need to take precautions to prevent transporting extraterrestrial microorganisms back to Earth.

What do you think are the most exciting areas for students entering microbiology today?

The most exciting areas are astrobiology and biophysics. Both fields have relevance to microbiology. Another exciting area is biodefense. This field will play a significant role in the future protection of our country against biological warfare. Finally, another important field to remember is bioethics, which will always be a compelling career choice.

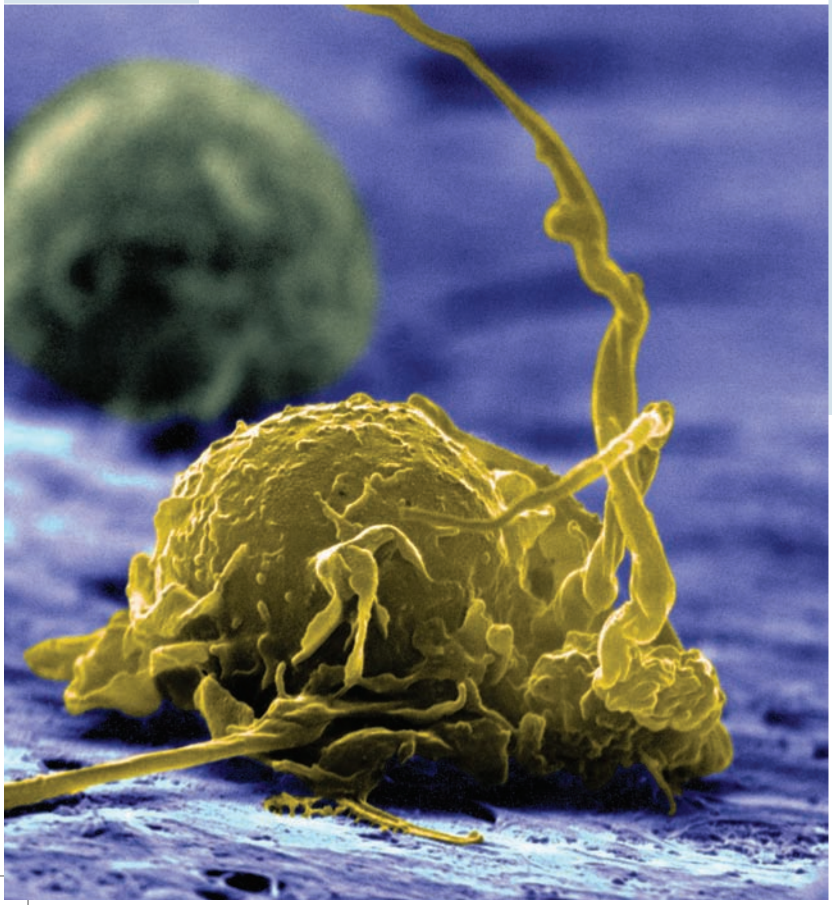
23.9 Fever

The human body teems with microbial hitchhikers. Most are harmless as long as they stay where they belong, such as on the skin or in the intestines, and some are even beneficial to their unsuspecting hosts. Consequently, organisms that are part of the normal human microflora typically exist in a symbiotic relationship with us. Of course, the human body is also under constant attack from microbial invaders that inhabit the surrounding environment. Fortunately, we have developed a series of barriers and elaborate fail-safe mechanisms that keep normal flora and invading pathogens at bay. Obstacles such as skin and stomach acid will repel most microorganisms; these are considered nonspecific defenses. But for those microbes able to breach these barriers, there await adaptive and nonadaptive immune defenses.



A human macrophage (10–15 □m diameter, colorized SEM). Found mainly in the liver, spleen, and lymph nodes, macrophages are a part of the immune system. Their primary function is to ingest (phagocytosis) and destroy anything they do not recognize as healthy tissue. Magnification □7000.
Source: David M. Phillips/Photo Researchers, Inc.

Imagine two vacationing tourists, unknown to each other, each visiting the Alabama gulf coast at the same time. Both decide to take a swim in the Gulf of Mexico. One, a 12-year-old girl, has a cut on her leg caused by the sharp edge of a scooter. The other vacationer, a man 66 years of age, has recently cut his arm on a nail protruding from a wooden handrail. Within moments of entering the Gulf of Mexico, several small gram-negative microbes invade both of their bodies through those cuts. Four days later, the young girl is heading back to Birmingham in the back of the family car, oblivious to the battle recently waged in her bloodstream. At the same time, the man lies dead of an aggressive blood infection.

Both swimmers were attacked by the same pathogen, *Vibrio vulnificus*. Why did one live and the other die? As is the case for most healthy people, a variety of nonspecific, innate immune factors present in the girl's body killed the invading pathogen before it could multiply. The man, on the other hand, was an alcoholic with liver disease. He was deficient in several of those defense mechanisms—mechanisms that made the difference between life and death. What are these powerful innate factors? How can they be nonspecific, able to attack many different microbes without ever previously encountering any of them? And why do they kill the invaders and not our own cells?

Before exploring these questions of immunity and self-defense, we must first understand that each of us is a self-contained ecosystem, home to numerous microbes inhabiting all sorts of body niches. This ecological relationship helped shape our immune system. The day-to-day presence of these microbial guests also sharpens our immunity, but it is a benefit that comes with considerable risk.

23.1 Human Microflora: Location and Shifting Composition

From the moment of our birth to the time of our death, we are constantly exposed to microbes. As a result, humans—and all other higher life-forms—are heavily populated with bacteria. Colonization typically occurs where our body interfaces with the external environment (for example, mouth, skin, and parts of the genitourinary tract). The more sequestered body sites are sterile. For example, most internal organs, the blood, and the cerebrospinal fluid should not harbor any bacteria. Microbes discovered at these sites usually have deleterious effects on the host. Their presence means an infection is under way. Bacteria normally found at various nonsterile body sites (such as the intestine) are called **commensal organisms** (commensal, from the Latin "to share a table"). By strict definition, a commensal is an organism that derives benefit from the host but does not harm the host. However, many organisms originally defined as commensal were later shown to benefit the host in relationships that are called mutualistic (see Section 17.6). The organisms, however, are still called commensal, especially in human hosts. A remarkable variety of bacterial species populate these sites, coexisting with each other in delicate, balanced ecosystems. In this section, we describe some of these organisms and why they populate different sites. **Figure 23.1** illustrates various human body sites colonized by bacteria and provides examples of the bacteria found there.

First, we will consider microbe-human interactions that take place in the host's outermost host layers—the skin and the eye—followed by the environments of the nose and throat. We will then take up the relatively commensal-free respiratory tract and the commensal-rich digestive tract. Finally, normal flora of the genitourinary tract, with its widely diverse environments, is described. **Table 23.1** lists the four prominent ecosystems of humans along with the number of microorganisms that typically inhabit them (called the **bioburden**). It includes the ratio of aerobes to anaerobes and the initial origins of resident species. Note that the composition of microflora will vary throughout life as a result of continual reseeding from the environment. Viruses are not included in this list because they are not considered commensal organisms.

Skin

The human adult, on average, is covered with 2 m^2 (over 9 ft^2) of skin (**epidermis**) populated by 10^{12} microorganisms. As with all colonized body sites, there are resident (normal) and transient microflora. But even a resident microbe exhibits diversity in that different strains colonize at different times. Thus, our microflora does not comprise a static population but represents a vibrantly changing milieu of strains and species.

Several features of epidermis make it difficult to colonize. Large expanses are subject to drying, although some harbor enough moisture to support microbial growth; these areas include scalp, ear, armpit, and genital and anal regions. The skin also has an acidic pH (pH 4–6) owing to the secretion of organic acids by oil and sweat glands. As noted in Section 5.5, organic acids inhibit microbial growth by lowering bacterial cytoplasmic pH. Epidermal secretions are also high in salt and low in water activity (see Section 5.4), and they contain enzymes such as lysozyme that degrade bacterial peptidoglycan.

Despite these hurdles, many species of bacteria manage to colonize the epidermal habitat. Most of these organisms are gram-positive because they tend to be more resistant to salt and dryness. *Staphylococcus epidermidis*, various *Bacillus* species, and yeast such as *Candida* are common examples of normal skin flora. Though normal, they are not always innocuous. One member of the skin's resident microflora, the gram-positive, anaerobic rod *Propionibacterium*

Figure 23.1 **Examples of normal microbial flora present at various colonizing sites.** *Staphylococcus* species are differentiated by their differing abilities to produce coagulase, an enzyme that coagulates serum. *S. aureus* is generally coagulase-positive (there are some coagulase-negative mutants), whereas other species of staphylococci normally found on skin are coagulase-negative. Some organisms, *S. pneumoniae*, for example, are pathogens but can be found as normal flora in some individuals.

Table 23.1 The prominent bacterial ecosystems of humans.

Microbial reservoirs	Total "bioburden" or colony-forming units	Aerobe-to-anaerobe ratio	How acquired
Skin	10^{4-6}/sweat gland	1:10	Birth canal Oral environments
Mouth	10^{6-8}	1:10	Birth canal Caregiver
Genitourinary tract	$10^{8\text{-}9}$/vagina/ureter	1:100	Surrounding external environment
Intestine	$10^{11}/\text{cm}^3$	1:1,000	Baby formula Mother Caregiver

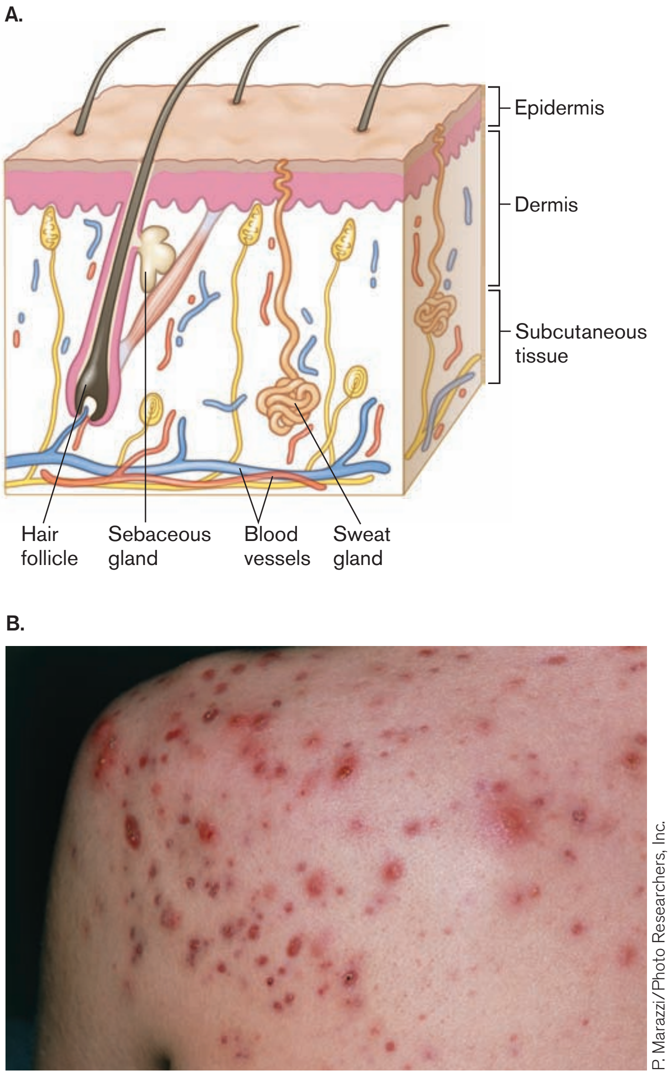
acnes, causes acne, a very visible plague of adolescence. Curiously, this is the same genus (but different species) that makes Swiss cheese (see Section 16.2). Increased hormonal activity during the teen years stimulates oil production by the sebaceous glands (**Fig. 23.2**). *P. acnes* readily degrades the triglycerides in this oil, turning them into free fatty acids that then promote inflammation of the gland. One consequence of the inflammatory response is the formation of a blackhead, a plug of fluid and keratin that forms in the gland duct. The result is the typical skin eruptions of acne. Because of its microbial basis, treatments for acne include tetracycline to kill the microbe.

Eye

Because the eye is exposed to the outside environment, one might expect it to be heavily colonized. Actually, this is not the case; colonization is inhibited by the presence of antimicrobial factors such as lysozyme in the tears that continually rinse the eye surface (**conjunctiva**). Despite this, a few commensal bacteria can be found on the conjunctiva. Skin flora such as *S. epidermidis* and diphtheroids (gram-positive rods that look like clubs) as well as some gram-negative rods such as *Escherichia coli*, *Klebsiella*, and *Proteus* manage to at least temporarily make the eye their home without causing damage. Occasionally, bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae*, as well as some viruses, can cause an ocular disease known as pinkeye, in which the eye becomes reddened with a watery discharge.

Oral and Nasal Cavities

Within hours of birth, a human infant's mouth becomes colonized with nonpathogenic *Neisseria* species (gram-negative cocci), *Streptococcus*, *Actinomyces*, *Lactobacillus* (all gram-positive), and some yeasts. These organisms come from the environment surrounding the newborn, such as



P. Marazzi/Photo Researchers, Inc.

Figure 23.2 Microbiology of skin and development of acne. **A.** Location of sebaceous glands in skin. **B.** Acne.

the mother's skin and garments. As teeth emerge in the newborn, the anaerobic nature of the space between teeth and gums supports the growth of anaerobes such as *Prevotella* and *Fusobacterium* (**Fig. 23.3**). Whatever the organism, colonizers of the oral cavity must be able to adhere to surfaces, like teeth and gums, to avoid mechanical removal and flushing into the acidic stomach. The teeth and gingival crevices are colonized by over 500 species of bacteria.

Organisms like *Streptococcus mutans*, which attaches to tooth enamel, and *Streptococcus salivarius*, which binds gingival surfaces, form a glycocalyx that enables them to firmly adhere to oral surfaces and to each other. They are but two of the microbes that lead to dental plaque formation. The acidic fermentation products of these organisms cause demineralization of teeth and dental caries (that is, tooth decay).

Important microbial habitats of the throat include the **nasopharynx**, which is the area leading from the nose to the oral cavity, and the **oropharynx**, which lies between the soft palate and the upper edge of the epiglottis (see **Fig. 23.3A**). Organisms like *Staphylococcus aureus* and *S. epidermidis* populate these sites. The nasopharynx and oropharynx can also harbor relatively harmless streptococci such as *S. salivarius* and *S. oralis*, as well as *S. mutans*, a major cause of tooth decay. Other oropharyngeal organisms include a large number of diphtheroids and the small gram-negative rod *Moraxella catarrhalis*. Within the tonsillar crypts (small pits along the tonsil surface) lie anaerobic species such as *Prevotella*, *Porphyromonas*, and *Fusobacterium*.

Even though the oral microflora is normally harmless, it does hold potential for disease. Dental procedures, for instance, will often cause these organisms to enter the bloodstream, producing what is called **bacteremia** (infection of the bloodstream). Normal immune mechanisms typically clear these transient bacteremias quite easily; but in patients who have a heart mitral valve prolapse (heart murmur), microbes can become trapped in the defective valve and form bacterial vegetations. Vegetations are formed by a large number of bacterial cells encased within glycocalyx, a polysaccharide or peptide polymer secreted by the organism, and fibrin, produced by clotting blood. Because the onset of disease is often insidious (slow), it is called subacute bacterial endocarditis (**Fig. 23.4**). Once ensconced within a vegetation, the microbes are extremely difficult to kill with antibiotics.

THOUGHT QUESTION 23.1 How can an anaerobic microorganism grow on skin or in the mouth, both of which are exposed to air?

THOUGHT QUESTION 23.2 What can a person with mitral valve prolapse do to prevent formation of subacute bacterial endocarditis when visiting the dentist?

The Respiratory Tract

The lungs and trachea do not harbor normal microflora. Many organisms entering the nasopharynx are trapped in the nose by cilia that beat toward the pharynx. Their ultimate destination is the acidic stomach and death. Microorganisms that make it into the trachea are trapped by mucus produced by ciliated epithelial cells that line the airways leading to the lung, and the cilia themselves

usher the microbes up and away from the lungs. The ciliated mucous lining of the trachea, bronchi, and bronchioles makes up the **mucociliary elevator** (**Fig. 23.5**). The mucociliary elevator constantly sweeps foreign particles up and out of the lung. This is extremely important for preventing respiratory infections. When the mucociliary elevator fails or is overwhelmed by inhaling too many infectious microbes, infections such as the common cold (for example, rhinovirus) or pneumonia (for example, *Streptococcus pneumoniae*) can result.

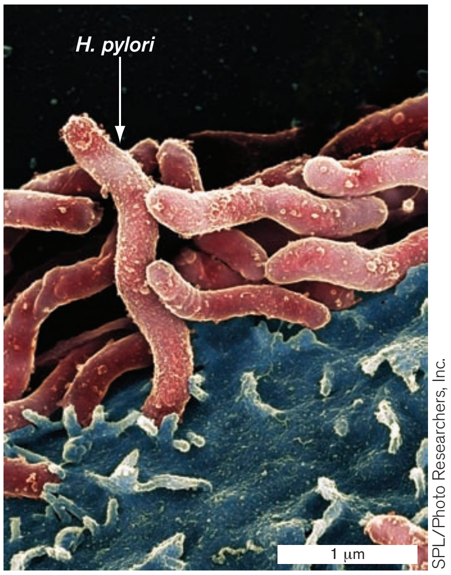
Stomach

We have known for a hundred years that the stomach contents are acidic and that gastric acidity can kill bacteria. Just how important that acidity is for protection against microbes is illustrated by the infection caused by *Vibrio cholerae,* the causative agent of cholera. Cholera is a severe diarrheal disease endemic to many of the poorer countries of the world. The toxin produced by the organism acts on the intestinal lining to cause voluminous diarrhea—as much as 10 liters a day. Death can occur rapidly as a result of dehydration and shock. Although cholera actually affects the intestines, not the stomach, the bacteria must survive passage through the stomach to reach the intestines.

In the middle of the last century, the U.S. government was concerned that troops dispatched to endemic countries could develop cholera and become incapacitated in large numbers, so the U.S. Army decided to test potential cholera vaccines for their efficacy. The vaccines were living cultures of genetically weakened cholera bacteria that could not cause serious disease. Living strains were preferred because they were expected to grow in the gastrointestinal tract and stimulate natural mucosal immunity (discussed later and in Section 24.3). But after administration of huge numbers of virulent organisms to healthy volunteers (as a control group), very few contracted cholera. This was confusing because hundreds of thousands of malnourished people in India easily contract the disease.

Why did volunteers given live cholera generally fail to develop the disease? Variations in resistance to cholera were discovered to be related to differences in stomach acidity. The organism *V. cholerae* is extremely sensitive to low pH; even a pH of 4 will readily kill it. Because the pH in the stomachs of healthy volunteers was well below 4, it easily killed *V. cholerae*. Malnourished people, however, suffer from achlorhydria (loss of stomach acid). This permissive environment gives ingested microbes time to enter the less acidic intestine, where they can thrive and cause disease. Cholera epidemics in which thousands of people die, even today, typically occur among poor, malnourished populations. Because the U.S. populace is better nourished, cholera is not a major problem in the United States.

Although the contents of the stomach are very acidic, the mucous lining of the stomach is much less so. It is there that some bacteria can take refuge. In fact, the stomach harbors a diverse microflora (as detected using cultural and molecular techniques such as polymerase chain reaction (PCR) identification of 16S rDNA). A classic stomach pathogen is *Helicobacter pylori*. Although this organism has a remarkable ability to resist acid pH (it survives at pH 1 using the enzyme urease to generate ammonia), it will not grow at that pH. It can, however, grow and divide in the mucous lining of the stomach, where the pH is closer to 5 or 6 (**Fig. 23.6**). The U.S. Centers for Disease Control and Prevention (CDC) estimates that *Helicobacter* colonizes the stomachs of half the world's population. Most of the time, *Helicobacter* does not cause any apparent problem, but on occasion, the organism can produce gastric ulcers and even cancer.



SPL/Photo Researchers, Inc.

Figure 23.6 ***Helicobacter pylori* defies stomach acidity.** *Helicobacter pylori* (colorized SEM) growing in the mucus on stomach epithelium. *Helicobacter pylori* bacteria attach to gastric epithelial cells and induce specific changes in cellular function, such as an increase in the expression of laminin receptor 1, a protein associated with malignancy.

The Human Intestine

The gastrointestinal tract beyond the stomach consists of an extremely long tube made of several sections, each of which provides a uniquely different environment that supports the growth of different bacterial species (see **Fig. 23.1**). Pancreatic secretions (at pH 10) enter the intestine at a point just past the stomach and raise the intestinal pH to about pH 8, which immediately relieves the acid stress placed on microbes. The relatively high pH and bile content of the duodenum and jejunum allow colonization by only a few resident, mostly gram-positive, bacteria (enterococci, lactobacilli, and diphtheroids). These particular gram-positive organisms possess a bile salt hydrolase that helps them grow in the presence of intestinal bile salts. The distal parts of the human intestine (ileum and colon) have a slightly acidic pH (pH 5–7) and a lower concentration of bile salts, conditions that support a more vibrant ecosystem. The intestine actually contains roughly 10^9–10^{11} bacteria per gram of feces (**Fig. 23.7**). This generally anaerobic environment is populated by both anaerobic and facultative microbes in a ratio of 1,000 anaerobes to one facultative organism. Why is the intestine anaerobic? The small amount of oxygen that diffuses from the intestinal wall into the lumen is immediately consumed by the facultative microbes, which render the environment anaerobic.

One such anaerobe, *Bacteroides thetaiotaomicron*, provides us with a great benefit. Much of this organism's genome is dedicated to taking many of the complex carbohydrates we eat and breaking them down into products that can be absorbed by the body. We humans actually absorb 15–20% of our daily caloric intake in this way.

Only recently have we really begun to ascertain what microbes inhabit our intestines (mainly because we cannot culture them). Through the use of culture-independent techniques (like ribotyping), we now have a sense of the identity, diversity, and variation among individuals of the human microflora. For example, of 395 unique "phylotypes" recently identified in humans, 60% were unknown at the species level, 80% have never been cultured, and huge differences in the population of microbes were observed between individuals.

All resident organisms normally present in the intestine are innocuous and considered **normal flora**. But if they accidentally escape into nearby tissues, they can cause serious disease. Intestinal bacteria, encompassing 400–500 different species, have special talents that allow them to bind and colonize the intestinal cell wall. One reason why such a large and eclectic mix of species is supported is that different bacteria attach to different host cell receptors. Another reason is that many different food sources are available to support diverse groups of microbes.

Organisms that inhabit the intestine include the family Enterobacteriaceae, of which *E. coli* is a member, and many anaerobes such as *Bacteroides* (gram-negative rods), *Peptostreptococcus* (gram-positive cocci), and *Clostridium* (gram-positive, spore-forming rods). In fact, the vast majority of our intestinal flora consists of the phyla Bacteroidetes and Firmicutes, of which *Bacteroides* species and *Clostridium* species, respectively, are members. Besides bacteria, other common and innocuous inhabitants are the yeast *Candida albicans* and protozoa such as *Trichomonas hominis* and *Entamoeba hartmanni*.

The large intestine is both rich and diverse in terms of nutrient availability. The majority of intestinal bacteria require a fermentable carbohydrate for growth, so it has generally been assumed that carbohydrate metabolism is necessary for colonization by most species. In the large intestine, carbohydrates are derived from partially digested food and from host secretions. Naturally occurring sugar acids, such as galacturonate from pectin and gluconate and ketogluconate from muscle tissues, are present in the foods we eat. The mucous layer covering epithelial tissues is also recognized as an important source of carbohydrates in the intestine. Mucus is a complex gel of glycoproteins and glycolipids. The sugar substituents of mucus include *N*-acetylglucosamine, *N*-acetylgalactosamine, galactose, fucose, sialic acids, and lesser amounts of glucuronate and galacturonate. Interestingly, *E. coli* will grow rapidly in mucus by catabolizing gluconate, a component of secreted mucus, using the Entner-Doudoroff pathway (see Section 13.5). The organism grows very poorly in feces itself. Thus, *E. coli* doesn't grow on what we *eat* but on what we *secrete*.

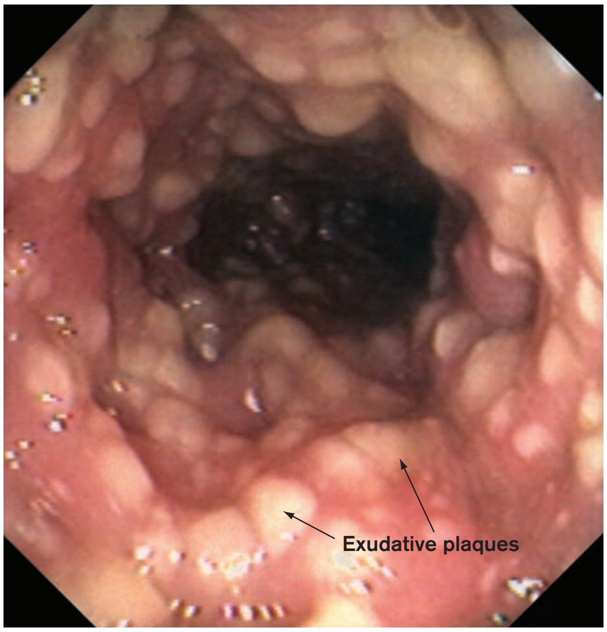
Despite this buffet-like assortment of food, many species still end up vying for the same nutrient, so competition for food is fierce. Perturbing the balance of power with antibiotics, diet, or stress can lead to disease.

Although we have considerable knowledge of the gastrointestinal microflora, there remains much to learn. For example, many of the species that inhabit the intestine have never been cultured in the laboratory. Molecular techniques such as PCR are now being used to identify the nonculturable organisms in this environment.

THOUGHT QUESTION 23.3 Why do many gram-positive microbes that grow on the skin, such as *S. epidermidis*, grow poorly or not at all in the gut?

THOUGHT QUESTION 23.4 How might normal flora escape the intestine and cause disease at other body sites?

Probiotics. As already noted, the microbial composition of the intestine is complex but balanced. It is complex because there are many species residing there. It is balanced because these species manage to coexist without eliminating each other. The rival organisms help prevent infection by competing with pathogenic species for nutrients and can actually contribute to nutrition (for example, *E. coli* makes vitamin B_{12}, whereas other organisms help digest complex substrates). Emotional stress, a change in diet, or antibiotic therapy can throw off that balance and lead to poor digestion or disease, such as pseudomembranous enterocolitis (**Fig. 23.8**). Some people favor restoring the natural microbial balance by orally ingesting living microbes such as the lactobacilli present in yogurt. Taking these supplements, called **probiotics** (from the Greek meaning "for life"), is thought to restore balance to the microbial community and return the host to good health. The most commonly used probiotic genera are *Lactobacillus* and *Bifidobacterium* (**Fig. 23.9**). The potential mechanisms by which they improve intestinal health include competitive bacterial interactions (normal flora prevent growth of pathogenic bacteria), production of antimicrobial compounds, and immune modulation (an ability to change the activity of cells of the immune system). The emerging use of probiotics in several gastrointestinal disorders (including inflammatory bowel disease, IBS) has led to increased interest in their use in patients. Early results are promising, but much of the research remains controversial.



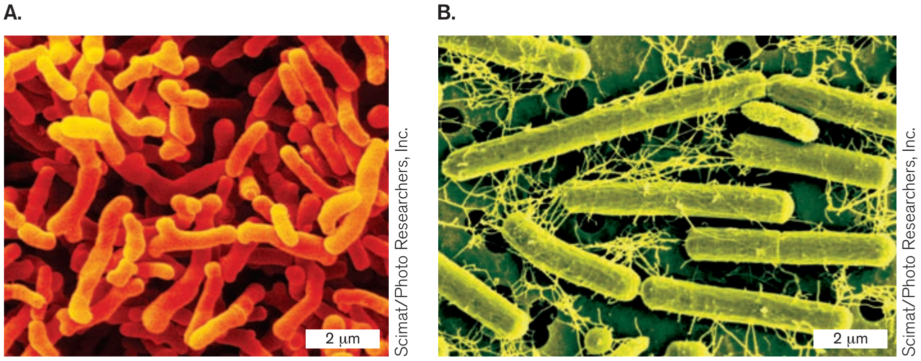
David M. Martin

Figure 23.8 Pseudomembranous enterocolitis caused by *Clostridium difficile*. The organism is often a part of the normal intestinal microflora, but antibiotic treatment, especially following surgery, can kill off competing microbes, leaving *C. difficile* to grow unabated. A toxin produced by the organism growing at the epithelial surface damages and kills host cells, causing exudative plaques to form on the intestinal wall. The small plaques eventually coalesce to form a large pseudomembrane that can slough off into the intestinal contents.

THOUGHT QUESTION 23.5 Why can the colon be considered a fermenter?

Genitourinary Tract

A significant portion of the genitourinary tract is usually free from microbes. These areas include the kidneys, which remove waste products from the blood; ureters, which remove the urine from the kidneys; and the urinary bladder, which holds urine until it is excreted. The distal



Scimat/Photo Researchers, Inc.

Scimat/Photo Researchers, Inc.

Figure 23.9 Commonly used probiotic microorganisms. Colorized SEMs of **A.** *Bifidobacterium* (note the "Y" shape of some cells) and **B.** *Lactobacillus acidophilus*.

urethra, however, because of its proximity to the outside world, normally contains *S. epidermidis*, *Enterococcus* species, and some members of Enterobacteriaceae. Some of these organisms, if they can make their way into the bladder (for example, via catheterization), will cause bladder disease (known as **urinary tract infection**, or **UTI**).

The large surface area and associated secretions of the female genital tract make it a rich environment for microbes. Composition of the vaginal microflora changes with the menstrual cycle, owing to changing nutrients and pH. The mildly acidic nature of vaginal secretions (approximately pH 4.5) discourages the growth of many microbes. As a result, the acid-tolerant *Lactobacillus acidophilus* is among the most populous vaginal species. As with all microbial ecosystems associated with the human body, the balance between competing species is crucial to preventing infection. Antibiotic therapy to treat an infection can also cause the loss of normal flora. In the vagina, this allows infection by *C. albicans* (yeast infection), which is not susceptible to antibiotics designed to kill bacteria.

TO SUMMARIZE:

- The **normal microflora** present on body surfaces constantly changes.
- **Normal flora can cause disease** if microbes breach the surfaces they colonize and gain access to the circulation or deeper tissues.
- **Colonization of skin** by microbes is difficult owing to surface dryness, an acidic pH, high salinity, and the presence of degradative enzymes.
- **Skin flora** consists primarily of gram-positive microbes, including *Propionibacterium acnes*, which can cause acne.
- **Microbe-free areas of the body** are the lungs, cerebrospinal fluid, and bladder. The eyes are generally microbe-free, although some microbes can be present for short periods.
- **Oral and nasal surfaces** are colonized by aerobic and anaerobic microbes.
- **The intestine** is populated by 10^9–10^{11} microbes per gram of feces in a ratio of approximately 1,000 anaerobes to 1 aerobe.

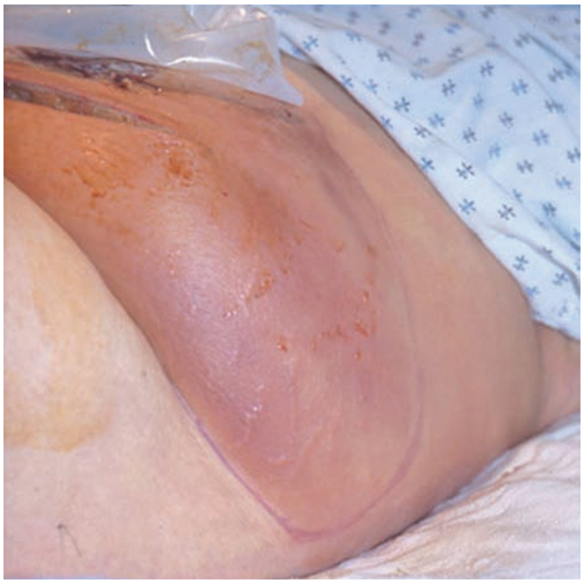
23.2 Risks and Benefits of Harboring Microbial Populations

It is enticing to portray colonizing bacteria as hostile armies encamped at our body's gates (also called portals of entry), just waiting for the opportunity to invade. But bacteria do not possess hostile intent, only the need to find food. The microbes of our normal microflora, unlike true pathogens, have not evolved mechanisms to specifically breach human defenses. For the most part, the needs of commensal organisms are met at the colonizing site. However, accidental penetration beyond these sites by normal flora can cause disease. A cancerous lesion in the colon, for example, can provide a passageway for microbes to enter deeper tissues, where they can begin to grow unabated. *Bacteroides fragilis*, a harmless anaerobe in the gut, can invade tissues through surgical wounds, causing abscesses that persist (and even lead to gangrene) after abdominal surgery (**Fig. 23.10**).

By and large, the barriers of defense work well to prevent incursions by normal flora or, in the event of an incursion, to kill the invader. These defenses sometimes break down in persons with an immune system compromised by medical treatments (such as anticancer drugs) or by disease (such as a deficiency in complement factors, discussed later). Such a person is described as a **compromised host** and can be repeatedly infected by normal flora. Organisms causing disease in this situation are called **opportunistic pathogens**.

Commensal species are often beneficial (mutualistic). They can interfere with the colonization of pathogens by competing for attachment receptors on host cells, competing for food sources, and synthesizing antimicrobial compounds such as fermentation end products. For example, the acidic fermentation products produced by lactobacilli in the female genitourinary tract help maintain a low pH. The low pH dissuades colonization by various pathogenic microbes.

Commensal organisms also enhance function of the immune system. Bacterial proteins such as catalase can



Abstr Hematol Oncol © 2003 Cliggott Publishing, Division of SCP Communications

Figure 23.10 Anaerobic gas gangrene of the abdominal wall caused by *Bacteroides*. This infection was an unfortunate result of bowel surgery. Organisms escaped from the intestine and initiated infection in the abdominal wall.

act as immunomodulins. **Immunomodulins** made by normal flora growing on mucosal surfaces modify the secretion of host proteins, such as cytokines and tumor necrosis factor, which influence the immune response. **Cytokines** are small secreted host proteins that bind to various cells of the immune system and regulate the extent and duration of responses by those cells. (Cytokines are discussed in Sections 23.5 and 24.6.)

Some toxic bacterial products are also "double-edged swords." **Enterotoxins**, for example, are proteins produced by some gram-negative pathogens that damage the small intestine of the host and cause diarrhea. But they may also protect against colorectal cancer by activating membrane calcium channels in intestinal epithelial cells. Increasing membrane conductance for calcium turns on an antiproliferative pathway that provides resistance to colon cancer.

A recently discovered benefit of commensal organisms has been their development as vaccine delivery systems. Select commensal species can be genetically engineered to produce proteins from pathogenic species on their cell surfaces. Colonization of a host by the modified commensal strain will elicit an immune response to the cloned protein and provide immunity to the pathogen. Commensal microbes such as *S. salivarius* (part of the oral and nasopharyngeal microflora), *Lactococcus* species (residents of the intestinal tract), and *Lactobacillus* species (present in the urogenital and rectal tracts) are being exploited in this way. For example, if one wished to provide protection against *Streptococcus pyogenes*, the causative agent of strep throat, an oral commensal organism could be engineered to present the conserved portion of the M protein (the streptococcal attachment pilus) to the oral mucosa. The resulting local immune response could protect the individual from strep throat—at least a strep throat caused by that M-protein-bearing strain of *S. pyogenes* (there are at least 80 different M-protein-type strains). This approach can be adapted, in theory, to virtually any pathogen that enters through or colonizes a given mucosal surface on any human or animal. It is important, however, to choose proteins from the pathogen that will not also confer pathogenicity on the commensal strain in which it is expressed.

The benefit that commensal organisms offer to their hosts is especially apparent in gnotobiotic animals. A **gnotobiotic animal** is an animal that is germ-free or one in which *all* the microbial species present are *known*. Developing a gnotobiotic colony of animals involves delivering offspring by cesarean section under aseptic conditions in an isolator. The newborn is moved to a separate isolator where all entering air, water, and food are sterilized. Once gnotobiotic animals are established, the colony is maintained by normal mating between the members. Germ-free animals, however, often have poorly developed immune systems, lower cardiac output, and thin intestinal walls, and they are more susceptible to infection by pathogens. The lesson from these animals is that the presence of normal flora continually challenges the immune system and keeps it active.

TO SUMMARIZE:

- **Opportunistic pathogens** infect only compromised hosts.
- **Benefits of commensal microbes** include interfering with pathogen colonization, the production of immunomodulatory proteins, and potential use as vaccine delivery vehicles.
- **Gnotobiotic animals** are germ-free or colonized with a known set of microbes.

23.3 Overview of the Immune System

Because we are surrounded by and host numerous bacteria, how is it we are not constantly infected? Here we begin our discussion of the many layers of protection designed to prevent infection and disease. As you will see, there are numerous physical and chemical barriers that provide an effective first line of defense against infection by invading microbes. As such, they play a critical role in managing our resident ecosystems. But these barriers are not unbreachable. Organisms can still slip through. Consequently, humans, as well as other mammals, have a more aggressive defense called the immune system. The **immune system** is an integrated system of organs, tissues, cells, and cell products that differentiates self from nonself and neutralizes potentially pathogenic organisms or substances. This complex collection of cells and soluble proteins is capable of responding to nearly any foreign molecular structure.

Immunity Is of Two Types: Innate and Adaptive

There are two broad types of immunity: **nonadaptive immunity**, often called **innate immunity**, and **adaptive immunity**. Innate and adaptive immunity have several key differences. Innate immunity includes physical barriers such as skin, chemical barriers such as stomach acid, and relatively nonspecific cellular responses to infection that engage if the physical and chemical barriers are breached. Innate immunity is essentially "hardwired" into the body. It is present at birth, so that mechanisms of innate immunity exist before the body ever encounters a microbe. The protection they afford is nonspecific, capable of blocking or attacking many different types of foreign substances and organisms.

In contrast to innate immunity, adaptive immunity is designed to react to very specific structures called **antigens**. An antigen is any chemical, compound, or structure foreign to the body that elicits an immune response. Adaptive immune responses to a specific antigen do not occur until the body "sees" that antigen. Once activated, adaptive immune mechanisms can recognize at least 10^{10} different antigenic structures and specifically launch a directed attack against each one. Once such an attack has been activated, the organism keeps a "memory" of the exposure in the form of specific memory cells, and an encounter with the microbe years later will reactivate the memory cells specific to the antigen.

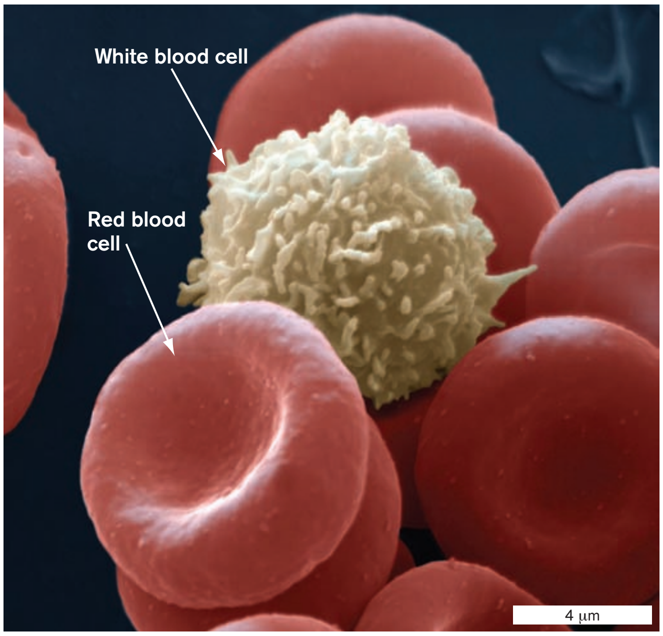
The two types of immunity are illustrated by the response of the immune system to infection by the microorganism *Neisseria gonorrhoeae*, which causes the sexually transmitted disease gonorrhea. A component of the innate immune response is **complement**, comprised of several soluble protein factors constantly present in the blood. Within moments of an initial infection, complement attacks the bacterial membrane. Complement proteins form holes in bacterial membranes, thereby killing the microbe (see Section 23.8). On the other hand, the adaptive immune response will generate specific antibodies made to the cells of *N. gonorrhoeae* that escaped the innate mechanisms. These antibodies, however, are not made until well after the organism infects a person. Together, innate and adaptive immunity can help ward off disease caused by this organism. Note that contact with an infectious agent does not guarantee that a person will actually contract the disease. If the number of infecting organisms is small and the immune system (innate and adaptive) is effective, the individual may not develop disease (see chapter introduction), although a person known to have been exposed to certain microorganisms will be treated with antibiotics as a preventive measure. Chapter 26 will more fully discuss the difference between being infected and having a disease.

Any microbe that launches a successful attack on a human or other animal and causes disease must first breach the host's physical and chemical barriers to gain entrance to the body. It must then survive the innate defense mechanisms and begin to multiply. Finally, the microbe must surmount the last line of defense, adaptive immunity, which begins to respond as the microbe struggles to overcome innate immune defenses. The rest of this chapter will discuss the various innate defense mechanisms. Adaptive immunity is discussed in Chapter 24.

Although innate and adaptive immunity are often treated as separate entities, certain kinds of cells and organs play a role in both types of immunity. We will thus introduce here the various cells and organs of the immune system as a whole before focusing on innate immunity. Our coverage of innate immunity will include physical and chemical barriers to infection, inflammation and nonspecific killing through phagocytosis, interferon, natural killer cells, and complement.

Cells of the Innate and Adaptive Immune Systems

Blood is composed of red blood cells, white blood cells, and platelets (**Fig. 23.11**). The many types of white blood cells are formed by differentiation of stem cells produced in bone marrow (**Fig. 23.12**). Among these white blood cells are various components of innate immunity that



Eye of Science/Photo Researchers, Inc.

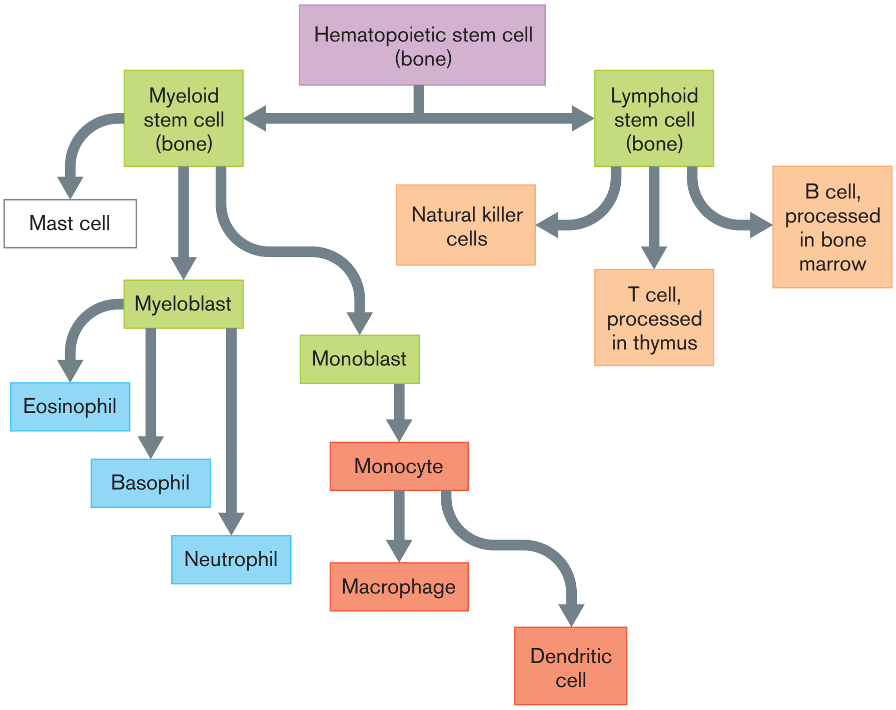

Figure 23.12 Development of white blood cell components of the immune system. Pleuripotent stem cells in bone marrow divide to form two lineages. One lineage consists of the myeloid stem cells, which develop into polymorphonuclear leukocytes (PMNs) and monocytes. These cells primarily function as part of innate immunity. The other branch consists of the lymphoid stem cells, which ultimately form natural killer cells, B cells, and T cells. Final maturation into B cells and T cells (the principle cells involved in adaptive immunity) occurs in the bone marrow and thymus, respectively. Colors indicate a group of differentiated cells that arise from the same progenitor.

differentiated from myeloid stem cells. These differentiated cells include:

- Polymorphonuclear leukocytes (PMNs)
- Monocytes
- Macrophages
- Dendritic cells
- Mast cells

PMNs, also called granulocytes, have multilobed nuclei, differentiate from an intermediate cell called the myeloblast, and contain enzyme-rich lysosome organelles (**Fig. 23.13B**). PMNs are of several types named for their different staining characteristics. Each cell type has a different function. **Neutrophils**, making up the vast majority of white cells in the blood, can engulf microbes by phagocytosis and kill them by fusing enzyme-gorged lysosomes with the phagosomes containing the organism (**Fig. 23.14**). **Phagosomes** are the vacuoles formed around a microorganism as it is engulfed by a host cell. Enzymes spilling from the lysosome into the phagosome will destroy various components of the microbe and, ultimately, the microbe itself. **Basophils**, which stain with basic dyes, and **eosinophils**, which stain with the acidic dye eosin, do not phagocytize microbes but release products, such as major basic protein, that are toxic to the microbe (**Fig. 23.13D**). These blood cells also release chemical mediators (called vasoactive agents) that affect the diameter and permeability of blood vessels (the significance of which is discussed in Section 23.5). **Mast cells** are similar to basophils in structure but differentiate in a lineage separate from PMNs. Unlike PMNs, mast

cells are residents of connective tissues and mucosa and do not circulate in the bloodstream. Basophils and mast cells also contain high-affinity receptors for a class of antibody called immunoglobin E (IgE) associated with allergic responses (detailed in Section 24.8).

Monocytes (**Fig. 23.13C**) are white blood cells with a single nucleus (not multilobed like a PMN); they engulf (phagocytize) foreign material. Monocytes circulating in the blood can migrate out of blood vessels into various tissues and differentiate into **macrophages** and **dendritic cells** (**Fig. 23.15**). Macrophages are phagocytic and form a major part of the amorphous **reticuloendothelial system**, which is widely distributed throughout the body. The reticuloendothelial system is a group of cells with the ability to take up and sequester inert particles. In addition to macrophages, the system is composed of specialized endothelial cells lining the sinusoids of the liver, spleen, and bone marrow as well as reticular cells of lymphatic tissue (macrophages) and of bone marrow (fibroblasts). The function of macrophages and the reticuloendothelial system is to phagocytize microorganisms. Macrophages are the cells most likely to make first contact with invading pathogens. They have two functions. As part of innate immunity, they kill invaders directly. Protrusions from the macrophage surface extend and clasp nearby bacteria, pulling them into the cell (see **Fig. 23.15C**). Once ingested by the macrophage, the bacteria are destroyed.

(Colorized SEM.)

Subsequently, the remnants are, as the first step in adaptive immunity, processed (degraded) into smaller peptides (called antigens), which are then presented on the macrophage cell surface. Specific white blood cells called T cells (a type of lymphocyte) can bind the displayed antigens and become activated as part of the adaptive immune response. Thus, macrophages are considered **antigen-presenting cells** (see Chapter 24).

Dendritic cells are also antigen-presenting cells. Present in the spleen and lymph nodes, they, like macrophages, can take up, process, and present small antigens on their cell surface. The Chapter 24 opening photo shows the interaction between a dendritic cell and a T cell. Dendritic cells are different from macrophages in structure and in the fact that dendritic cells primarily take up small soluble antigens from their surroundings rather than through phagocytosis and degradation of whole bacteria.

Lymphoid Organs

Lymphocytes, which are the main participants in adaptive immunity, are present in blood at about 2,500 cells per microliter, accounting for over one-third of all peripheral white blood cells (**Fig. 23.13A**). However, an individual lymphocyte spends most of its life within specialized solid tissues (lymphoid organs) and enters the bloodstream only periodically, where it migrates from one place to another, surveying tissues for possible infection or foreign antigens. No more than 1% of the total lymphocyte population can be found in the blood at any one time.

The tissues of the immune system where the great majority of lymphocytes are found are classified as primary or secondary lymphoid organs or tissues, depending on their function (**Fig. 23.16**). The primary lymphoid organs and tissues are where immature lymphocytes mature into antigen-sensitive B cells and T cells. **B cells**, which ultimately produce antibodies (see Chapter 25), develop in bone marrow tissue, whereas T cells, which modulate various facets of adaptive immunity, develop in the thymus, an organ located above the heart.

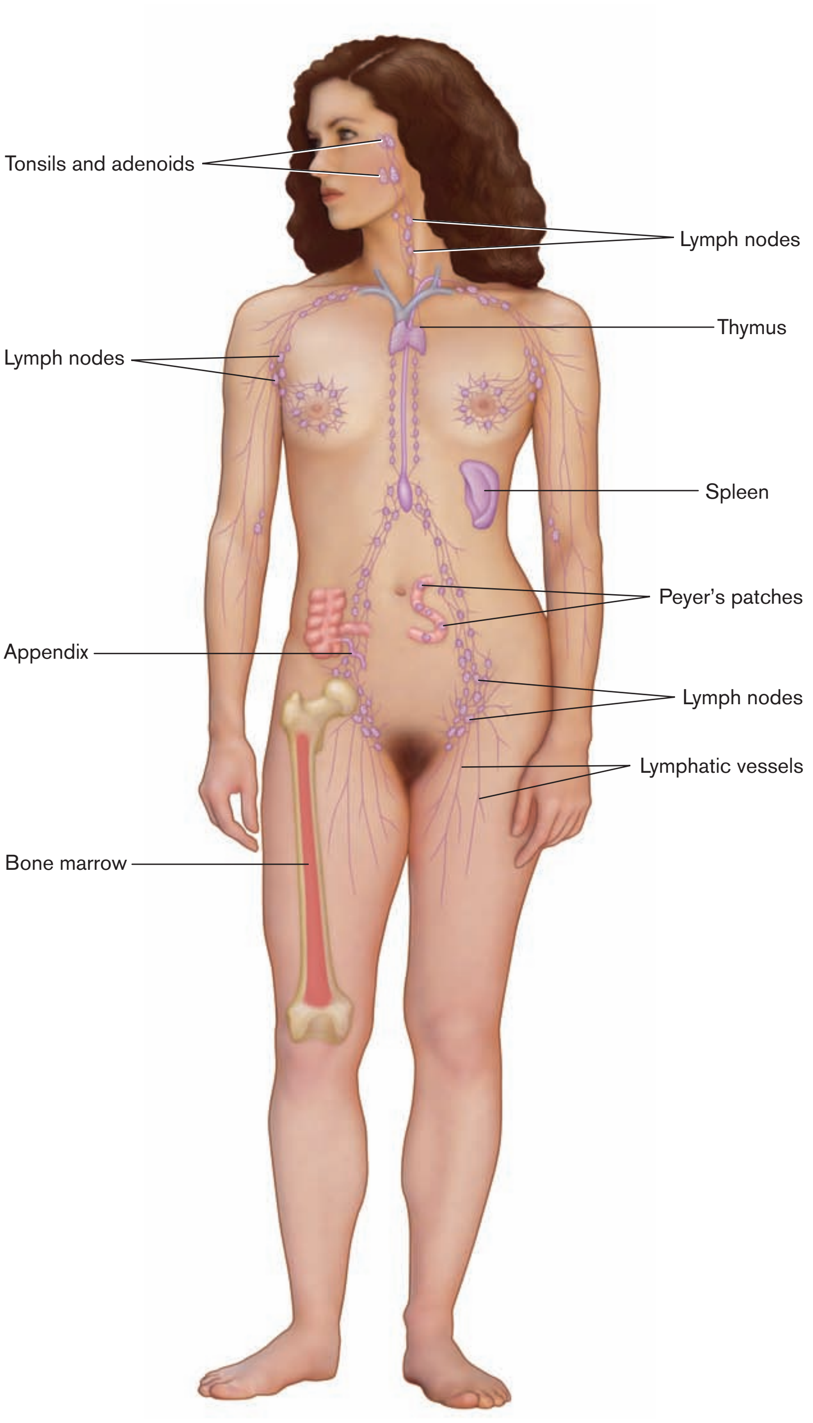

Figure 23.16 Lymphoid organs.

The secondary lymphoid organs serve as stations where lymphocytes can encounter antigens. These encounters lead to the differentiation of B cells into antibody-secreting plasma cells, and T cells into antigen-specific helper cells, as will be discussed in Chapter 24. The spleen is an example of a secondary lymphoid organ. It is designed to filter blood directly and detect microorganisms. Macrophages in the spleen engulf these organisms and destroy them, and then migrate to other secondary lymph organs and present pieces of the microbe (called antigens) to the B and T cells, which then become activated.

The **lymph nodes** are another kind of secondary lymphoid organ. Lymph nodes are arranged to trap organisms from local tissues, not from blood. Lymph nodes are situated at various sites in the body where lymphatic vessels converge (for example, under the armpits). There are also lymphoid tissues in the mucosal regions of the gut and respiratory tracts (for example, Peyer's patches and gut-associated lymphoid tissue or GALT, discussed later). Other secondary lymphoid organs are the tonsils, adenoids, and appendix.

TO SUMMARIZE:

- **The immune system** consists of both innate and adaptive mechanisms that recognize and eliminate pathogens.
- **Myeloid bone marrow stem cells** differentiate to form cells of the innate immune system—phagocytic PMNs, monocytes, macrophages, antigen-presenting dendritic cells, and mast cells.
- **Lymphoid stem cells** differentiate into natural killer cells (part of the innate immune system), and lymphocytes (cells of the adaptive immune system). Lymphocytes are classified as B cells, which ultimately produce antibodies, and T cells, which regulate adaptive immunity.

23.4 Barbarians at the Gate: Innate Host Defenses

When defending a castle in medieval times, the first lines of defense included physical barriers (the castle wall), chemical barriers (boiling oil tossed onto invaders trying to scale the wall), and finally hand-to-hand combat once the wall was breached. Similarly, the body's initial defenses against infectious disease are composed of physical, chemical, and cellular barriers designed to prevent a pathogen's access to host tissues. Although generally described as nonspecific, some innate defense systems are more specific than others.

Physical Barriers to Infection

The first line of defense against any potential microbial invader (either commensal or pathogenic) occurs where parts of the body interface with the environment. These interfaces (skin, lung, gastrointestinal tract, genitourinary tract, and oral cavities) have similar defense strategies, although each has unique characteristics.

Skin. Few microorganisms can penetrate skin due to the thick **keratin** armor produced by closely packed cells called **keratinocytes**. Keratin protein is a hard substance (hair and fingernails are made of this) that is not degraded by known microbial enzymes. An oily substance (sebum) produced by the sebaceous glands also covers and protects the skin. Its slightly acidic pH inhibits bacterial growth. Competition between species also limits colonization by pathogens, and microorganisms that manage to adhere are continually removed by the constant shedding of outer epithelial skin layers.

There are other, more specialized cells just under the skin that can recognize microbes managing to slip through the physical barrier. They are part of a consortium of cells called **skin-associated lymphoid tissue (SALT)**. **Langerhans cells** make up a significant portion of SALT. They are specialized dendritic cells that can phagocytize microbes. Once a lymphoid Langerhans cell has ingested a microbe, the cell migrates by ameboid movement to nearby lymph nodes and "presents" parts of the microbe to the immune system to activate antimicrobial immunity.

NOTE: Do not confuse phagocytic Langerhans cells with the pancreatic "islets of Langerhans" that secrete insulin.

Mucous membranes. Mucosal surfaces form the largest interface (200–300 m^2) between the human host and the environment (the intestine alone is 23–26 ft long). Mucous membranes in general present a containment problem. They must be selectively permeable in order to exchange nutrients as well as to export products and waste components. At the same time, they must constitute a barrier against invading pathogens. Mucosal membranes are covered with special tight-knit epithelial layers that support this barrier function. The mucus secreted from stratified squamous epithelial cells coats mucosal surfaces and traps microbes. Compounds within the mucus can serve as a food source for some commensal organisms, but other secreted compounds like the enzymes lysozyme, which cleaves cell wall peptidoglycan, and lactoperoxidase, which produces superoxide radicals, can kill an organism trapped in the mucus.

There are also semispecific innate immune mechanisms associated with mucosal surfaces. Host cells, even epithelial cells, in mucosa have evolved mechanisms to distinguish harmless compounds and commensal microorganisms from dangerous pathogens. Patterns of conserved structures on pathogenic microbes are recognized by host cell surface receptors such as various Toll-like receptors and CD14.

First discovered in insects and named Toll receptors, **Toll-like receptors (TLRs)** are evolutionarily conserved cell surface glycoproteins present on the cells of many eukaryotic genera. They are transmembrane proteins with an extracellular leucine-rich repeat domain and an intracellular Toll/interleukin 1 receptor domain (TIR domain). Humans have numerous Toll-like receptors, each of which recognizes different pathogen-associated molecular patterns (PAMPs) present on pathogenic microorganisms. This makes them an innate defense mechanism with some degree of specificity. For example, TLR2 binds to lipoarabinomannan from mycobacteria, zymosan from yeast, lipopolysaccharide (LPS) from spirochetes, and peptidoglycan. TLR4, on the other hand, binds to LPS as well as host proteins released at sites of infection (for example,

heat-shock protein 60). CD14, mentioned earlier, serves as a coreceptor for LPS. Note that these receptors bind fragments of structures after they are released from the microbe. They don't interact with the whole organism.

Once bound to their ligands, the TLRs trigger an intracellular regulatory cascade via their TIR domain that causes the host cell to release proteins called cytokines that diffuse away from the site, bind to receptors on various cells of the immune system, and direct them to engage the invader. Cytokines are discussed further in Chapter 24.

Like skin, the gastrointestinal system possesses an innate mucosal immune system, in this case called **gut-associated lymphoid tissue (GALT)**. GALT includes tonsils, adenoids, and Peyer's patches (**Fig. 23.17A**). These tissues include specialized **M cells** that dot the intestinal surface and are wedged between epithelial cells. M stands for "microfold," which describes their appearance (**Fig. 23.17B**). These are fixed cells that take up microbes from the intestine and release them, or pieces of them, into a pocket formed on the opposite, or basolateral, side of the cell. Other cells of the innate immune system, such as macrophages (a type of white blood cell that migrates through tissues), gather here and collect the organisms that emerge. Macrophages engulf and try to kill the organism and then place small, degraded components of the organism on the macrophage cell surface where other immune system cells can recognize them. As a result, M cells are extremely important for the development of mucosal immunity to pathogens. However, M cells can also serve as a portal for some pathogens to gain entry to the body.

The lungs. The lung also has a formidable defense. In addition to the respiratory ciliary elevator discussed in Section 23.1, microorganisms larger than 100 μm become trapped by hairs and cilia lining the nasal cavity and trigger the forceful expulsion of air from the lungs (a sneeze). The sneeze is designed to clear the organism from the respiratory tract. Organisms that make it to the alveoli are met by phagocytic cells called **alveolar macrophages**. These cells can ingest and kill most bacteria.

Lung epithelia can also internalize and destroy organisms. This mechanism is thought to explain why *Pseudomonas aeruginosa* does not typically infect healthy lungs but readily infects the lungs of cystic fibrosis patients, whose cells cannot bind and kill the bacteria.

Cystic fibrosis is a genetic disease in which a membrane chloride channel called the **cystic fibrosis transmembrane conductance regulator (CFTR)** is defective. CFTR is important for regulating chloride movement across the membrane, an essential part of hydrating mucus in healthy individuals. Localization of the protein at the lung cell surface is depicted in **Figure 23.18**. In addition to its role in regulating chloride channels, CFTR appears to serve as a receptor for internalizing *P. aeruginosa* by lung epithelial cells, which helps clear the organism from the lung. While normal lung epithelial cells prevent *Pseudomonas* infection, cells defective in CFTR cannot bind and clear the organism, leading to life-threatening disease. The strains of *P. aeruginosa* that are the most serious threat produce a thick slimy material (alginate) that retards other lung clearance mechanisms (**Fig. 23.19**).

Chemical Barriers to Infection

Some examples of chemical barriers were mentioned previously, such as the acid pH of the stomach, lysozyme in tears, and generators of superoxide. In addition, a vari-

ety of human cells generate small antimicrobial, cationic (positively charged) peptides called **defensins** (**Table 23.2**). These antimicrobial peptides are important components of innate immunity against microbial infections.

Defensins. Defensins range in length from 29 to 47 amino acids and are found in mammals, birds, amphibians, and plants. They kill by destroying the invader's cytoplasmic membrane and are effective against gram-positive and gram-negative bacteria, fungi, and even some viruses (those with membranes, such as HIV). To kill gram-negative bacteria, the peptides must first bind outer membrane lipopolysaccharides, which are negatively charged, and move into the periplasm. The defensins then insert into the cytoplasmic membrane of either gram-positive or gram-negative bacteria. Insertion is driven by the transmembrane electrical potential, which in bacteria is about –150 mV (cell interior more negative than exterior). The negative charge pulls the small cationic peptides into the membrane, where they assemble into channels that destroy the cytoplasmic membrane barrier, killing the bacterial cell. Defensins generally do not affect eukaryotic cells because these cells have a very low membrane potential (–15 mV) across their plasma membrane. Defensins are produced by many human cells, including cells of the skin, lungs, genitourinary tract, and gastrointestinal tract (**Fig. 23.20**).

There are two classes of vertebrate defensins, alpha (α) and beta (β). The alpha defensins are stored in membrane-bounded granules within neutrophils and in Paneth cells

Table 23.2 Categories of natural antimicrobial peptides.

Class	Examples	Major presence in humans	Source
Alpha defensins	-1, -2, -3, -4[a]	Neutrophils	Stored in granules
Alpha defensins	-5, -6	Paneth cells, small intestine	Stored in granules

in the small intestine (see **Fig. 23.20A**). When stimulated, these cells **degranulate** (release their granule contents) by fusing their granule membranes to cytoplasmic or vacuolar membranes, dumping their contents into the surroundings or into phagocytic vacuoles, where the alpha defensins can destroy engulfed microbes (**Fig. 23.20B**). In contrast, the beta defensins are not stored in cytoplasmic granules. Their synthesis is activated only after contact with bacteria or their products.

Cathelicidins. Cathelicidins are also cationic antimicrobial peptides, but their structure differentiates them from defensins. Initially synthesized as inactive precursor proteins, cathelicidins contain a 100-amino-acid N-terminal domain called cathelin that is attached to a smaller antimicrobicidal domain at the N-terminus. Extracellular proteolytic cleavage of the large proprotein releases the now-active antimicrobial peptide. As with the defensins, most cathelicidins are thought to function by assembling within bacterial membranes, where they disrupt membrane integrity. Some cathelicidins, however, penetrate to the cell interior and disrupt protein synthesis.

Other antimicrobial peptides are listed in Table 23.2.

THOUGHT QUESTION 23.6 Why do defensins have to be so small?

TO SUMMARIZE:

- **Skin defenses** against invading microbes include closely packed keratinocytes and a SALT lymphoid system made up largely of phagocytic Langerhans cells.
- **Mucous membrane defenses** involve secreted enzymes, cytokines, and GALT tissues, such as Peyer's patches, that contain phagocytic M cells.
- **Phagocytic alveolar macrophages** inhabit lung tissues, contributing to nonspecific defense.
- **Chemical barriers against disease** include cationic defensins, acid pH in the stomach, and superoxide produced by certain cells.

23.5 Innate Immunity: The Acute Inflammatory Response

The boil shown in **Figure 23.21** is an inflammatory response triggered by infection with the organism *Staphylococcus aureus*. Inflammation is a critical innate defense in the war between microbial invaders and their hosts. It provides a way for phagocytic cells (such as neutrophils) normally confined to the bloodstream to gain access to infected sites within tissues. Movement of these cells out of blood vessels is called **extravasation**, which we discuss later. Once at the infection site, the neutrophils begin engulfing microbes. The white pus associated with an infection is teeming with these white blood cells. The five cardinal signs of inflammation, first described over 2,000 years ago, are redness, warmth, pain, swelling, and altered function at the affected site.

Although many things can trigger inflammation, our focus is on how microbes cause the response. The process begins with the infection itself. Microorganisms introduced into the body, for example on a wood splinter, will begin to grow and produce compounds that damage host

Special Topic 23.1 Do Defensins Have a Role in Determining Species Specificity for Infection?

Differences in cationic peptides between host species may explain why some bacteria cause devastating disease in certain animals and only mild disease in others. *Salmonella enterica* serovar Typhimurium, for example, usually kills mice, but most humans survive. Insects, completely lacking an immune system, resist invading pathogens altogether. Could these differences be due to the type of defensin made?

Studies suggest that differences in immunity across species may indeed reflect species-specific defensins. Scientists placed the gene for human defensin-5 (made in human intestinal Paneth cells) into mice, which do not normally produce this peptide. When exposed to high doses of *S.* Typhimurium, the engineered mice did not get sick, while normal mice became profoundly ill (**Fig. 1**).

Studies of defensins and their selectivity offer the promise of a new class of antibiotics. Frog skin, for example, is rich with antimicrobial peptides called maganins. The effectiveness of these peptides is impressive. Frog skin maganins are so powerful that frogs do not become infected when put into natural pond water teeming with bacteria. Harnessing these peptides as antibiotics would be a tremendous advance in medicine. The potential to discover new antibiotics is another reason for protecting our rain forests, which harbor many undiscovered species, including frogs, whose unique chemical defenses have yet to be studied.

cells (**Fig. 23.22**⏯). Resident macrophages that wander into the infected area engulf these organisms and then release inflammatory mediators (chemoattractants) that "call" for more help. These mediators include **vasoactive factors** such as leukotrienes, platelet-activating factor, and prostaglandins, which act on blood vessels of the microcirculation, increasing blood volume and capillary permeability to help deliver white blood cells to the area. In addition, the small protein molecules called cytokines are secreted, diffusing to the vasculature and stimulating expression of specific receptors (selectins) on the endothelial cells of capillaries and venules.

Vasoactive Factors and Cytokines Begin the Extravasation Process

The eventual passage of neutrophils through vascular walls (extravasation; **Fig. 23.23**) requires a relaxation of endothelial cell adhesion. The process is initiated by vasoactive factors released by macrophages; these vasoactive factors increase vascular permeability and stimulate vasodilation. Vasodilation slows blood flow and, as a result, increases blood volume in the affected area. The more permeable vessel also allows the escape of plasma into tissues. Both events cause localized swelling, redness, and heat. Vasoactive factors also stimulate local nerve endings, causing pain, which draws awareness to the infected area.

There are many kinds of cytokines, all of which are involved in regulating the immune response. Cytokines such as **interleukin 1 (IL-1)** and **tumor necrosis factor alpha** (**TNF**-α) are released by macrophages and stimulate the production of adhesion molecules (**selectins**) on the inner lining of the capillaries. P-selectin is produced first, followed by E-selectin. The selectins snag neutrophils zooming by in the bloodstream, slow them down, and cause them to roll along the endothelium (see **Fig. 23.23**). Rolling neutrophils that encounter inflammatory mediators are activated to produce and display integrin adhesion molecules on their surface. The integrins on the neutrophils lock onto endothelial adhesion molecules ICAM-1 (intracellular adhesion molecule 1) and VCAM-1 (vascular cell adhesion molecule 1). This stops the neutrophils from rolling and initiates extravasation, where the

Figure 23.22 Basic inflammatory response. Neutrophils (a type of phagocyte) circulate freely through blood vessels and can squeeze between cells in the walls of a capillary (extravasation) to the site of infection. They then engulf and destroy any pathogens they encounter. ⏯

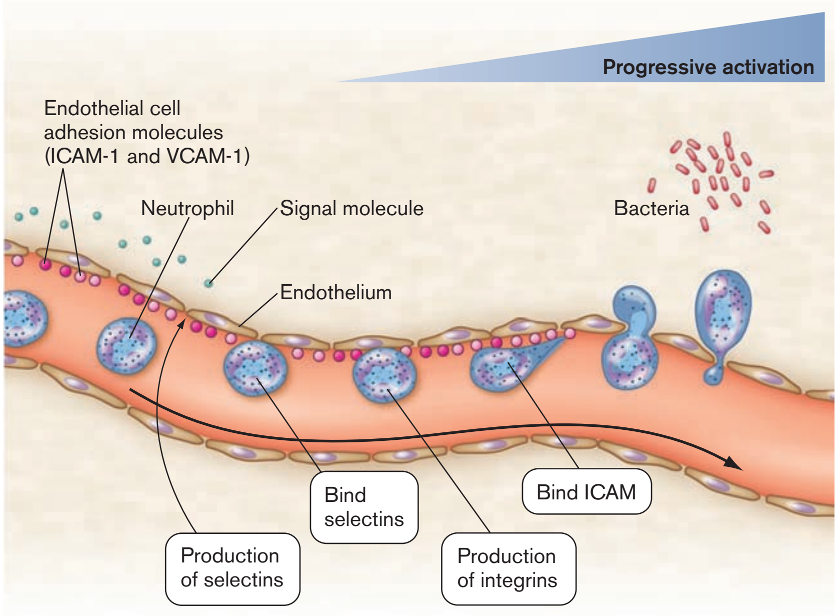

Figure 23.23 Mechanism of extravasation. Extravasation is the process by which leukocytes move from the bloodstream into surrounding tissues. Signal molecules produced by damaged tissue cells induce the production of selectins (produced early in process) on the surfaces of endothelial cells and integrins on the surface of the white blood cell (selectins and integrins not shown). Selectins capture leukocytes traveling through blood vessels. Leukocytes begin to roll along the vessel wall, and the integrins on their surface lock onto the endothelial cell's adhesion molecules (ICAM-1 or VCAM-1). The leukocytes are progressively activated while rolling. The neutrophil ultimately squeezes through the wall between endothelial cells (extravasation).

white blood cells squeeze through the endothelial wall and into the tissues, where they can help macrophages attack the invading microbes.

Damaged tissue cells in the area of inflamation will release **bradykinin**, a nine-amino-acid polypeptide that helps loosen the tight junctions between endothelial cells to promote extravasation (**Fig. 23.24**). Bradykinin molecules also bind to mast cells in the area, causing a calcium influx that triggers degranulation. The histamine released from mast cells further loosens the endothelial cell junctions, which allows more fluid and cells to move out (increased vascular permeability), adding to fluid accumulation (edema). Bradykinin will attach to capillary cells and induce synthesis of prostaglandins that in turn stimulate nerve endings, causing pain in the area. A key enzyme involved in prostaglandin synthesis is cyclooxygenase (COX). Aspirin as well as the popularly prescribed anti-inflammatory agents Vioxx and Celebrex are COX inhibitors that prevent the synthesis of prostaglandins and thus reduce inflammatory pain.

Once neutrophils have passed through the vascular wall, chemotactic factors are needed to lure them to the proper location. One of these, f-met-leu-phe peptide, is made by the bacterium itself. Many bacterial proteins have f-met (*N*-formylmethionine) as their N-terminal amino acid, but mammalian proteins, in general, do not. Bacteria will often cleave off the f-met peptide, which can then diffuse away from the bacterium. The f-met peptide binds to neutrophil receptors and stimulates pseudopod projections aimed toward the microbe. This causes the white blood cell to migrate in the direction of the infection. In addition, **chemokine** peptides (IL-8 and MCP-1) produced by damaged tissues can serve as chemoattractants for these white blood cells. Thus, much of what takes place at the site of an infection is not due directly to substances produced by the microbe, but is the result of the body's reaction to the presence of the intruding organism. Once the cascade of inflammatory events delivers phagocytic cells to the site of infection, they begin devouring the microbes in an attempt to cure the infection.

Chronic Inflammation Causes Permanent Damage

Chronic inflammation is a response of long duration provoked by the persistent presence of a causative stimulus. This type of inflammation inevitably causes permanent tissue damage, even though the body attempts repair. The causes of chronic inflammation are many. For example, infectious organisms such as *Mycobacterium tuberculosis*, *Actinomycetes bovis*, and various protozoan parasites can avoid or resist host defenses (**Fig. 23.25A**). As a result, they persist at the site and continually stimulate the basic inflammatory response. Nonliving, irritant material like wood splinters, inhaled asbestos particles, or surgical implants can also lead to chronic inflammatory responses. Autoimmune diseases are another important cause. Autoimmunity (reaction against self) occurs when there is a failure to regulate some aspect of adaptive immunity (see Chapter 24). As a result, the immune system does not recognize one specific component of the body as self and begins to react against it. Rheumatoid arthritis is one example of the body attacking itself.

Whatever causes autoimmune disease, there is continual recruitment of macrophages and lymphocytes from the circulation. The body attempts to "wall off" the site of inflammation by forming a **granuloma**. A granuloma begins as an aggregation of the mononuclear inflammatory cells surrounded by a rim of lymphocytes. The body then deposits fibroconnective tissue around the lesion, causing tissue hardening known as fibrosis.

Figure 23.24 Summary of the inflammatory response.

Several forms of granulomas are shown in **Figure 23.25**. Mycobacteria are resistant to killing by macrophages and can be found living within these cells (**Fig. 23.25A**). This resistance to host defense can lead to long-term chronic infections and the production of granulomas. For example, skin infections caused by *Mycobacterium marinum* will produce skin granulomas, while *M. tuberculosis* can cause liver granulomas (**Figs. 23.25B** and **C**). Crohn's disease, which commonly manifests as abdominal pain, frequent bowel movements, and rectal bleeding, has been attributed to an autoimmune reaction possibly activated in some way by intestinal microflora. In this case, the intestinal bacteria are thought to cause a chronic inflammation resulting in characteristic granulomas (**Figs. 23.25D** and **E**).

TO SUMMARIZE:

- **Inflammation** begins with a mechanism (extravasation) that moves neutrophils from the bloodstream into infected tissues.
- **Macrophages** in tissues engulf microorganisms and release vasoactive factors that increase vascular permeability, cytokines that stimulate production of selectin receptors, and chemoattractant molecules that call in neutrophils.
- **Extravasation** is the process by which neutrophils pass between cells of the endothelial wall. Once out of the circulation, the neutrophils travel to the site of infection.
- **Bradykinin** produces pain in the affected area.
- **Chronic inflammation** results from the persistent presence of a foreign object.

23.6 Phagocytosis

Phagocytosis is an effective nonspecific immune response. However, it would be disastrous were white blood cells to indiscriminately phagocytize host as well as nonhost structures. Fail-safe controls built into our immune defenses prevent this from happening. Without these restraints, the mammalian immune system would constantly attack itself, causing more problems than it solves. When one of these fail-safe mechanisms fails, autoimmune diseases can arise.

Phagocytes Recognize Alien Cells and Particles

For phagocytosis to proceed, macrophages and neutrophils must first "see" the surface of a particle as being foreign. Only then is phagocytosis possible (**Fig. 23.26**). When a phagocyte surface interacts with the surface of another body cell, the phagocyte becomes temporarily paralyzed (inept at pseudopod formation). Paralysis allows the phagocyte to evaluate whether the other cell is friend or foe, self or nonself. Self-recognition involves glycoproteins located on the white blood cell membrane binding inhibitory glycoproteins present on all host cell membranes. The inhibitory glycoprotein on human cells is called CD47. Because invading bacteria lack these inhibitory surface molecules, they can readily be engulfed.

In addition to the method of self-recognition, macrophages have a molecular recognition apparatus specific for bacteria—the TLRs. Toll-like receptors specifically recognize bacterial structures such as lipopolysaccharide (LPS),

Figure 23.25 Chronic inflammation. **A.** The fluorescent orange organisms shown here are *Mycobacterium tuberculosis* (2 µm long, fluorescence microscopy) within macrophages in a tuberculosis abscess. Mycobacteria have a thick, waxy cell wall that protects them against the mechanisms used by macrophages to destroy microorganisms. As a result, they survive for prolonged periods within macrophages. This sequestration also protects the bacteria from other cellular and humoral mechanisms that deal with invading organisms. The continual stimulation of an inflammatory response leads to chronic inflammation. **B.** Fish tank granuloma. *Mycobacterium marinum* can cause tuberculosis-like infection in fish. The organism can accidentally enter the human body through an open wound or abrasion during cleaning of an aquarium containing infected fish. The infection is first noted as a lesion that heals very slowly on the hand or forearm. Once it does heal, it often forms a granuloma at the site that contains live organisms. **C.** Cross section of liver showing a necrotizing granuloma caused by *M. tuberculosis* that spread through the bloodstream to this site after escaping the lung. **D.** Healthy colon. **E.** Intestinal granulomas of Crohn's disease.

flagella, or peptidoglycan. There are different TLRs for each structure. Interaction between one of these receptors and its ligand initiates a signal transduction cascade in the phagocyte that stimulates phagocytosis and triggers release of chemokines and cytokines to call for more help.

Although many bacteria, such as *Mycobacterium* or *Listeria* species, are easily recognized and engulfed by phagocytosis (**Figs. 23.26A–C**), others, such as *S. pneumoniae*, possess polysaccharide capsules that are too slippery for pseudopods to grab (**Fig. 23.26D**). This is where innate immunity and adaptive immunity join forces. Adaptive immunity produces anticapsular antibodies that aid the innate immune mechanism of phagocytosis through a process known as **opsonization** (**Fig. 23.27**). The anticapsular antibodies coat the surface of the bacterium, leaving the tail ends of the antibodies, called the Fc region (see Section 24.3), pointing outward. The Fc regions of these antibodies are recognized and bound by specific receptors on phagocyte cell surfaces. As a result, the antibodies bind the bacteria to phagocytic Fc receptors, allowing the phagocyte to engulf the invader.

Phagocytes Kill through Oxygen-Independent and Oxygen-Dependent Mechanisms

During phagocytosis, the cytoplasmic membrane of the phagocyte flows around, and then engulfs, the bacterium, producing an intracellular phagosome, as described earlier. Subsequent phagosome-lysosome fusion (producing a phagolysosome) results in both oxygen-independent and oxygen-dependent killing pathways. Oxygen-independent

mechanisms include enzymes like lysozyme to destroy the cell wall, compounds such as lactoferrin to sequester iron away from the microbe, and defensins, small cationic antimicrobial peptides (described in Section 23.4).

Oxygen-dependent mechanisms are probably activated through the TLRs. They kill through the production of various oxygen radicals. NADPH oxidase, myeloperoxidase, and nitric oxide synthetase in the phagosome membrane are extremely important. NADPH oxidase yields superoxide ion (O_2^-), hydrogen peroxide, and, ultimately, hydroxyl (·OH) radicals.

$$\mathrm{NADPH} + 2\mathrm{O}_2 \xrightarrow{\text{NADPH oxidase}} \mathrm{NADP}^+ + \mathrm{H}^+ + 2\mathrm{O}_2^- \xrightarrow{\text{Superoxide dismutase}}$$

$$\mathrm{H}_2\mathrm{O}_2 + \mathrm{Cl}^- \xrightarrow{\text{Myeloperoxidase}} \mathrm{OH}^- + \mathrm{HOCl}$$

Myeloperoxidase, present only in neutrophils, converts hydrogen peroxide and chloride ions to hypochlorous acid (HOCl).

Macrophages, mast cells, and neutrophils also generate reactive nitrogen intermediates that serve as potent cytotoxic agents. Nitric oxide (NO) is synthesized by NO synthetase. Further oxidation of NO by oxygen yields nitrite (NO_2^-) and nitrate (NO_3^-) ions. All of these reactive oxygen species attack bacterial membranes and proteins. These mechanisms are responsible for the large increase in oxygen consumption noted during phagocytosis, called the **oxidative burst**. The reactive chemical species formed during the oxidative burst do little to harm the phagocyte because the burst is limited to the phagosome and because the various reactive oxygen species, such as superoxide, are very short-lived.

TO SUMMARIZE:

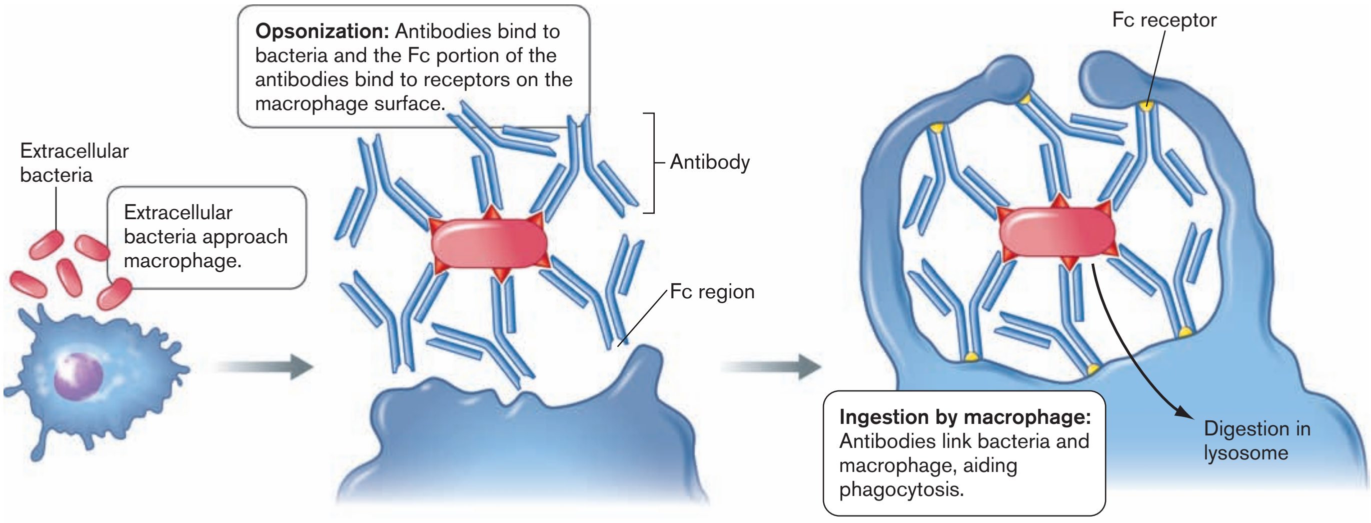
- **Phagocytosis** is selective for particles recognized as foreign to the body.
- **Different Toll-like receptors (TLRs)** on macrophage surfaces recognize different microbial structures.
- **Oxygen-independent** and **oxygen-dependent mechanisms of killing** are initiated by fusion between a lysosome and a bacteria-containing phagosome.
- **The oxidative burst**, a large increase in oxygen consumption during phagocytosis, results in the production of superoxide ions, nitric oxide, and other reactive oxygen species.

23.7 Innate Defenses by Interferon and Natural Killer Cells

When a community is threatened by a thief, a neighbor who has been robbed alerts others to take precautions. And if the thief is discovered, police are called to arrest him. Similarly, interferon peptides and natural killer cells are two innate mechanisms of defense that, respectively, warn healthy host cells of a nearby infection and seek out and then destroy cells already infected.

Interferons Are Host Specific, Not Virus Specific

In 1957, it was discovered that cells exposed to inactivated viruses produce at least one soluble factor that can "inter-



Opsonization: Antibodies bind to bacteria and the Fc portion of the antibodies bind to receptors on the macrophage surface.

fere" with viral replication when applied to newly infected cells. The term **interferon** was coined to represent these molecules. Actually, several different macromolecules have the property of interfering with viral replication. Interferons are low-molecular-weight cytokines (14–20 kDa) produced by many eukaryotic cells in response to intracellular infection—that is, infection by viruses or by bacterial pathogens, such as *Listeria*, that can grow intracellularly. The action of interferons is usually species specific (that is, interferon from mice will not work on human cells) but virus nonspecific (human interferon will help protect against both poliovirus and influenza virus, for example).

There are two general types of interferons, which differ in the receptors they bind and the responses they generate (**Table 23.3**). Type I interferons have high antiviral potency; they consist of IFN-alpha (IFN-α), IFN-beta (IFN-β), and IFN-omega (IFN-□). Type II interferon, IFN-gamma (IFN-γ), has more of an immunomodulatory function that will be discussed in the next chapter.

Type I interferons can bind to specific receptors on uninfected host cells and render those cells resistant to viral infection. The host cell becomes resistant because interferon induces the intracellular production of two classes of proteins. One class encompasses double-stranded RNA-activated endoribonucleases that can cleave viral RNA. Proteins in the second class are protein kinases (PKRs) that phosphorylate and inactivate eukaryotic initiation factor eIF2, which is required to translate viral RNA. These mechanisms affect both RNA and DNA viruses because protein synthesis is required for the propagation of all viruses. However, RNA viruses are better than DNA viruses at inducing interferon.

Type II interferon functions by activating various white blood cells—for example, macrophages, natural killer cells, and T cells—to increase the number of **major histocompatibility complex (MHC)** antigens on their surfaces. MHC proteins are important for recognizing self and for presenting foreign antigens to the adaptive immune system. They will be discussed more fully in Chapter 24.

Natural Killer Cells Recognize Infected Cells and Cancer Cells

Body cells that are infected or that are cancerous can be a major problem for the host. Infected cells can harbor the pathogenic microbe, hiding it from the immune system. Cancer cells, on the other hand, can take over and kill the

Table 23.3 Classes of interferon.

Type	Examples	Function	Mechanism of action
Type I	IFN-alpha IFN-beta IFN-omega	Antiviral	Induce dsRNA endonuclease, eIF2 kinase
Type II	IFN-gamma	Immunomodulatory	Triggers signal cascades in macrophages, NK cells, and T cells; increases MHC II on cell surfaces

Special Topic 23.2 Immune Avoidance: Outsmarting the Host's Innate Immune System

While the innate immune mechanisms described in this chapter are quite effective, many pathogens have developed mechanisms to subvert both the innate and adaptive immune systems of their host. For example, many organisms can develop resistance to defensins, *Legionella* can prevent phagosome-lysosome fusion, *Listeria* can escape from phagosomes, and uropathogenic strains of *E. coli* can invade bladder epithelium to avoid clearance by defense mechanisms associated with host cell surfaces.

Some other avoidance mechanisms are quite clever in their design. *Salmonella enterica*, a major cause of diarrheal disease, can engage in close-contact duels with phagocytic macrophages to see which can kill the other first. The macrophage, of course, tries to engulf the microbe and destroy it via oxygen-dependent and oxygen-independent mechanisms within a phagolysosome. For its part, *Salmonella* sidles up to the macrophage and uses a syringe-like type III secretion system (see Section 25.5) to penetrate the eukaryotic cell membrane and then inject the bacterial protein SipB directly into the cytoplasm. SipB binds to and activates a protein in the macrophage called caspase 1. Caspase 1 is part of a cascade of caspase enzymes that, when activated, cause the macrophage to commit suicide in a programmed response called apoptosis. Apoptosis is a process normally used by the host to kill unwanted host cells. For example, the differentiation of human fingers requires the cells between the fingers to initiate apoptosis so that the fingers can separate. However, apoptosis is also triggered as a last resort by a host cell that is heavily compromised by a bacterial or viral infection. An infected macrophage, for instance, will sacrifice itself in an attempt to take the invading microbe with it, thereby halting, or at least slowing, infection. *Salmonella* and other microbes (like *Shigella*) inject caspase-activating proteins to trick the host into killing itself before it can engulf and kill the microbe. Part of the evidence for this is that *Salmonella* will not trigger apoptosis in caspase-deficient cells in Peyer's patches (**Fig. 1**). However, even if the macrophage wins this duel, *Salmonella* has other subversive mechanisms at its disposal that can protect it after phagocytosis (see Section 25.5).

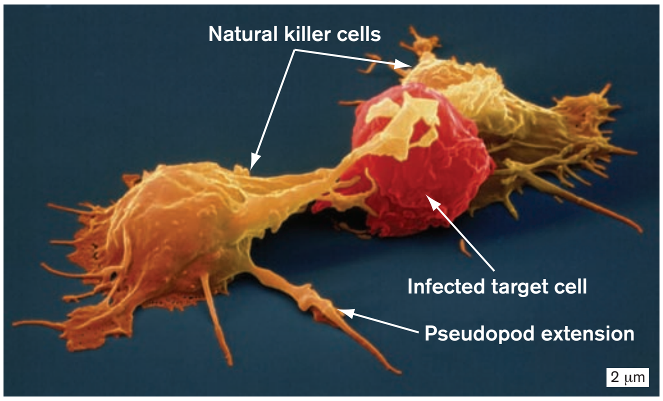
host. A class of lymphoid cells called **natural killer (NK) cells** identifies and handles these situations. Instead of killing microbes, the mission of these cells is to destroy host cells that harbor microorganisms or that have been transformed into cancer cells (**Fig. 23.28**). Natural killer cells recognize changes in cell surface proteins of compromised cells and then degranulate to release chemicals that kill those cells.

Natural killer cells recognize their targets in two basic ways. One involves MHC class I molecules, and the other utilizes Fc receptors. A normal host cell displays two classes of MHC molecules on the outside of the cell membrane. MHC I is an indicator of "self." (MHC II molecules will be discussed in Chapter 24.) NK cells have specific receptors that bind to self MHC I molecules on the surfaces of other cells in the body. An NK cell that "touches" a self MHC I–containing cell from the same person will not attack that cell. However, if a host cell lacks MHC class I molecules (or has nonself MHC), NK cells perceive the target as foreign and a potential threat. Host cells can lose their MHC molecules during infection or as a result of malignant transformation. When an NK cell encounters a host cell lacking these markers, the NK cell inserts a pore-forming protein (**perforin**) into the membrane of the target cell, through which cytotoxic enzymes are delivered.

Natural killer cells also contain Fc receptors on their cell surface. The second killing mechanism, called **antibody-dependent cell-mediated cytotoxicity (ADCC)**, occurs when the Fc receptor on the NK cell links to an antibody-coated host cell. The part of an antibody that does not bind to a target molecule (antigen) is called the Fc region. Why would host cells be coated with antibodies? During their replication, many viruses place viral proteins in the membrane of the infected cell. Antibodies to those viral proteins will coat the compromised cell, tagging it for ADCC. Once the compromised cell is targeted, it is killed by the NK cell in the same way as



Eye of Science/Photo Researchers, Inc.

Figure 23.28 Natural killer cells. Natural killer (NK) cells attack eukaryotic cells infected by microbes, not the microbes themselves. Perforin produced by the NK cell punctures the membrane of target cells, causing them to burst.

described for cells lacking MHC, by insertion of a perforin molecule. This killing mechanism is another example of cooperativity between innate (NK cells) and adaptive immunity (antibody producing lymphocytes).

THOUGHT QUESTION 23.7 If NK cells can attack infected host cells coated with antibody, why won't neutrophils?

TO SUMMARIZE:

- **Interferons are species-specific** molecules that can nonspecifically interfere with viral replication (type I) and modulate the immune system (type II).
- **Natural killer (NK) cells** are a class of white blood cell that destroy cancer cells or cells harboring microorganisms.
- **Natural killer cells target host cells** that have lost MHC class I receptors as a result of infection or cancer, or host cells that are coated with antibody (antibody-dependent cell-mediated cytotoxicity, ADCC).
- **Natural killer cells kill** by inserting perforin pores into the membranes of target cells.

23.8 Complement's Role in Innate Immunity

Bacterial invaders can also be attacked by a mechanism known as the complement cascade. Complement was first discovered as a heat-labile component of blood that enhances (or complements) the killing effect of antibodies on bacteria. The complement system consists of up to 20 proteins, several of which are proteases that sequentially cleave each other. Once a complement cascade is triggered, a number of things can happen. Pores are inserted into membranes and cause cytoplasmic leaks; in addition, pieces of the complement system can attract white blood cells and also facilitate phagocytosis (opsonization).

Pathways of Complement Activation Produce a Membrane Attack Complex (MAC)

The three routes to complement activation are officially known as the classical pathway, the alternative pathway, and the lectin pathway. The classical complement pathway depends on antibody, so it is part of adaptive rather than innate immunity and is discussed in Chapter 24 (Section 24.7). The lectin pathway requires synthesis of mannose-binding lectin by the liver in response to macrophage cytokines. This lectin coats the surface of invading microbes and activates complement without antibody. We focus in this chapter on the alternative pathway because it is a well-characterized part of innate resistance. Like the lectin pathway, the alternative pathway is a nonspecific defense mechanism (does not require antibody for activation). The alternative complement pathway can attack invading microbes long before a specific immune response can be launched.

The goal of the complement cascade is to insert pores into target microbial membranes. The pores destroy membrane integrity, which kills the cell. The alternative complement pathway begins with the complement factor C3 (**Fig. 23.29**). In blood, C3 slowly cleaves into C3a and C3b (step 1). C3b, under normal circumstances, is rapidly degraded, a process that thwarts inadvertent complement activation. However, if C3b meets LPS on an invading gram-negative microbe, the bound C3b becomes stable and binds another factor, designated Factor B (step 2), and makes Factor B susceptible to cleavage by yet another protein, Factor D (step 3). The resulting complex, called C3bBb, is changed into what is called C5 convertase by properidin, another serum protein (step 4). C5 convertase cleaves C5 in serum to C5a and C5b (step 5). (C3bBb is also called C3 convertase because it can quickly cleave more C3 and amplify the cascade.) C5b now starts to form a prepore complex by binding to C6 and C7 (step 6). The resulting C5bC6C7 complex binds to membranes. Finally, C8 and C9 factors join in to form the **membrane attack complex (MAC)**, creating a destructive pore in the membrane of the target cell (step 7).

If the target of complement is a eukaryotic cell, Na^+ and H_2O enter and the cell osmotically lyses. Eukaryotic cells infected with viruses and coated with antibody can activate complement via the classical complement pathway (see Section 24.7). When complement affects gram-negative cells, lysozyme (present in serum) enters through outer membrane pores and cleaves peptidoglycan, making the cell membrane more susceptible to the

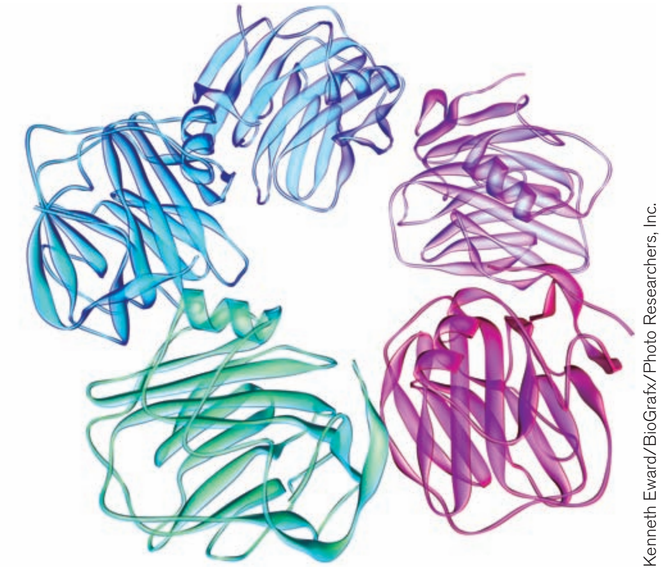
membrane attack complex. Teichoic acid on gram-positive cell walls can induce the complement cascade but is less effective than LPS. Nevertheless, gram-positive bacteria are resistant to complement because they lack an outer membrane (no LPS to efficiently start the cascade) and have a thick peptidoglycan layer that hinders access of complement components. However, even in the absence of LPS, there are ways to activate complement involving antigen-antibody complexes (see Section 24.7).

The Association between Acute Phase Reactants, Complement, and Heart Disease

As noted earlier, inflammation is associated with the production of various cytokines by macrophages. Some of these cytokines (such as IL-1, TNF-α, and IL-6) travel to the liver, where they stimulate synthesis of several so-called acute phase reactant proteins, including **C-reactive protein.** This protein, named for its ability to activate complement, is an acute phase reactant that will bind to components of bacterial cell surfaces but not to host cell membranes (**Fig. 23.30**). Once tied to the bacterial cell surface, C-reactive protein will bind complement factor C3 and convert it to C3b, initiating the complement cascade. Although C3 can spontaneously produce C3b, C-reactive protein accelerates C3b production at the bacterial surface, where it can do the most damage.

Elevated levels of C-reactive protein have been linked to an increased risk of cardiovascular disease. The hypothesis is that fatty deposits in the arteries trigger inflammation in the area of deposition. Inflammation then triggers an increase in C-reactive protein, which can be measured as an indicator of cardiovascular disease. Taking an aspirin a day may reduce the risk of heart attack by preventing inflammation and, in turn, reducing levels of C-reactive protein. Whether C-reactive protein has a direct role in cardiovascular disease is not known.



Kenneth Eward/BioGrafx/Photo Researchers, Inc.

Figure 23.30 C-reactive protein. The three-dimensional structure of human C-reactive protein (CRP) is unique. CRP is synthesized as a 206-amino-acid polypeptide that folds to form a flattened jellyroll structure, which then assembles into a radially symmetrical pentamer that circulates in serum. This structure can bind bacterial cell surfaces and C3 complement factor.

TO SUMMARIZE:

- **Complement** is a series of 20 proteins naturally present in serum.
- **Activation of the complement cascade** results in a pore being introduced into target membranes.
- **The three pathways for activation** are the classical pathway, the alternative pathway, and the lectin pathway.
- **The alternative activation pathway** begins when complement factor C3b is stabilized by interaction with the LPS of an invading microbe.
- **The cascade of protein factors** C3b ⟶ B ⟶ Factor D ⟶ properidin ⟶ C5 ⟶ C6 ⟶ C7 ⟶ C8 and C9 results in formation of a membrane attack complex in target membranes.
- **C-reactive protein** in serum is activated when bound to microbial structures and will convert C3 to C3b, which can start the complement cascade.

23.9 Fever

In a healthy individual, body temperature is kept constant within a very small range (36–38°C), despite large differences in surrounding temperature and physical activity. Body temperature is normally regulated by blood flow through the skin and subcutaneous areas. Vasoconstriction (tightening of blood vessel diameter) allows the increased accumulation of heat, while vasodilation secures its quick release. If body temperature increases above 42–43°C, irreversible damage to the brain occurs.

Information about the body's skin temperature is relayed through the nervous system to the hypothalamus, which acts as a thermostat. If body temperature is too high, the hypothalamus directs increased blood flow through the skin to accelerate heat release. If body temperature is too low, blood flow will decrease to conserve heat, and shivering increases to generate heat.

Fever (elevated body temperature) is a natural reaction to infection. Fever is usually accompanied by general symptoms, such as sweating, chills, sensation of cold, and other subjective sensations. Substances that cause fever are known as **pyrogens**. Pyrogens fall into two classes: exogenous and endogenous. Exogenous pyrogens are those that originate outside the body, such as bacterial toxins. Endogenous pyrogens, on the other hand, are formed by the body's own cells in response to an outside stimulus (such as a bacterial toxin). Exogenous pyrogens generally cause fever by inducing the release of endogenous pyrogens. Endogenous pyrogens include cytokines (interferon, tumor necrosis factor, IL-6, others). These cytokines indirectly cause the hypothalamus to reset the normal temperature level. Cytokine receptors are located on neurons in proximity to the anterior hypothalamus, the location of the thermoregulatory center. The cytokine-receptor interaction stimulates production of phopholipase A2, an enzyme required to make prostaglandins. As a result, prostaglandin E2 is made and crosses the blood-brain barrier, where it changes the responsiveness of the thermosensitive neurons that make up the thermoregulatory center. In other words, it turns up the thermostat.

Because the ideal growth temperature for many microbes is 37°C, elevated temperature can place the organism outside its "comfort zone" of growth. There is also evidence that fever reduces iron availability to bacteria. Slower growth of the pathogen allows the body's immune system time to subdue the infection before it is too late. Consequently, interventions that reduce a moderate fever caused by infection may be counterproductive to a speedy recovery.

THOUGHT QUESTION 23.8 If increased fever limits bacterial growth, why would bacteria make pyrogenic toxins?

TO SUMMARIZE:

- **The hypothalamus** acts as the body's thermostat.
- **Exogenous and endogenous pyrogens** elevate body temperature by stimulating production of prostaglandins.
- **Prostaglandins** change the responsiveness of thermosensitive neurons in the hypothalamus.

Concluding Thoughts

The various “hardwired” innate immune mechanisms described in this chapter keep our normal microbial flora at bay and provide an effective first line of defense against potential pathogens. The next chapter addresses what happens when microbes breach these innate defenses. Unlike the general protective mechanisms discussed in this chapter, the system of acquired immunity generates a molecular defense specifically tailored to a given pathogen.

CHAPTER REVIEW

Review Questions

1. Name some sterile body sites.
2. What body sites are colonized by normal microbial flora?
3. Under what circumstances can commensal organisms cause disease?
4. Why are commensal organisms beneficial to the host?
5. Name and describe various types of innate immunity.
6. What are probiotics? How do they help maintain health?
7. How does the lung avoid being colonized?
8. What is a gnotobiotic animal?
9. Describe GALT and SALT.
10. Describe some chemical barriers to infection.
11. Discuss the different types of white blood cells.
12. What is a lymphoid organ?
13. Outline the process of inflammation.
14. Explain why phagocytes do not indiscriminately phagocytize body cells.
15. What is interferon?
16. Describe antibody-dependent cell cytotoxicity.
17. How does complement kill bacteria?
18. Why might fever be helpful in fighting infection?

Chapter 24

The Adaptive Immune Response

24.1 Adaptive Immunity

24.2 Factors That Influence Immunogenicity

24.3 Antibody Structure and Diversity

24.4 Humoral Immunity: Primary and Secondary Antibody Responses

24.5 Genetics of Antibody Production

24.6 T Cells, Major Histocompatibility Complex, and Antigen Processing

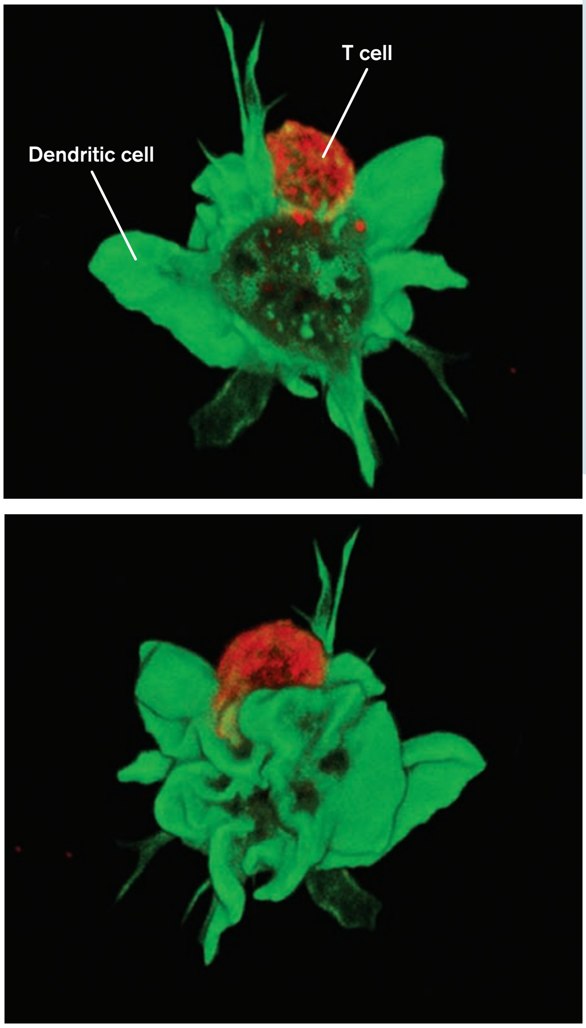
24.7 Complement as Part of Adaptive Immunity

24.8 Failures of Immune System Regulation: Hypersensitivity and Autoimmunity

Memory does not reside solely in the brain. Adaptive immunity also depends on a kind of memory that does not rely on nerves and neurons. Our immune system's memory relies on special lymphocytes in the circulation called memory B cells and T cells that form during an infection and "remember" it for years. Although a single member of these cells can recall exposure to only one part of an infecting agent, collectively memory cells remember every microbe that has managed to breach our innate defenses. Armed with this knowledge, they circulate throughout the body like tiny sentries, ready to detect and quickly respond to a second attack.

From birth, the naive immune system is able to recognize billions of possible foreign antigens. How is this possible? Our chromosomes seem too small. The system relies on genetic shuffling of a limited number of gene cassettes to produce each antibody.

But will a system this flexible not attack itself? Or does it? Type 1 diabetes, hypothyroidism, and arthritis are three examples of the immune system reacting against self. So why don't we all suffer from these autoimmune diseases? This chapter will answer these questions and demystify the phenomenon of adaptive immunity.



A naive, antigen-specific T cell is seen (red) contacting an antigen-presenting dendritic cell (DC, green). Ultimately, the T cell will be activated by this interaction. Red staining shows the distribution of the T-cell receptor (TCR) by staining with an antibody. The TCR binds to foreign antigens placed on the surface of antigen-presenting cells. Green shows staining for actin by phalloidin-FITC. Both figures show the same cell pair. The lower image is rotated 180° on the vertical axis to show the DC membrane veils more precisely. Note the homogeneous distribution of the TCR on the T-cell surface despite its interaction with the DC. The TCR signal is not enriched at the T-cell-DC interface called the immunological synapse interface.

David Philip Vetter was born in 1971 without an immune system. Better known as the "bubble boy," he was the only human known to live in a plastic, germ-free bubble for his entire 12 years of life (1971–1984; **Fig. 24.1A**). His predicament stemmed from a genetic disease known as severe combined immunodeficiency (SCID). In the most serious form of this disease, the patient harbors no T cells and has dysfunctional (or sometimes no) B cells, so the body cannot launch a meaningful immune defense against any invading microbe—whether it be pathogen or normal flora. Because David's elder brother had died of SCID before David was born, physicians were alerted that he might have the disorder, too. Consequently, David was transferred to a sterile environment within seconds after birth to await a bone marrow transplant. Water, air, food, diapers, clothes all were disinfected with special cleaning agents before entering his sterile plastic bubble. He was handled only through special plastic gloves attached to the wall. He lived for 12 years physically isolated in this plastic, sterile environment, venturing out only in a NASA-designed sterile space suit. A bone marrow transplant was attempted in 1984, but his defective immune system failed to protect him from Epstein-Barr virus undetected in the transplanted cells. He died just before his 13th birthday.

One in every million people develops SCID. The two most common forms of the disease result from genetic abnormalities linked to the X chromosome. Patients with X-linked SCID either lack an enzyme called adenosine deaminase (resulting in the toxic accumulation of deoxyguanosine triphosphate) or cannot produce an important cytokine receptor that T cells need for their development and to communicate with B cells. Cytokines are discussed in Section 23.2.

Figure 24.1 Living without an immune system. **A.** David Vetter, the bubble boy, inside his environmental bubble. The tube behind him is a port that was used to introduce sterile food, clothes, etc. **B.** Adrian J. Thrasher, University Hospital London, conducted a successful gene therapy trial on children with severe combined immunodeficiency.

A dramatic therapeutic attempt to cure the disease took place in 2004 using stem cells. Stem cells are undifferentiated, but are capable of changing into many different cell types, including B cells and T cells (see Section 23.3). A team of scientists headed by Dr. Adrian Thrasher of University College, London, removed stem cells from the bone marrow of four SCID children who lacked the gene for the cytokine receptor. They inserted the gene encoding the normal cytokine receptor into a severely defective leukemia virus that can infect cells without causing disease. The debilitated leukemia virus served as a gene vector to deliver the normal cytokine receptor gene into the patient's stem cells. Once the genetic material entered the nucleus, the healthy copy of the gene began to function and the corrected stem cells were reintroduced into the patients. After this gene replacement therapy, all four children started making T cells with the correct receptor and produced functional B cells. The patients developed an immune system, were discharged, and are now living at home.

SCID dramatically illustrates the importance of our immune system and how fragile is its development. All it takes is a small defect in a single gene to subvert the entire process.

This chapter begins by describing the two types of adaptive immunity and the factors that influence the immunogenicity of foreign proteins, lipids, and so on. We will explore how B cells ultimately differentiate into plasma cells and make antibodies (defining what is called humoral, or circulating, immunity) and how certain T-cell lymphocytes develop to directly kill infected host cells in what is called cell-mediated or cellular immunity. You will also learn that another type of T cell controls the balance between humoral and cell-mediated responses to a given infection. Ultimately, you will appreciate that adaptive immunity is a major reason the human race still exists.

24.1 Adaptive Immunity

As Chapter 23 points out, the immune system has both nonadaptive and adaptive mechanisms. Nonadaptive (innate, or nonspecific) immune mechanisms are present from birth. Adaptive immunity, in contrast, develops as the need arises. For instance, adaptive immunity against malaria is not developed until the individual has encountered the plasmodial parasite responsible for the disease. The **adaptive immune response** is a complex, interconnected, and cross-regulated defense network.

NOTE: The terms *adaptive immune response* and *immune response* are often used interchangeably.

Two types of adaptive immunity are recognized: humoral immunity and cell-mediated immunity. In **humoral immunity**, **antibodies** are produced that directly target microbial invaders. The term *humoral* means "related to bodily fluids." Thus, antibodies are proteins that circulate in the bloodstream and recognize foreign structures called antigens. An **antigen** (also called an **immunogen**) is any molecule that will, when introduced into a person, elicit the synthesis of antibodies that specifically bind the antigen. Antigens stimulate B cells (B lymphocytes) to differentiate into antibody-producing cells. **Cell-mediated immunity**, the second type of adaptive immunity, employs teams of T cells (T lymphocytes) that can also recognize antigens and then destroy host cells infected by the microbe possessing the antigen. In truth, the humoral and cellular immune responses are intertwined, each relying on some facet of the other to work efficiently. T cells serve a central role in adaptive immunity by determining whether humoral or cell-mediated mechanisms predominate in response to a specific antigen.

Adaptive immunity develops over a three- to four-day period after exposure to an invading microbe. The immune system does not recognize the *whole* microbe, but innumerable tiny *pieces* of it. Each small segment of an antigen that is capable of eliciting an immune response is called an **antigenic determinant** or **epitope**. Many single-protein antigens are recognized when the larger antigen is broken into smaller segments upon being phagocytized. Even distinct tertiary (three-dimensional) shapes within a protein may be counted as antigenic determinants if they produce a specific response. This happens when two or more stretches of amino acids are far removed from each other in a protein's primary sequence, yet protein folding aligns them side by side in three-dimensional space (**Fig. 24.2**). Such a three-dimensional structure may be recognized by the immune system as a single entity or antigen. Besides proteins, other structures in the cell, such as complex polysaccharides, can have linear and three-dimensional epitopes. So the immune response to a microbe is really a composite of responses to different epitopes by thousands of individual B cells, which are the cells responsible for producing antibodies. The response to each individual epitope is **clonal**; that is, it gives rise to a population of cells that originate from a single cell. This means that each clone of immune host cells will target a unique epitope.

As mentioned previously, the humoral response starts when an antigen triggers the differentiation of B cells into antibody-producing cells. In contrast, the cell-mediated immune response occurs when certain types of T cells become activated by microbial antigens placed on infected host cell surfaces or on the surface of phagocytic cells that have engulfed the microbe. In cellular immunity, the activated T cell can directly kill the infected host cell in an attempt to kill the invading microbe. In addition, T cells synthesize soluble growth factors called cytokines (introduced in Section 23.5) that incite nearby macrophages to indiscriminately attack cells in the local area. Thus, cellular immunity, in general, is critical for dealing with intracellular pathogens such as viruses, whereas humoral immunity is most effective against extracellular bacterial pathogens like *Streptococcus pneumoniae*, one cause of pneumonia.

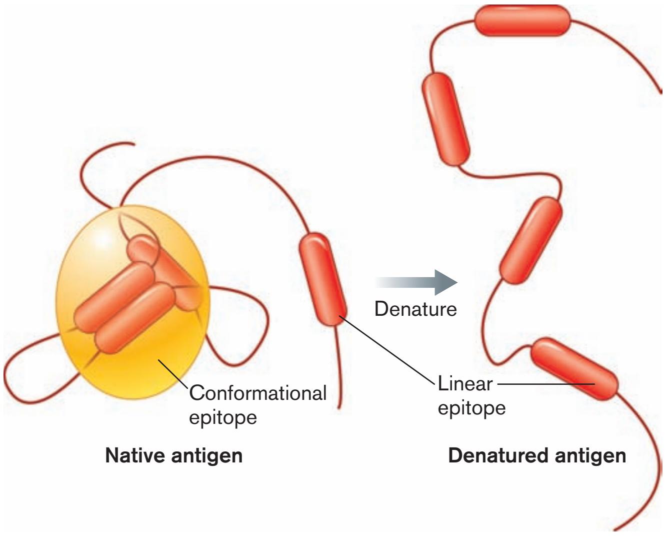

Figure 24.2 Antigens and epitopes. Native proteins fold into a three-dimensional shape, where several regions separated in the linear sequence can reside next to each other to form a conformational epitope. Denaturing the protein with the detergent sodium dodecyl sulfate (SDS) and reducing agents like dithiothreitol (to remove disulfide bonds) will unfold the protein and separate the various amino acid stretches that formed the conformational epitope.

As we proceed through the chapter, we will reveal how the immune system functions in layers, with each layer building upon the previous one. As a result, we will periodically return to a particular aspect of the immune response—for example, B-cell differentiation into plasma cells—to integrate seemingly distinct parts of the immune system into a unified concept of immunity.

THOUGHT QUESTION 24.1 Two different stretches of amino acids in a single protein form a three-dimensional antigenic determinant. Will the specific immune response to that three-dimensional antigen also respond to one of the two amino acid stretches alone?

TO SUMMARIZE:

- **An antigen** can elicit an antibody response. An antigen is usually made of many different epitopes (antigenic determinants), each of which binds to a different, specific antibody.
- **Humoral immunity** against infection is the result of antibody production originated by B cells.
- **Cellular immunity** involves a type of lymphocyte called T cells, which control antibody production and can directly kill host cells.

24.2 Factors That Influence Immunogenicity

Immunogenicity measures the effectiveness by which an antigen elicits an immune response. One antigen can be more immunogenic than another. For example, proteins are the strongest antigens, but carbohydrates can also elicit immune reactions. Nucleic acids and lipids are usually weaker antigens. This is, in part, because these molecules are very flexible and present a variable three-dimensional structure that does not easily interact with antibodies. Nucleic acids and lipids are also weak antigens because they are both made of relatively uniform repeating units. Proteins are more effective antigens for three reasons: They form a variety of shapes, they maintain their tertiary structure, and they are made of many different amino acids that can be assembled in many different combinations. These features provide stronger interactions with antibodies in the bloodstream and enable better recognition by lymphocytes, the cellular workhorses of the immune system.

Several other factors contribute to the immunogenicity of proteins (**Table 24.1**). For example, the larger the antigen, the more likely it is that phagocytic cells will "see" and engulf it. This is important because for an immune response to occur, phagocytic cells such as macrophages and dendritic cells must first engulf large antigens and degrade them, presenting the epitopes on their cell surface. Phagocytic cells that degrade larger antigens and thus expose antigenic determinants are called **antigen-presenting cells (APCs)**. The immune response begins once a B cell binds to a foreign peptide and a T lymphocyte binds to the same foreign peptide displayed on the surface of an antigen-presenting cell.

Presentation of antigens on APCs requires that the antigen be placed on a membrane surface protein structure called the **major histocompatibility complex**, or **MHC** (discussed later). The better an antigen can bind to these MHC surface proteins, the more immunogenic it is. The stronger the binding, the easier it is for T cells to recognize the complex.

Each specific antigen shows a different **threshold dose** needed to generate an optimal response. A dose higher or lower than that threshold will not generate as strong an immune response. Lower doses activate only a few B cells. Exceedingly high doses of antigen can cause **B-cell tolerance**, a state in which B cells have been overstimulated to the point at which they do not respond to subsequent antigen exposures and make antibody. Tolerance is part of the reason your immune system does not react against your own protein antigens.

As you might expect, the body must regulate the immune system carefully so that a response is not leveled against itself. In effect, the immune system must become "blind" to its own antigens; as a result, the host will often be blind to foreign antigens that resemble epitopes of its own cells. Therefore, the more complex the foreign protein is, the more likely it will possess antigenic determinants that a lymphocyte can recognize as nonself. The further an antigen is from "self," the greater its immunogenicity will be.

Specific Interactions between Antibodies and Antigens Create Immunological Specificity

Smallpox is a devastating disease that caused enormous suffering and killed millions of people in the seventeenth and eighteenth centuries (**Fig. 24.3**). There was no cure,

Table 24.1 Factors that influence immunogenicity of antigens.

Parameter	High immunogenicity	Low immunogenicity
Size	Large	Small
Dose	Intermediate	High or low
Inoculation route	Subcutaneous > intraperitoneal > intravenous >	intragastric[a]
Composition	Complex	Simple
Form	Particulate	Soluble
	Denatured	Native
Differences from self proteins	Many	Few
Interactions with host MHC proteins	Effective	Ineffective

[a]Route of inoculation affects immunogenicity of a given antigen. In general, subcutaneous inoculation gives the strongest immune response while intragastric yields the weakest response.

Figure 24.3 Immunological specificity is the basis of vaccination. A. Photo of a smallpox patient, showing the white pox pustules. **B.** The smallpox virus, variola major (300 nm long, TEM). **C.** The vaccinia virus that causes cowpox (360 nm long, electron micrograph). Edward Jenner recognized the similarity between the deadly smallpox and less severe cowpox diseases and used cowpox scrapings to vaccinate humans against smallpox.

and the only available preventive treatment was to take dried material from lesions of a previous smallpox sufferer, place it on a healthy person, and hope the person survived. Those who survived were protected from subsequent bouts of smallpox but were still susceptible to other diseases. This early observation gave rise to the idea of **immunological specificity**, which means that an immune response to one antigen is not effective against a different antigen. In other words, the immune response to smallpox will not protect someone against the plague bacillus (*Yersinia pestis*), which is antigenically different from smallpox.

While immunological specificity is important, it is not absolute. As described in Chapter 1, an English country physician named Edward Jenner (see Fig. 1.19) in the late eighteenth century (long before viruses were discovered) learned to protect townsfolk from deadly smallpox disease by inoculating them with scrapings from lesions produced by a tamer disease, cowpox. By this process, Jenner unwittingly transferred the vaccinia virus (which we now know causes cowpox; see **Fig. 24.3C**) to villagers susceptible to smallpox (caused by the related but more dangerous, variola virus). The resulting immune reaction to vaccinia produced an effective cross-protection against variola and thus prevented smallpox. This illustrates that an immune reaction against one organism or virus may be sufficient to protect against an antigenically related, if not identical, organism. The technique of exposing individuals to "tame" microbes to protect them against pathogens, now generally called **vaccination**, has been used to protect humans against many microbial and viral pathogens (**Table 24.2**). Most vaccinations today involve administering crippled (attenuated) strains of the pathogenic microbe or inactivated microbial toxins (for example, diphtheria toxin).

Cross-protection, where immunization against one microbe protects against a second, will work only if two proteins critical to the pathogenesis of the two different microorganisms share key antigenic determinants. No cross-protection occurs if these determinants differ significantly. A good example is the common cold, which is caused by hundreds of closely related rhinovirus strains (rhinitis, a runny nose, is one of the symptoms of this viral disease). Infection with one strain will not immunize the victim against a second strain. The reason is that the structures of the viral proteins used to attach to the ICAM-1 protein on host cells differ dramatically between different strains of rhinovirus (**Fig. 24.4A**). Antibodies called neutralizing antibodies, which bind to the attachment protein on one strain of rhinovirus, will prevent infection by the same virus strain (**Fig. 24.4B**) but will not bind a similar but antigenically distinct ICAM-1 receptor protein from a different strain. A key to one lock will not work on a different lock.

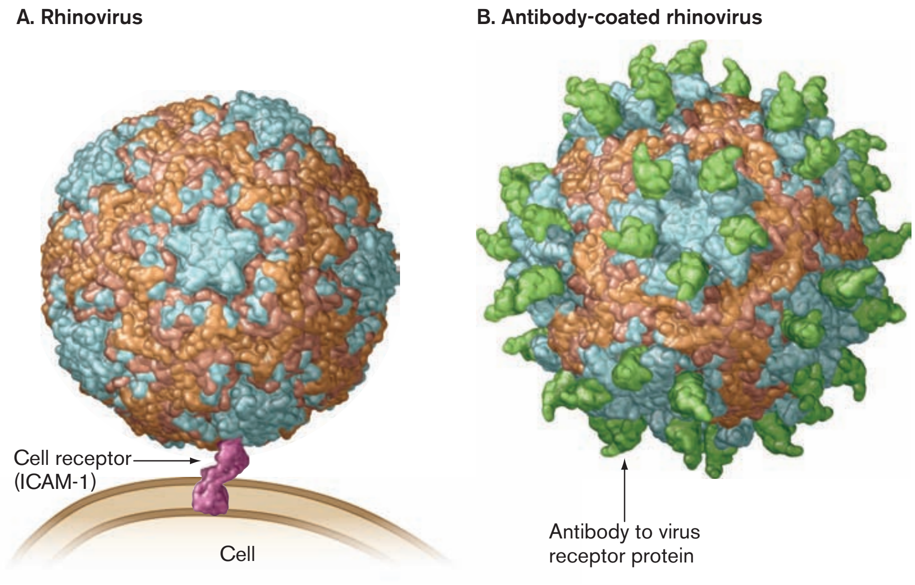
THOUGHT QUESTION 24.2 How does a neutralizing antibody that recognizes a viral coat protein prevent infection by the associated virus?

Antigens, Immunogens, and Haptens

Karl Landsteiner (1868–1943) discovered the ABO blood group system in 1901, for which he received the 1930 Nobel Prize in Physiology or Medicine (**Fig. 24.5A**). He observed that red blood cells (RBCs) from a type A individual, whose RBCs contained the A antigen, were destroyed (lysed) when transfused into a type B person, whose RBCs contained the B antigen. However, type A RBCs remained intact when introduced into another type A individual, and type B RBCs were undamaged when introduced into a type B individual (**Fig. 24.5B**). This is the phenomenon of blood group incompatibility, which occurs when specific antibodies in the serum of an individual of one blood type bind to antigens on red blood cells of a different type (that is, foreign RBCs). We now know that type B individuals carry specific anti-A antibodies in their bloodstream, while type A individuals carry specific anti-B antibodies. (Type AB people carry neither antibody, and type O individuals, whose RBCs contain neither A nor B antigen, carry both anti-A and anti-B antibodies.) The discovery by Landsteiner defined the basic concept of immunological specificity and explains why a type A person cannot donate blood to a type B individual, and vice versa. It also explains why a type O person (called a universal donor) can donate to type A, B, AB, or O individuals.

Table 24.2 Vaccines against viral and bacterial pathogens.

Disease	Vaccine	Vaccination recommended for:
Viral		
Chickenpox	Attenuated strain (will still replicate)	Children 12–18 months
Hepatitis A	Inactivated virus (will not replicate)	Travelers to endemic areas
Hepatitis B	Viral antigen	Medical personnel, children 1–18 months
Influenza	Inactivated virus or antigen	Adults over 65 years
Measles	Attenuated viruses; MMR combined vaccine	Children 15–19 months
Mumps		
Rubella		
Polio	Attenuated (oral, Sabin) Inactivated (injection, Salk)	Children 2–3 years
Rabies	Inactivated virus	Persons in contact with wild animals
Yellow fever	Attenuated virus	Military personnel
Bacterial		
Anthrax	*B. anthracis*, components of toxin Unencapsulated strain	Agricultural and veterinary personnel, key health care workers
Cholera	*Vibrio cholerae,* components	Travelers to endemic areas
Diphtheria	Toxoid (inactivated toxin)	Children 2–3 months
Pertussis	Acellular *Bordetella pertusis*	
Tetanus	Toxoid	
Haemophilus influenzae type b (meningitis)	Bacterial capsular polysaccharide	Children under 5 years
Lyme disease	Lipoprotein OspA surface antigen, *Borrelia burgdorferi*	Individuals in endemic areas
Meningococcal disease	Bacterial capsular polysaccharides, *Neisseria meningitidis*	Military and high-risk individuals
Pneumococcal pneumonia	Bacterial capsular polysaccharides, *Streptococcus pneumoniae*	Adults over 50 years
Tuberculosis (*Mycobacterium tuberculosis*)	Attenuated *Mycobacterium bovis* (BCG vaccine)	Exposed individuals
Typhoid fever	Killed *Salmonella typhi*	Individuals in endemic areas
Typhus fever	Killed *Rickettsia prowazekii*	Medical personnel in endemic areas and scientists



A. Rhinovirus

B. Antibody-coated rhinovirus

Figure 24.4 Antibodies prevent rhinovirus attachment to cell receptors. **A.** This figure illustrates the complexity of the rhinovirus capsid and shows the attachment of the virus to the cell surface molecule ICAM-1 (intercellular adhesion molecule, shown in reddish brown). (PDB code: 1rhi) **B.** This figure shows rhinovirus coated with protective (neutralizing) antibodies (green) that block the ICAM-1 receptors on the virus. As a result, the virus fails to attach to and infect the host cell. (PDB code: 1rvf)

Type A
Type B
RBCs from a type A person are coated with A antigen. RBCs from a type B person are coated with B antigen.
A antigen
Transfusion
B antigen
Type A blood contains anti-B antibodies. Type B blood contains anti-A antibodies.
Anti-B antibody
Anti-A antibody
The anti-A antibodies in a type A person will attack and destroy transfused type B red blood cells.
Type A RBC is lysed
C.
Carrier-specific antibodies
Protein carrier
The small hapten molecule benzene cannot stimulate antibody production in a mouse.
No response
Benzene hapten
Carrier-specific and hapten-specific antibodies
Protein-hapten complex
Attaching the hapten to a larger carrier molecule (e.g., BSA protein) will result in production of antibodies to both the carrier and the hapten molecules.

Karl Landsteiner. *The Specificity of Serological Reactions.* Dover Publications

Figure 24.5 Karl Landsteiner, ABO blood groups, and haptens. **A.** Karl Landsteiner discovered ABO blood groups and haptens. **B.** Individuals with type A antigens on their red blood cells possesses antibodies to B antigen, while type B individuals have B antigens on RBCs and carry anti-A antibodies. Transfusing RBCs from a type B individual into a type A individual will lead to the anti-B antibodies attacking and destroying the type B red blood cells. **C.** Basic concept of a hapten.

Landsteiner wanted to better understand this idea of immunological specificity. Because at that time nothing was known about antigen or antibody structure, he chose to study very simple molecules that, by themselves, were too small to elicit antibodies. Molecules of molecular weight less than 1,000 are generally not immunogenic (we now know the reason is that they do not bind MHC molecules); however, Landsteiner discovered that these small molecules would elicit production of specific antibodies if they were covalently attached to a larger carrier protein or other molecule. He called these types of small antigens **haptens** (derived from the Greek word meaning "to fasten" and the German word for "stuff"). Haptens can be thought of as small incomplete antigens. An example of a hapten is the antibiotic penicillin, a serious cause of immune hypersensitivity reactions in some individuals (see Section 24.8).

Landsteiner chose to work with benzene haptens with sulfate bound at different positions of the ring. As illustrated in **Figure 24.5C**, a protein carrier like bovine serum albumin (BSA) injected into a mouse would elicit antibodies that react against BSA. Because BSA antigen elicits an immune response to itself, it is called an immunogen. In contrast, a mouse injected with the benzenesulfate hapten alone fails to produce antibodies to the hapten. However, when the hapten is attached to BSA and the hapten-BSA complex is injected, the mouse produces antibodies that react to the carrier (BSA) as well as other antibodies that react against the benzene hapten. The reason for this carrier effect will be evident later as we describe how antigens are processed by cells of the immune system. Thus, antigens include immunogens that elicit an immune response by themselves, and haptens that must be attached to an immunogen in order to generate an immune response.

TO SUMMARIZE:

- **Proteins are better immunogens** than nucleic acids and lipids, because proteins have more diverse chemical forms.
- **Antigen-presenting cells** are cells, such as phagocytes, that degrade microbial pathogens and present distinct pieces on their cell surface MHC proteins.
- **Immunological specificity** means that antibody made to one epitope will not bind to different epitopes (although some weak cross-binding can happen).
- **A hapten** is a small compound that must be conjugated to a larger carrier antigen to elicit production of an antibody.

24.3 Antibody Structure and Diversity

Antibodies, also called **immunoglobulins**, are members of the larger immunoglobulin superfamily of proteins. Antibodies are the keys to immunological specificity. They are glycoproteins made by the body in response to an antigen. The immunoglobin superfamily of proteins has in common a 110-amino-acid domain with an internal disulfide bond. The immunoglobulin superfamily includes antibodies and other important binding proteins, such as the major histocompatibility proteins and B-cell receptors described later.

Like miniature "smart bombs," antibody immunoglobulins individually circulate through blood, ignoring all antigens except those for which they were designed. When an antibody finds its antigenic match, it binds to the antigen and initiates several events designed to destroy the target. Antibodies, in addition to being free-floating, are also strategically situated on the surfaces of B cells, where they enable these lymphocytes to recognize specific antigens.

An antibody consists of four polypeptide chains. There are two large **heavy chains** and two smaller **light chains** (**Fig. 24.6**). The four polypeptides combine to form a Y-shaped tetrameric structure held together by disulfide bonds. Two bonds connect the two identical heavy chains to each other. One light chain is then attached near its carboxyl end to the middle of each heavy chain by a single disulfide bond. The antigen-binding sites are formed at the amino-terminal ends of the light and heavy chains. One antibody molecule possesses two identical antigen-binding sites, one on each "arm" of the molecule.

Antibodies Have Constant and Variable Regions

There are five classes of antibodies, defined by five different types of heavy chains called alpha (α), mu (μ), gamma (γ), delta (δ), and epsilon (ε). The heavy-chain classes are distinguished one from another by regions of highly conserved amino acid sequences, known as **constant regions** (denoted C, **Fig. 24.7**). Antibodies containing gamma heavy chains are called IgG; those with alpha, delta, mu, and epsilon heavy chains are called IgA, IgD, IgM, and IgE, respectively. Each antibody class serves a specific purpose in the immune system.

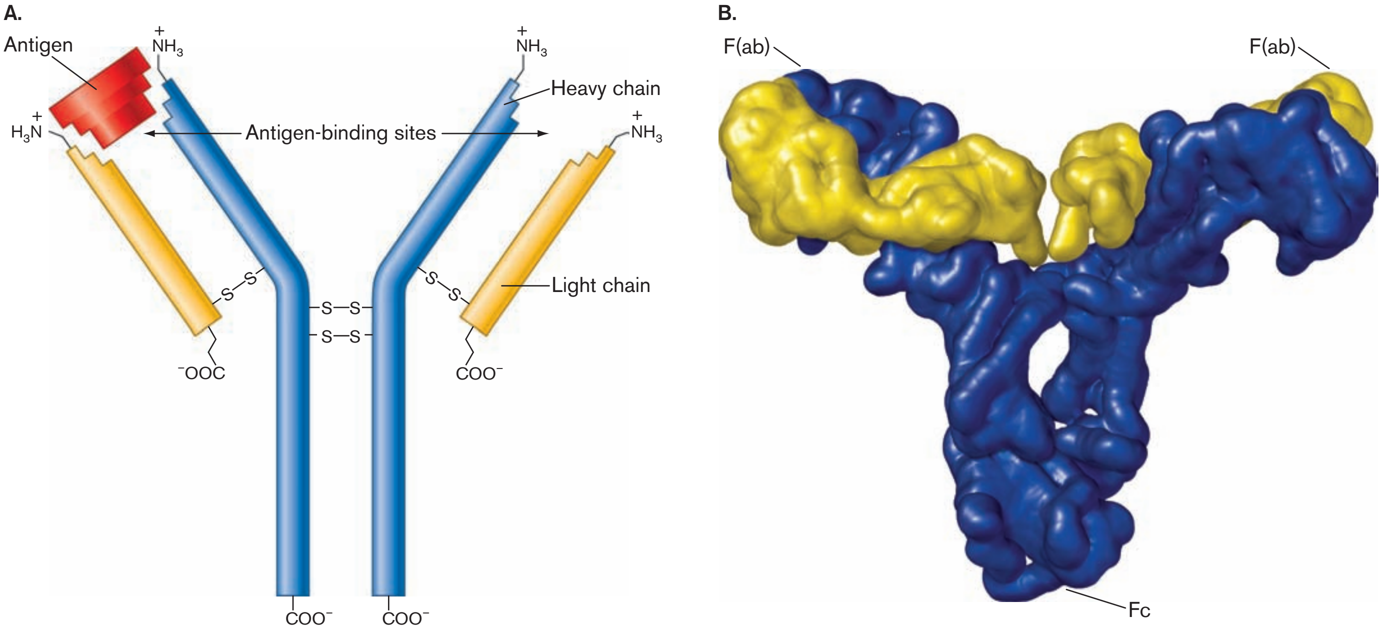

Figure 24.6 Basic antibody structure. A. Each antibody contains two heavy chains and two smaller, light chains held together by disulfide bonds. The Y-shaped structure contains two antigen-binding sites, one at each arm of the molecule. The two antigen-binding sites are formed by the amino-terminal regions of the heavy and light chain pairs. **B.** Three-dimensional structure of an antibody. The heavy chains are shown in blue, the light chains in yellow. The F(ab) regions represent the antigen-binding sites. The Fc portion points downward and is used to attach the antibody to different cell surface molecules. (PDB code: 1r70)

In contrast to heavy chains, there are only two classes of light chains: kappa (κ) and lambda (λ). An antibody of any heavy-chain class may contain two kappa chains or two lambda chains, but never one of each. Two-thirds of all antibody molecules carry kappa chains; the rest have lambda chains.

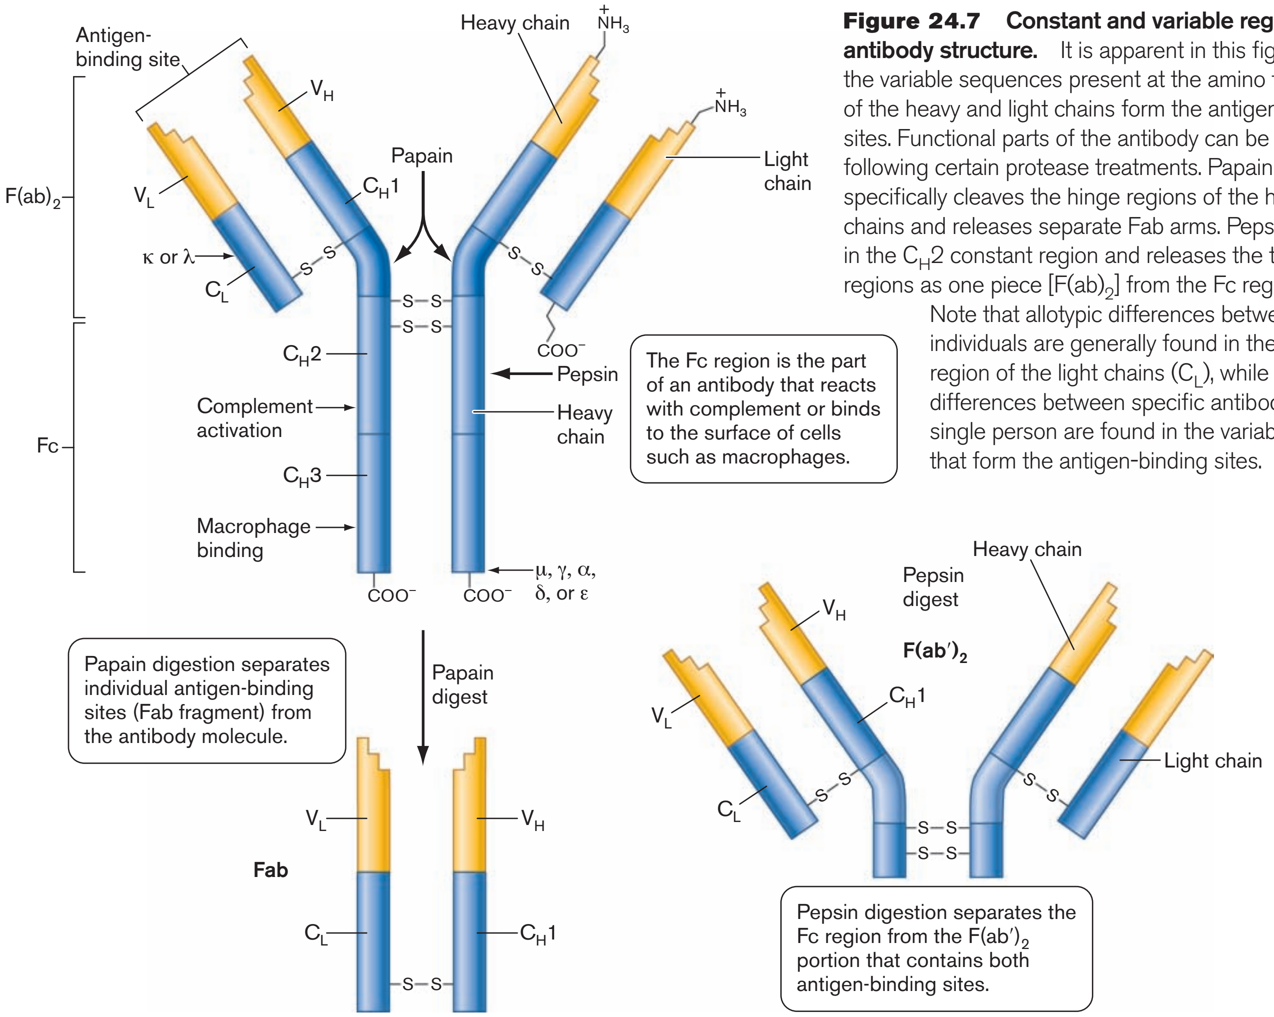
The antigen-binding part of an antibody is formed by highly variable amino acid sequences situated at the amino-terminal ends of the light and heavy chains. These **variable regions** are referred to as the V_L region and the V_H regions (see **Fig. 24.7**). The rest of the immunoglobulin chains are composed of the highly conserved constant regions. C_H1, C_H2, and C_H3 denote the three different constant regions in each heavy chain. Each light chain also has a constant region, designated C_L. Section 24.5 discusses the genes that code for these regions and the combinatorial possibilities underlying the formation of different antibody molecules.

In addition to the two "arms" that bind antigen, every antibody contains a "tail" that serves a different function. Intact antibodies can be dissected into their two functional parts through digestion with the protease papain. This endoprotease cleaves the molecule at the hinge region, which releases the tail of the antibody (called the **Fc region**) from the antigen-binding portion of the molecule (called the **F(ab)$_2$ region**) (see **Fig. 24.7**). The c in Fc refers to the ease with which this fragment can be crystallized. The Fc region is not involved in antigen recognition but is important for anchoring antibodies to the surface of certain host cells and for binding components of the complement system.

Isotypes, Allotypes, and Idiotypes Represent Different Levels of Antibody Diversity

As noted earlier, antibodies are classified based on variations in amino acid sequences in regions of the light and heavy chains. Certain differences in the constant region give rise to **isotypes**, which are common to all members of a particular species. IgG, IgM, IgA, IgD, and IgE are antibody isotypes. The IgG isotype is identical among humans but is different from the IgG isotype of monkeys.

Within an isotype, there are amino acid differences in the constant region that are shared by some, but not all, members of a species. These are called *allo-*



The Fc region is the part of an antibody that reacts with complement or binds to the surface of cells such as macrophages.

Papain digestion separates individual antigen-binding sites (Fab fragment) from the antibody molecule.

Pepsin digestion separates the Fc region from the F(ab′)$_2$ portion that contains both antigen-binding sites.

Figure 24.7 Constant and variable regions in antibody structure. It is apparent in this figure that the variable sequences present at the amino termini of the heavy and light chains form the antigen binding sites. Functional parts of the antibody can be separated following certain protease treatments. Papain specifically cleaves the hinge regions of the heavy chains and releases separate Fab arms. Pepsin cleaves in the C_H2 constant region and releases the two F(ab) regions as one piece [F(ab)$_2$] from the Fc region.

Note that allotypic differences between individuals are generally found in the constant region of the light chains (C_L), while idiotypic differences between specific antibodies in a single person are found in the variable regions that form the antigen-binding sites.

typic differences. Allotypic differences in an amino acid sequence usually occur in the light chains. For example, John possesses circulating IgG molecules that have allotypic differences from the IgG antibodies circulating in Sherrie. (John and Sherrie have different IgG **allotypes**.)

On another level, alterations in *hyper*variable regions within a single antibody class in a single person are referred to as *idiotypic* differences. These differences occur in the antigen-binding sites of the various antibodies of a single individual. Thus, the IgG molecules in Sherrie that bind to epitope A possess idiotypic differences from Sherrie's IgG molecules that bind epitope B. In sum, the human IgG isotype is composed of different allotypes (constant region differences between individuals), and each allotype is comprised of different **idiotypes** (variable region differences within an individual).

Note that antibodies are proteins and as such are themselves antigens. Thus, the amino acid differences found within a single class of antibody—IgG for example—also represent different *epitopes* within that class. Isotypic, allotypic, and idiotypic differences define epitopes in antibody molecules that can be detected using immunological techniques such as immunoprecipitation and Western blotting assays described in **Special Topic 24.1**.

Different Antibody Isotypes Have Different Functions and "Super" Structures

All antibody isotypes have the same basic structure. However, each isotype has a unique "super" structure (for example, monomer, dimer), and each is designed to carry out a different task. Some key properties of the five different immunoglobulin classes are listed in **Table 24.3.** IgG is the simplest and most abundant antibody in blood and tissue fluids. It is made as a monomer but has four subclasses. Each subclass varies in its amino acid composition and by the number of interchain cross-links. IgG molecules carry out several missions for the immune system. First, they bind and **opsonize** microbes; that is, they make the microbe more susceptible to phagocytes. Opsonizing IgG antibodies coat the microbe with their Fc portions protruding outward. Phagocytes possess surface Fc receptors that can attach to the Fc region of the antibody to gain a firmer "grip" on the microbe, facilitating phagocytosis (discussed in Section 23.6). IgG can also directly neutralize viruses by binding to virus attachment sites and is one of only two antibody types that can activate complement by the classical pathway (to be described in Section 24.7).

IgA is secreted across mucosal surfaces and is most commonly found as a dimer (**Fig. 24.8A**). This explains why IgA can bind four molecules of antigen (each monomer can bind two molecules of antigen). The components of the IgA dimer are linked by disulfide bonds to a protein called the J chain, which joins two IgAs by their Fc regions. A sixth protein, the secretory piece, is wrapped around the IgA dimer during the secretion process. The secreted molecule, now called **sIgA** (secretory IgA), is found in tears, breast milk, and saliva and on other mucosal surfaces. The molecule sIgA is important for mucosal immunity against pathogens.

Circulating **IgM** is a huge, Ferris wheel–shaped molecule formed from five monomeric immunoglobulins tethered together by the J-chain protein (**Fig. 24.8B**). It can also be found in monomeric form on the surfaces of B

Table 24.3 Properties of human immunoglobulins.

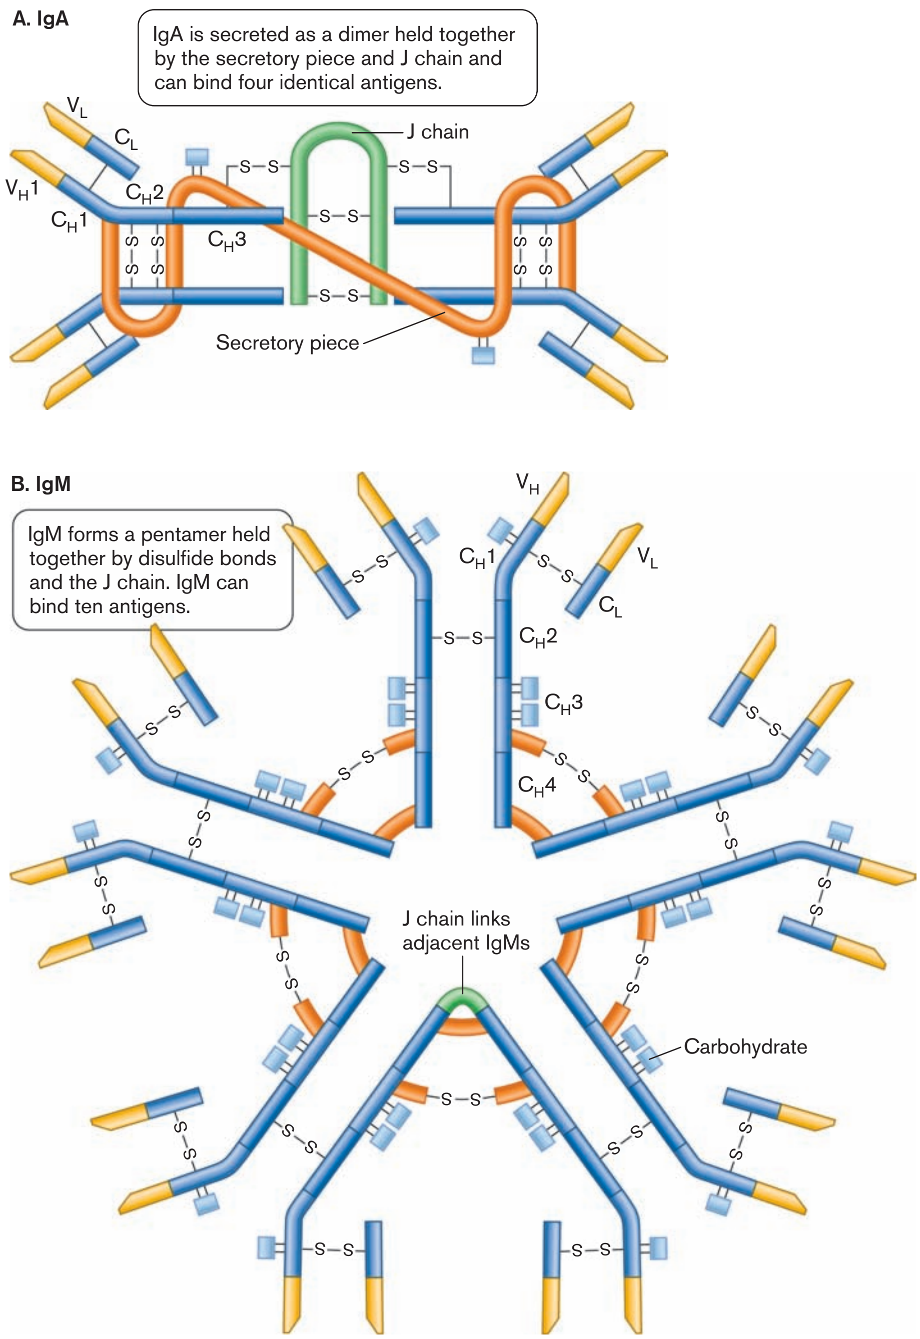
cells, where it forms part of the B-cell receptor. IgM is the first antibody isotype detected during the early stages of an immune response. Unlike the smaller IgG immunoglobulins, IgM is so large that it cannot cross the placenta (see **Table 24.3**).

Two other antibody isotypes are present at very low levels in the blood. **IgD** is a monomer that can neither bind complement nor cross the placenta. These molecules are, however, abundantly found on the surface of B cells. Attached to the cell surface by their Fc regions, IgD, along with monomeric IgM, can bind antigen and signal B cells to differentiate and make antibody.

IgE is also present in trace amounts in the blood, but is found more prominently bound to the surface of mast cells and basophils, where it has potent biological activity. Mast cells and basophils contain granules loaded with inflammatory mediators. The primary role of IgE is to amplify the body's response to invaders. Once secreted into serum, IgE



IgA is secreted as a dimer held together by the secretory piece and J chain and can bind four identical antigens.

IgM forms a pentamer held together by disulfide bonds and the J chain. IgM can bind ten antigens.

Figure 24.8 Structures of IgA and IgM. The antibodies are made as multimers of two (IgA) or five (IgM) immunoglobulin molecules.

Special Topic 24.1

Applications Based on Antigen-Antibody Interactions

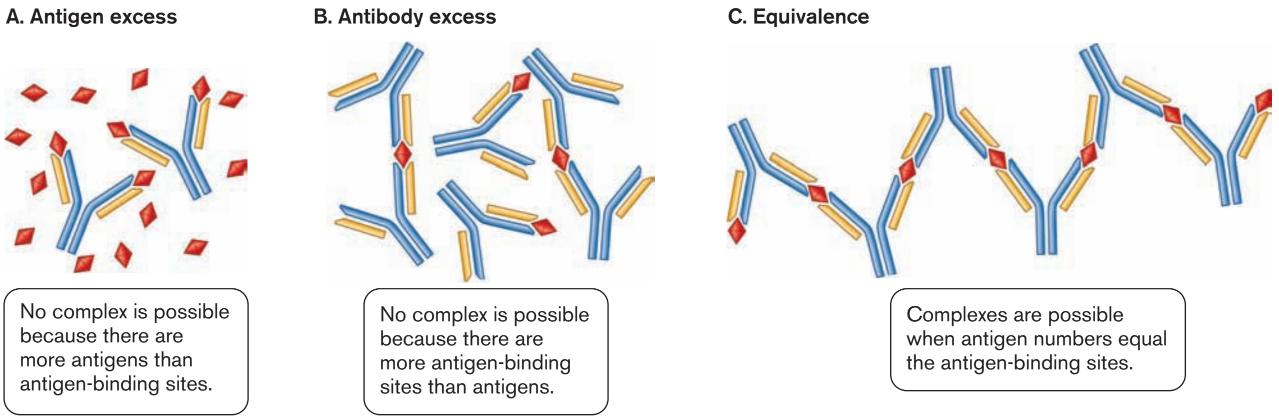
A typical antibody molecule will bind only one type of antigen but has two antigen-binding sites. Because of the ability to bind to more than one antigen molecule, antibodies can cross-link antigens in solution, ultimately forming complexes too large to remain soluble (**Fig. 1**). The phenomenon, called **immunoprecipitation**, is normally only observed in vitro, where the concentration of antigen and antibody can be manipulated experimentally.

Immunoprecipitation occurs only with appropriate ratios of antigen and antibody molecules. Too many antigen molecules (antigen excess; **Fig. 1A**) or too few antigen molecules (antibody excess; **Fig. 1B**) result in complexes too small to immunoprecipitate. Large complexes are formed only at an appropriate antigen:antibody ratio called **equivalence** (**Fig. 1C**). Equivalence is the point where the number of antigenic sites is roughly equal to the number of antigen-binding sites.

Immunoprecipitation is the basis for many experimental immunological techniques. For example, the concentration of an antigen can be determined in vitro, or antibodies can be used to identify and remove specific antigens from a complex mixture because the specific antigen-antibody complex falls out of solution (**Figs. 2A** and **B**). **Figure 2B** shows how specific proteins can be isolated from a complex cell extract using immunoprecipitation. Antibody is added to a complex mix of different antigens. The antibody, however, can only bind to its specific antigen. Beads coated with a molecule known as protein A (derived from *Staphylococcus aureus*) are added to specifically purify that antigen-antibody complex. Protein A binds to the Fc portion of an IgG antibody molecule. Consequently, all the antigen-antibody complexes will become bound to the bead. Because the bead is heavy, centrifugation will remove the desired antigen from the complex mixture.

Another application, called **radial immunodiffusion**, allows the concentration of an antigen in a solution to be determined (**Fig. 2C**). This technique involves visualizing a ring of precipitation in an agarose gel impregnated with antibody. Antigen placed within a well will diffuse outward until reaching a zone of equivalence with the embedded antibody. At this point, antigen-antibody complexes precipitate and form a ring a certain distance from the well. Antigen concentration progressively decreases the farther the antigen diffuses away from the well. Consequently, the higher the concentration of antigen that is originally present in the well, the farther it will have to diffuse before the zone of equivalence is reached and a ring of precipitation forms. The concentration of antigen in an unknown solution is determined by comparing the radius of immunoprecipitation formed against a standard curve in which known concentrations of antigen are plotted against the radius of the ring of precipitation.

Another important research technique involving antibodies is the **Western blot**, which is used to detect the presence of a specific protein in cell extracts. As described in Section 12.1, proteins are separated using SDS PAGE



A. Antigen excess

No complex is possible because there are more antigens than antigen-binding sites.

B. Antibody excess

No complex is possible because there are more antigen-binding sites than antigens.

C. Equivalence

Complexes are possible when antigen numbers equal the antigen-binding sites.

Figure 1 Basis of immunoprecipitation. Only when the number of epitopes and antigen-binding sites are roughly equivalent will a large complex form and fall out of solution.

electrophoresis. The proteins are transferred (that is, blotted) from the gel onto a nitrocellulose or other membrane. The membrane is then probed with an antibody directed against a specific protein. Antibody sticks to the protein in question, and because that antibody is labeled in some way (for example, a radioactive or fluorescent probe has been added), the protein band can be visualized by autoradiography or phosphoimaging.

Figure 2 Applications based on antigen-antibody behavior. A. Precipitating aggregate. Antibodies to different antigenic determinants residing on antigen molecules can cross-link the antigens to make a huge, insoluble complex that precipitates. **B.** Purifying proteins. Removing specific proteins from a complex cell extract using immunoprecipitation. In the experiment, antibody to a specific cellular protein (shown as yellow box) is added to a lysed cell extract. Protein A beads are then added. Protein A will bind to the Fc region of the antigen-antibody complex. Centrifugation then is used to pull down the beads and the protein with it. The protein is eluted from the antibody and analyzed by SDS PAGE (Protein A remains covalently attached to the bead). **C.** Radial immunodiffusion. The agarose plate shown is embedded with antibodies specific for a certain antigen. Different concentrations of the antigen are placed in each well. The antigen diffuses into the agarose. A ring of precipitation occurs when the concentration of the diffusing antigen reaches a zone of equivalence with the antibody in the plate. The more antigen placed in the well, the larger the diameter of the precipitation ring. Well A was loaded with more antigen than wells B or C.

attaches to mast cells (**Figs. 24.9A** and **B**), again by way of its Fc region, and, like a Venus flytrap, waits until its matched antigen binds to its antigen-binding site. When surface IgE molecules of two mast cells are cross-linked by antigen, a signal is sent internally that triggers degranulation (see hypersensitivity, Section 24.8). The subsequent release of histamine and other pharmacological mediators from these granules helps orchestrate the acute inflammation that takes place during early host responses to microbial infection (that is, while the antibody response is gearing up). The system is also responsible for severe allergic hypersensitivities, such as anaphylaxis, and milder forms like hay fever (see **Fig. 24.9C**).

TO SUMMARIZE:

- **Antibodies, or immunoglobulins**, are members of the immunoglobulin superfamily.
- **Antibodies are Y-shaped** molecules that contain two heavy chains and two light chains.
- **There are five classes (isotypes) of heavy chains.** Each antibody isotype is defined by the structure of the heavy chain.
- **Each antibody molecule contains two antigen-binding sites.** Each binding site is formed by the hypervariable ends of a heavy and light chain pair.
- **The Fc portion** of an antibody can bind to specific receptors on host cells. This binding is antigen independent.

THOUGHT QUESTION 24.3 There are immune disorders in which an individual overproduces a specific class of antibody, for example hypergammaglobulinemia. How could the radial immunodiffusion technique be used to identify what class of antibody is in excess?

24.4 Humoral Immunity: Primary and Secondary Antibody Responses

After a lag period of several days following primary immunization or natural infection, antibodies begin to appear in the **serum** (the fluid that remains after blood clots). During the lag period, a series of molecular and cellular events occur that cause a distinct subset of B cells to proliferate and differentiate into antibody-secreting **plasma cells** and **memory B cells**. This process is known as the **primary antibody response**, the events of which will be discussed later. A secondary exposure to the antigen, which can take place months or years after the initial encounter, will trigger a rapid, almost instantaneous increase in the production of antibodies and is called the **secondary antibody response** (**Fig. 24.10**). This quick response occurs thanks to the memory B cells formed during the primary response. Once stimulated, memory B cells rapidly differentiate into plasma cells and secrete antibody.

The net result of the primary antibody response is the early synthesis and secretion of IgM molecules specifically directed against the antigen, also called the immunogen. Later during the primary response, a process known as **isotype switching (class switching)** occurs, by which the predominant antibody type produced becomes IgG rather than IgM (discussed shortly). Antibodies made during this primary phase, while specific for the immunogen, are actually *not* of the highest affinity. Mechanisms to increase antibody affinity occur later.

As the immunogen is cleared from the body, the levels of both IgG and IgM decline because the plasma cells that produced them die. Plasma cells have a life span of only 100 days. However, the immune system has been primed to respond more aggressively to the immunogen should it encounter it again. This is because the memory B cells produced as a result of the primary response react to anti-

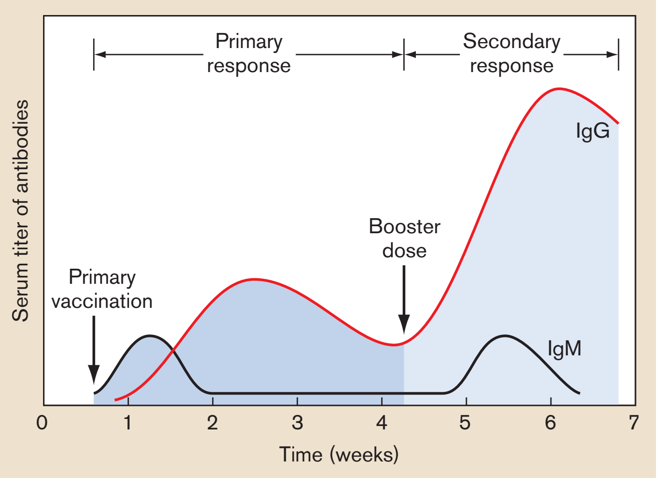

Figure 24.10 **Primary versus secondary antibody response.** Primary vaccination or infection leads to the early synthesis of IgM followed by IgG. Reinfection or a second, booster dose of a vaccine results in a more rapid antibody response comprised mainly of IgG due to memory B cells formed during the primary response.

gen more quickly and take less time to make antibody than naive B cells that had no prior exposure to the antigen.

B cells are maintained in the body because, unlike plasma cells, they continue to divide. If a person encounters the same antigen at a later time, memory B cells quickly proliferate and differentiate into plasma cells with no lag phase. Thus, memory B cells quickly initiate the secondary antibody response (or anamnestic response, from the Greek *anamnesis*, meaning "remembrance"). During the secondary response, copious amounts of IgG antibody are secreted from plasma cells made from memory B cells that have undergone isotype switching. These antibodies have a higher specificity for the antigen than the antibodies produced during the primary response. Small amounts of IgM are also produced from the few memory cells that did not undergo isotype switching during the primary response. (Most memory B cells undergo isotype switching and produce IgG rather than IgM, but a few do not.)

The speedy production of antibody during the secondary response is the basis of immunization. Pathogens can do considerable harm during the lag phase of the primary response. To avoid this, an innocuous version of a pathogen, or a harmless piece of it, can be injected into a person to trigger the primary response without producing disease (or, at worst, producing only a mild form of the illness). Immunization thus primes the immune system to respond efficiently and without delay upon encountering the real pathogen. **Table 24.2** lists a variety of viral and bacterial diseases for which immunizations are available.

THOUGHT QUESTION 24.4 The mother of a newborn was found to be infected with rubella, a viral disease. Infection of the fetus could lead to serious consequences for the newborn. How could you determine if the newborn was infected while in utero?

B-Cell Differentiation into Plasma Cells Occurs by Clonal Selection

As mentioned earlier, each B cell circulating throughout the body or ensconced in a lymphoid organ is programmed to synthesize antibody that reacts with a *single* epitope. In a process called **clonal selection**, an invading antigen will inadvertently select which B-cell clone will proliferate to large numbers and differentiate into antibody-producing plasma cells or memory B cells. In this way, large amounts of antibody specific for the antigen are made. The mechanism of clonal selection begins with the antigen binding to a matching B cell (a B cell preprogrammed to bind to that antigen) (**Fig. 24.11**).

Mature naive B cells (those that have not previously encountered antigen) can produce only IgM and IgD, both of which have identical antigen specificities. These two antibody classes are displayed like tiny satellite dishes on the B-cell surface, anchored by their Fc regions through hydrophobic transmembrane segments. These surface antibodies are the keys to stimulating the proliferation and differentiation of B cells into antibody-producing plasma cells or memory B cells. Upon binding to its corresponding antigen via these surface antibodies, the B cell is said to become **activated**, whereby it multiplies and differentiates into a plasma cell that ultimately synthesizes only one antibody isotype (for example, IgG1 or IgA2). Clonal selection has begun. (Remember that some of the activated B cells become memory B cells and do not become antibody-secreting plasma cells.)

Each membrane-bound antibody on the B cell is associated with two other membrane proteins called Igα and Igβ (these are not immunoglobulins but are designated Ig because they *associate* with the surface antibody). The complex is called the **B-cell receptor** (**Fig. 24.12**). Each B cell may have upwards of 50,000 B-cell receptors. When B cells bind antigen, they often, but not always, differentiate into plasma cells (some become memory cells). During this transformation process, antibody heavy-chain isotype switching (class switching) occurs. Class, or isotype, switching changes the class of antibodies produced. After binding to the antigen, the surface B-cell receptors begin to cluster in a process called **capping**. Capping activates Igα and Igβ to initiate a phosphorylation signal cascade directed into the nucleus (**Fig. 24.13**). The transcription factors at the end of the cascade stimulate transcription of genes that contribute to cellular activation and DNA recombination events involved in heavy-chain class switching. In addition, B-cell receptors trigger endocytosis of a bound antigen. Once inside the B cell, the antigen is degraded, processed, and repositioned on the B-cell membrane, a step that will ultimately enable T cells to directly bind and communicate with the B cell, giving the B cell "permission" to become an antibody-secreting plasma cell. How these antigens are placed on the B-cell membrane will be discussed in Section 24.6.

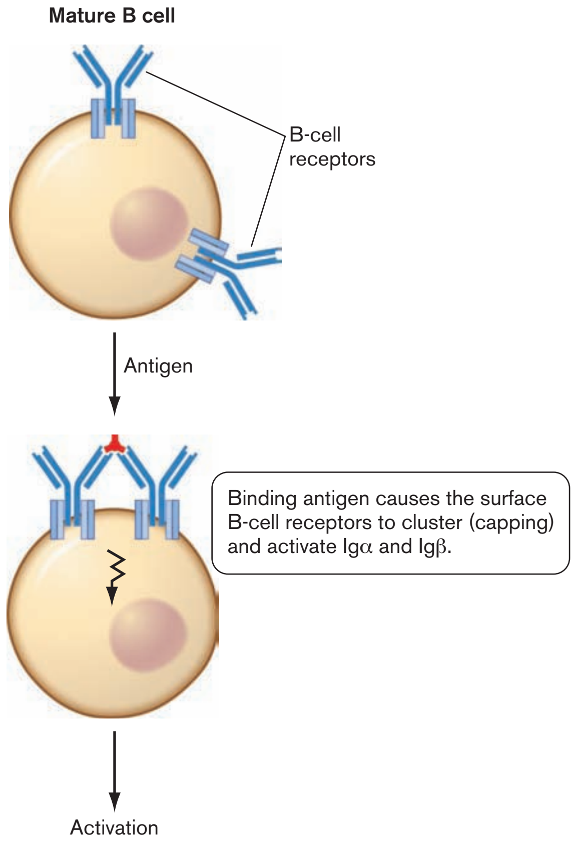
There are two routes by which antigens can stimulate B cells to differentiate into plasma cells. In one, called the T-cell-independent route, antigens that possess multiple repeating epitopes can directly cross-link B-cell receptors (the capping process), a step essential for triggering differentiation (see **Fig. 24.13**). Proteins, however, which are the largest group of antigens, do not contain multiple repeating units. Proteins possess many small, discrete, single epitopes, making cross-linking of B-cell receptors difficult. B-cell responses to these types of antigens require help from specific T cells, and this constitutes the second route to B-cell activation. Thus, B cells usually require multiple signals to initiate a primary response. How T cells help foster B-cell activation will be discussed in Section 24.6.

TO SUMMARIZE:

- **The primary antibody response** to an antigen begins when B cells differentiate into antibody-producing plasma cells and memory B cells. IgM antibodies are generally the first class of antibodies made during the primary response.
- **Isotype switching** occurs during the primary response when a subclass of B cells switches during differentiation from making IgM to making other antibody isotypes.
- **The secondary antibody response** occurs during subsequent exposures to an antigen and arises because memory B cells are activated. IgG is the predominant antibody made.



Mature B cell

Binding antigen causes the surface B-cell receptors to cluster (capping) and activate Igα and Igβ.
Activation

Figure 24.13 Capping and activation of the B cell. The capping process initiates a signal cascade that activates differentiation and proliferation of the B cell.

- **Clonal selection** is the rapid proliferation of a subset of B cells during the primary or secondary antibody response.
- **A B-cell receptor** consists of a membrane-bound antibody in association with the Igα and Igβ proteins. Binding of antigen to the B-cell receptor triggers B-cell proliferation and differentiation.

24.5 Genetics of Antibody Production

It is estimated that each human can synthesize 10^{11} different antibodies. Given that each B cell displays antibodies to only one antigenic determinant, it follows that there are 10^{11} different B cells in the body. We have learned, however, that each person possesses only about 1,000 genes or gene segments involved in antibody formation. How are 10^{11} different antibodies made from only 10^3 genes? Susumu Tonegawa was awarded the 1987 Nobel Prize in Physiology or Medicine for discovering that antibody genes can move and rearrange themselves within the genome of a differentiating cell. Three steps are involved: rearrangement of antibody gene segments (or cassettes), the random introduction of somatic mutations, and the generation of different codons during antibody gene splicing. In humans, the process of generating antibody diversity takes place constantly over a lifetime.

DNA Rearrangements in Gene Splicing and Hypermutation Generate Antibody Diversity

The first step in making a specific antibody occurs during the formation of a B cell from a progenitor stem cell in bone marrow. Immunoglobulin genes in a bone marrow stem cell consist of many gene segments that can rearrange in many possible combinations. During differentiation of a stem cell into a mature B cell, DNA segments are deleted in a process called **gene splicing**, decreasing the number of gene segments in the mature B-cell DNA. The process starts at the 5′ end of an immunoglobulin gene cluster, which corresponds to the variable (V) end of the ultimate peptide (**Fig. 24.14**). The 5′ end encodes the N-terminal end of the protein that ultimately binds antigen (that is, the antigen-binding site).

In both the heavy- and light-chain genes, there are a number of tandem gene cassettes encoding potential variable regions separated by **recombination signal sequences (RSS)**. These sequences allow recombination to bring two widely separated gene segments together. There are approximately 135 V gene segments for the heavy and light chains. The light-chain variable-region gene cluster lies upstream of a cluster of J (joint or joining)-region genes, which are ultimately used to join the variable region to the light-chain constant regions (C), whose genes reside farther downstream in the DNA. The arrangement of the heavy-chain genes is slightly more complex. In this case, the heavy-chain V cluster is followed by a D (diversity) cluster, then the J region.

NOTE: Do not confuse the J-region gene segments used to make heavy- and light-chain proteins with the J-chain protein that holds together IgM and IgA multimers. They are completely different and unrelated. The J-region gene segments do not encode the J chain.

During the formation of each mature B cell, recombination between the various recombination signal sequences deletes all but one heavy-chain variable region (see **Fig. 24.14**). As a result of the deletion, a single V segment is placed next to one D region. The structure of the particular peptide encoded by the selected V region begins to limit antigen recognition properties. At the same time, all but one D segment and one J segment are deleted. The result is the VDJ portion of the heavy chain. A similar sequence of events occurs for the light chains, only the product is VJ. **Table 24.4** illustrates the amount of

Table 24.4 Antibody diversity attributed to combinatorial joining in the human germ line.

	Number of			
Chain type	**V regions**	**D regions**	**J regions**	**Number of combinations**
λ light chains	30	0	4	30 × 4 = 120
κ light chains	40	0	5	40 × 5 = 200
Heavy chains	65	27	6	1,000 × 30 × 4 = 120,000
Number of possible antibodies	7,800 × 200 = 1.56 × 10^6			65 × 27 × 6 = 7,800
	7,800 × 120 = 0.94 × 10^6			
	1.56 × 10^6 + 0.94 × 10^6 = 2.5 × 10^6 combinations			

antibody diversity in humans that can be achieved simply by this combinatorial rejoining (a total of about 2.5×10^6 antigens can be recognized).

Where does the rest of the diversity arise? In addition to recombination, the V regions of the germ lines are susceptible to high levels of somatic mutation, resulting in the hypervariable regions. Hypermutation happens every time a memory B cell is exposed to the antigen: The memory B cells divide and the hypervariable regions mutate. Additional diversity comes from the junctions of VJ and VDJ, where recombinational splicing can occur between different nucleotides. Each gene splice event can generate additional codons, so the resulting peptides will differ by one or more amino acids. The interactions between the light- and heavy-chain hypervariable regions in an antibody form the antigen-binding sites.

In sum, a combination of gene splicing and random mutations creates the remarkable level of antibody diversity we each possess. As noted earlier, the human body is capable of responding to 10^{11} antigens; yet there are only 10^8 estimated antigens in nature. This apparent overkill suggests that the immune system is well prepared to cope with any possible antigen it could encounter. Unfortunately for humans, enterprising microbes, such as the trypanosomes that cause sleeping sickness, can stay one step ahead of the immune system by changing the structure of key surface antigens. Changing the antigenic structure of a protein renders useless those antibodies made to the previous structure.

It isn't hard to understand why multicellular organisms, like humans, need the capacity to make any one of billions of different antibodies quickly. Pathogens can undergo many generations of growth within the single life span of a human host. So humans have to generate recombinant clones of cells quickly to overcome rapidly dividing pathogens.

Isotype Class Switching Is the Result of Gene Splicing

The first stage in isotype switching involves the transition of the immature B cell in bone marrow to a mature B cell, which ends up in circulation or in lymph nodes. The immature B cell (a B cell that has not yet "seen" the antigen but has already assembled its immunoglobulin VDJ-binding site) produces only monomeric IgM as part of the B-cell receptor on its cell surface. The immature B cell ultimately differentiates into a mature B cell (a naive B cell), which then makes both IgM and IgD B-cell receptors (the naive B cell is referred to as IgM^+ IgD^+). This type of immunoglobulin class switching does not involve recombination at the DNA level, but occurs through the splicing of RNA. For instance, the immunoglobulin mRNA transcript in these cells includes both the mu- and delta-region sequences (the sequences that encode the IgM and IgD isotypes, respectively). Unprocessed, the transcript will yield IgM. However, the part of the transcript containing the mu constant region can be spliced out, in which case the processed transcript will make IgD.

The primary immune response is launched when a mature (naive) B cell receptor finds its matched antigen. As mentioned, in the early stages of the response, plasma cells produced from these B cells secrete only IgM, and an antigen-activated mature B cell will make IgM and IgD (IgM^+ IgD^+). If this activated B cell also receives appropriate signals from a certain type of T cell known as a **helper T cell (T_H cell)**, further immunoglobulin isotype switching will occur; the switched B cell may then make either IgG, IgA, or IgE. The type of switch is influenced by small peptides called **cytokines** that are secreted by helper T cells.

How does the switch occur? Notice in **Figure 24.15** that the constant-region gene segments defining different antibody heavy-chain classes are arranged in tandem *after* a VDJ region. The mechanism by which a B cell switches to make IgG (C regions gamma 1–4), IgE (C-epsilon), or IgA (C-alpha 1 and 2) is very similar to VDJ formation. Each constant segment, except delta, contains a repeating DNA base sequence called a **switch region**. Recombination between these switch regions will delete the intervening DNA between the VDJ region and one of the constant regions. The primary RNA transcript produced after this recombination event has all of its introns spliced out before translation. Because the VDJ region is the same regardless of which C_H gene is selected, whatever antibody is produced will have the same antigenic specificity as the original IgM. However, the heavy-chain switch selection process is *not* random. The type of cytokine present at the time of the switch will influence which C_H gene is selected.

Note that any heavy-chain peptide can combine with any light chain. However, a single, mature B cell can only make one type of heavy chain and one type of light chain.

THOUGHT QUESTION 24.5 Why does the delta region have no switch region?

THOUGHT QUESTION 24.6 Why do individuals with type A blood have anti-B and not anti-A antibodies?

Making Memory B Cells

As illustrated in **Figure 24.11**, an antigen-activated mature B cell may become a memory B cell. These are B cells that have already undergone class switching (that is, they are committed to making IgG) but are

Figure 24.15 **Heavy-chain class switching.** As a B cell becomes activated, a switch in antibody isotype will occur. The switch involves recombination between isotype cassettes that brings one heavy-chain constant region (Cα in the example, for IgA) in tandem with a VDJ sequence. RSS = recombination signal sequences.

very long-lived. Normally, chromosome ends (called telomeres) in every cell progressively shorten with each round of DNA replication. When they become too short, the cell dies. Memory B-cell production is associated with an increase in telomerase activity. Recall that telomerase is a reverse transcriptase that shares common ancestry with the reverse transcriptase of the virus HIV. Telomerase activity maintains the length of the telomeres and prolongs the life of the cell.

Memory B cells hypermutate the VJ regions of antibody genes (as already described). These mutations increase the affinity of the antibody produced during the secondary response. Hypermutation helps fine-tune the immune response, making it even more specific toward a given microbe. Note, too, that as an immune response progresses, antigen becomes scarce. This means that only B cells with the highest affinity antibodies as part of their B cell receptors will remain activated. The process is known as affinity maturation.

THOUGHT QUESTION 24.7 Why do immunizations lose their effectiveness over time?

TO SUMMARIZE:

- **Each B cell is programmed** to make primarily a single antibody isotype that specifically binds one epitope.
- **Antigens bound** to the surface IgM or IgD antibodies on mature B cells are internalized, degraded, and redisplayed on MHC molecules at the B-cell surface.
- **B cells differentiate** into antibody-secreting plasma cells after a helper T cell interacts with the MHC-antigen complex.

- **During the primary antibody response**, IgM is the predominant class of antibody secreted.
- **Memory B cells** rapidly proliferate and differentiate into antibody-secreting plasma cells upon a second encounter with an antigen/epitope. Most antibody made during this secondary response is IgG.
- **Diversity of idiotype** occurs via a complex series of splicing events between adjacent DNA cassettes as well as mutational events in DNA sequences encoding the hypervariable regions of heavy and light chains.

24.6 T Cells, Major Histocompatibility Complex, and Antigen Processing

The following section describes how antigens are recognized by T cells and how T cells then influence both humoral and cellular immunities. In the process, we will expand on how B cells become activated once they bind antigen, and will begin to explain why a host usually does not react against itself.

The T Cell Links Humoral and Cell-Mediated Immunity

Recall that there are two general types of immune response: humoral (antibody-based) immunity and cell-mediated immunity. Different types of infection tilt the immune response toward one or the other. B cells are clearly linked to the humoral immune system because they ultimately become plasma cells that make antibodies. T cells, on the other hand, serve as a nexus, or link, between humoral and cell-mediated responses. They play integral roles in both antibody production and cell-mediated immunity. Although derived from the same progenitor stem cell as B cells, T cells develop in the thymus (rather than in the bone marrow, where B cells develop) and contain surface antigens different from those of B cells. In general, T cells can be divided into two broad groups differentiated by the type of cellular differentiation (CD) proteins present on their cell surfaces (**Table 24.5**).

One of the two major types of T cells has already been mentioned: the so-called helper T cells (T_H cells). The second major type of T cells are known as **cytotoxic T cells (T_C cells)**. Helper T cells display the surface antigen CD4, while cytotoxic T cells display CD8.

Helper T cells come in three types: T_H1 cells, which assist in the activation of cytotoxic T cells; T_H2 cells, which stimulate B-cell differentiation into plasma cells; and T_H0 cells, which are really undifferentiated precursors of T_H1 and T_H2 cells. Cytotoxic T (T_C) cells are the "enforcers" of the cell-mediated immune response. They destroy the membranes of host cells infected with viruses or bacteria. The ratio between the number of T_H1 cells and T_H2 cells produced during an infection affects whether the immune response will lean more toward humoral (antibody, T_H2) or cell-mediated (T_H1) immune mechanisms. As will be described, different cytokines produced during infection influence whether an activated T_H0 cell develops into a T_H1 or T_H2 cell.

Why are T_H and T_C cells different? The reasons are many but it all starts with their relative abilities to recognize two different protein complexes that are present on antigen-presenting cells. These complexes are called the major histocompatibility proteins.

The Major Histocompatibility Complex (MHC) Is Critical to the Immune System

The factors affecting immune responsiveness are many, but the major histocompatibility complex (MHC) proteins encoded by a set of genes on a single chromosome, play a particularly important role. MHC proteins differ between species and among individuals within a species. They help determine whether a given antigen is recognized as coming from the host (a self antigen) or from another source (a foreign antigen), in a phenomenon called histocompatibility. Thus, the name major histocompatibility complex. There are two classes of MHC molecules found on cell surfaces. Both classes belong to the immunoglobulin family of proteins, but they are not immunoglobulins. Class I MHC receptors (**Fig. 24.16A**) are found on all nucleated cells. Class II MHC molecules (**Fig. 24.16B**), on the other hand, have a more limited distribution, principally on antigen-presenting cells.

Table 24.5 Major classes of T cells.

T-cell type	Coreceptor	MHC restriction	Cytokines produced	Major function
Helper T cell				
T_H1	CD4	Class II	IFN-γ, IL-2, TNF-β	Activating cytotoxic T cells
T_H2	CD4	Class II	IL-4, IL-5, IL-6	B-cell helper
Cytotoxic T cell	CD8	Class I	IFN-γ, TNF	Killing virus-infected and cancer cells

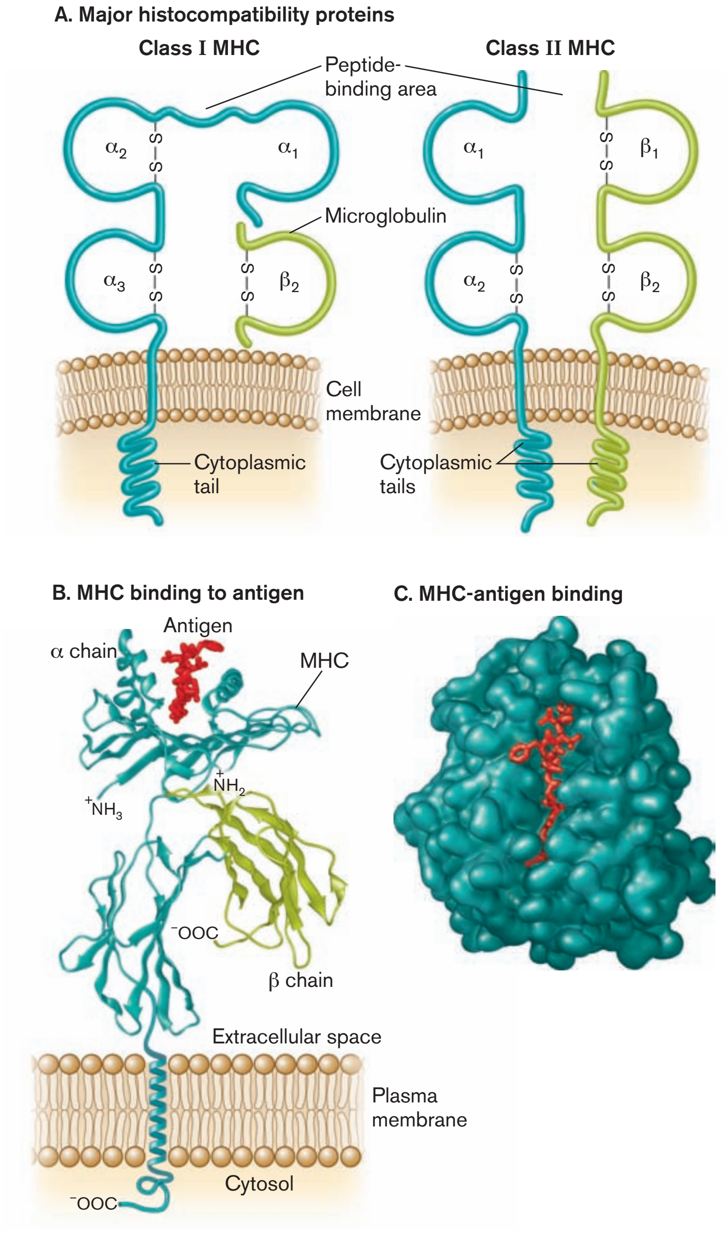

Figure 24.16 Major histocompatibility proteins. **A.** MHC Class I molecules are composed of a 45-kDa chain and a small peptide called β_2-microglobulin (12 kDa). MHC Class II molecules contain an alpha chain (30-34 kDa) and a beta chain (26–29 kDa). The peptide-binding regions of both classes show variability in amino acid sequence that yield different shapes and grooves. Peptide antigens nestle in the grooves and are held there awaiting interaction with T-cell receptors. CD8 T cells recognize antigen peptides associated with class I molecules, while CD4 T cells recognize peptides bound to class II molecules. **B.** Antigen binding to an MHC. **C.** Top view of antigen (red) nestled in the MHC peptide-binding site. (PDB code: 1bii)

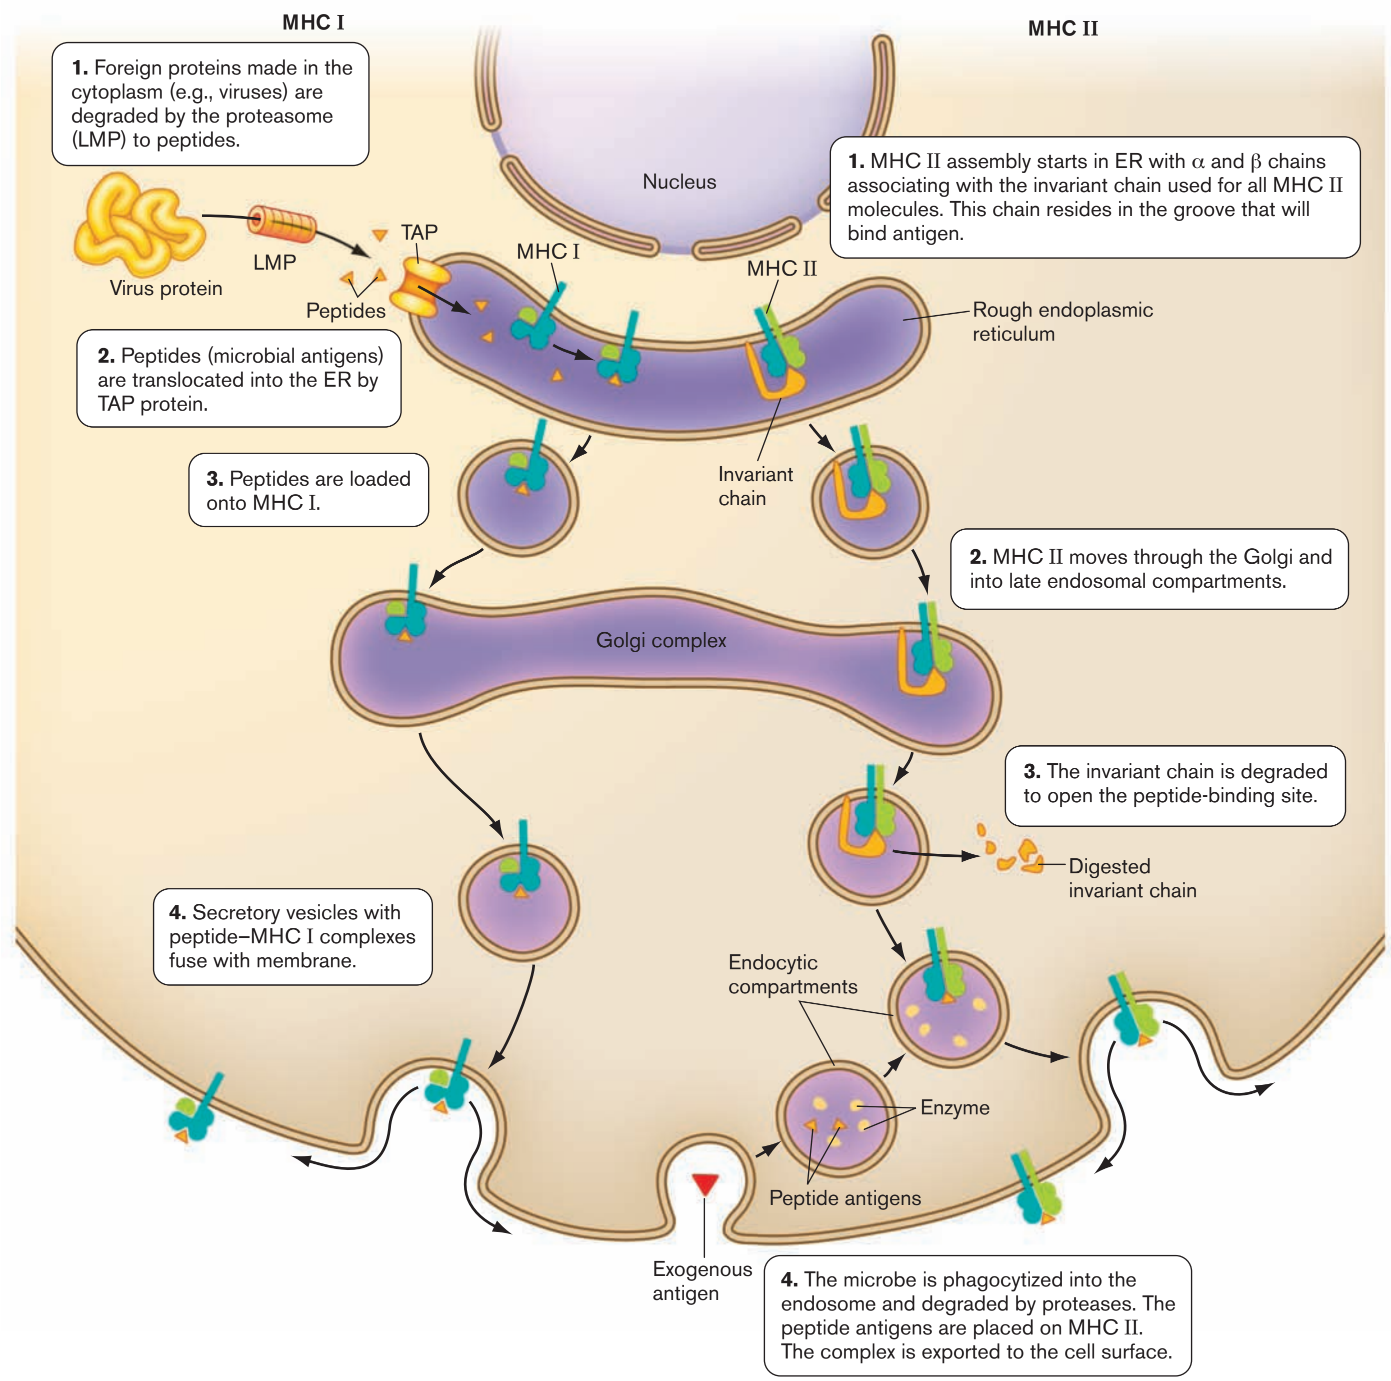
They are always expressed by the antigen-presenting dendritic cells and B cells, for example, but can also be made by macrophages under the influence of cytokines such as interferon-gamma (IFNγ). The salient feature of MHC molecules is that they bind antigen, presenting it on the cell surface. The antigen-binding clefts of different MHC molecules differ markedly and have distinct binding affinities for different antigenic peptides.

MHC molecules are critical to the immune system because T cells only recognize antigens associated with MHC proteins; they do not recognize free-floating antigens. (B cells, on the other hand, *do* recognize free-floating antigens.) Once a T cell recognizes an antigen-presenting cell with a foreign antigen attached to an MHC molecule, the T cell becomes activated and in turn activates the immune system. It is important to note that not all potentially antigenic peptides can be recognized in one animal. An animal will not respond to an antigen if its antigen-presenting cells lack the MHC molecule needed to bind that antigen. This is the basis of tolerance to the self antigens present on an animal's own tissues. Tolerance means your immune system does not launch an immune response to your own antigens. How tolerance to self-antigens develops is described in **Special Topic 24.2**.

Antigen Processing and Presentation Occur by Two Paths

How are foreign antigens placed, or presented, on host cell surfaces? In the initial stages of an immune response, microbes either infect (as with viruses) or are engulfed by (as with bacteria) antigen-presenting cells. Inside the APCs, foreign proteins are degraded into smaller pieces (for example, converted to peptides). These smaller pieces are placed within MHC-binding clefts and transported back to the cell surface. Whether an antigen peptide binds to class I or class II molecules generally depends on how the antigen initially entered the cell (**Fig. 24.17**). Antigens synthesized within the cytoplasm of an APC (called endogenous antigens), as would occur during infections with viruses and intracellular bacteria, will attach to class I MHC molecules on the endoplasmic reticulum and are moved to the cell surface. Antigens produced outside of the APC (called exogenous antigens), as are most bacterial antigens, will enter the cell via phagocytosis and attach to class II MHC molecules transported to the acidic phagosome or lysosome (**Fig. 24.17**, right side). The MHC class II–peptide complex is then carried to the cell surface. Once the antigen is presented on the APC cell surface, T cells can interact with it via the T-cell receptors. Interactions between antigen-presenting cells and naive T cells occur within the lymph nodes, the spleen, or Peyer's patches in the gut. So the APCs must make their way to those locations. How T cells then distinguish between MHC I and MHC II presentation is explained later.



MHC I

Peptide antigens
Exogenous antigen

1. Foreign proteins made in the cytoplasm (e.g., viruses) are degraded by the proteasome (LMP) to peptides.

2. Peptides (microbial antigens) are translocated into the ER by TAP protein.

3. Peptides are loaded onto MHC I.

4. Secretory vesicles with peptide–MHC I complexes fuse with membrane.

1. MHC II assembly starts in ER with α and β chains associating with the invariant chain used for all MHC II molecules. This chain resides in the groove that will bind antigen.

2. MHC II moves through the Golgi and into late endosomal compartments.

3. The invariant chain is degraded to open the peptide-binding site.

4. The microbe is phagocytized into the endosome and degraded by proteases. The peptide antigens are placed on MHC II. The complex is exported to the cell surface.

Figure 24.17 Processing and presentation of antigens by antigen-presenting cells on class I and class II MHC proteins. Microbial proteins made in the host cytoplasm (upper left) are degraded and peptides are placed on MHC class I molecules in the ER. Microbial proteins made outside the cell (lower center) are endocytosed, degraded in the endosome, and placed on MHC class II molecules. TAP = transporter of antigen peptides; LMP = low-molecular-mass polypeptide component of the proteasome.

Special Topic 24.2 T Cells That Recognize Self Too Strongly Are Weeded Out in the Thymus

Greek mythology tells of Narcissus, a young man punished by the gods for scorning the women who fell in love with him. One day Narcissus saw his own beautiful reflection in a pool of water. He unwittingly fell in love with his own reflection, fell into the pool, and drowned. Narcissus's inability to identify his own image is tantamount to the inherent danger posed by an immune system. To avoid disaster, immune systems must be able to distinguish what is self (meaning antigens present in our own tissues) from what is not self. Chapter 23 discusses how innate immunity accomplishes this task, in part through the use of pattern recognition proteins such as the Toll-like receptors. Equally important are the ways adaptive immune mechanisms avoid recognizing self. At the outset of development, the immune system is fully capable of reacting against self.

One protective mechanism the body uses to avoid attacking itself is to delete any T cells that react against self antigens. In humans, this occurs throughout life as new T cells are made. In this process, T cells undergo a two-stage selection or "education" process in the thymus to recognize self versus nonself. This education process involves the use of self antigens, not foreign antigens. T cells bearing T-cell receptors (TCRs) that *weakly* recognize self MHC proteins displayed on thymus epithelial cells are allowed to survive (**positive selection**). These T cells leave the thymus to seed secondary lymphoid organs such as the spleen. T cells in the thymus that recognize self MHC peptides *too strongly*, however, are killed, or deleted from the population (**negative selection**). Almost 95% of T cells entering the thymus die during these positive and negative selection processes.

The positive selection process is needed because T cells must be able to recognize self MHC to "see" the associated antigen. Antigen bound to MHC actually increases the affinity to the matched TCR. If our T-cell repertoire included cells that bound self MHC too tightly, then our T cells would constantly react to our own MHC molecules, regardless of what antigen peptides were attached.

In contrast to negative selection for B cells, which occurs in bone marrow, T-cell education is limited to the thymus. But, if the thymus only expresses thymus antigens, how can T cells that respond to antigens expressed on other host cells (for example, heart cells) be removed? The answer is a special gene activator in thymus cells that allows them to synthesize *all* human proteins in small amounts. This expression is necessary to complete T-cell education within the thymus.

You might ask how someone who has had their thymus removed (a treatment for myasthenia gravis) can live if the organ is critical for T-cell maturation and for deleting self-reactive T cells. Actually, within a few years after birth, the thymus begins to lose its utility such that very little function remains in adults. Research has shown that some T-cell maturation can occur extrathymically in secondary lymphoid tissues, although not as efficiently as in the thymus. This is at least part of the reason why children and adults with thymectomies are able to live relatively normal lives. The situation is more serious with newborns who have had their thymuses removed. Newborns have not had sufficient time to populate their secondary extrathymic lymphoid organs with T cells.

T-Cell Receptors Bind Antigens on Antigen-Presenting Cells (APCs)

T-cell receptors (TCRs) are antigen-binding molecules (not immunoglobulins) present on the surfaces of T cells (**Fig. 24.18**). These receptors do not bind *soluble* antigen. A TCR, in general, will only bind to antigens attached to MHC surface proteins that are present on antigen-presenting cells. However, the TCRs of cytotoxic T cells can also bind viral antigens present on any virus-infected cells, whether or not that cell is normally considered an APC.

The T-cell receptor is composed of several transmembrane proteins. The part used to recognize antigen is composed of two molecules, alpha and beta. Much like the immunoglobulins, the alpha and beta proteins of the TCR are formed from gene clusters that undergo gene rearrangements. The diversity of TCR antigen receptors comes from random recombinations of various V, D, and J segments (analogous to, but different from, the immunoglobulin genes) and to variability in the precise joining of segments. There is no hypermutation, however.

The TCR alpha and beta proteins are found in a complex with four other peptides; together these form the CD3 complex. When stimulated, these ancillary CD3 complex proteins recruit and activate intracellular protein kinases and launch a phosphorylation cascade that triggers proliferation of the T cell.

Activation of T_H0 Helper Cells

Figure 24.19 summarizes the steps that lead to T-cell activation in the lymph node and highlights how acti-

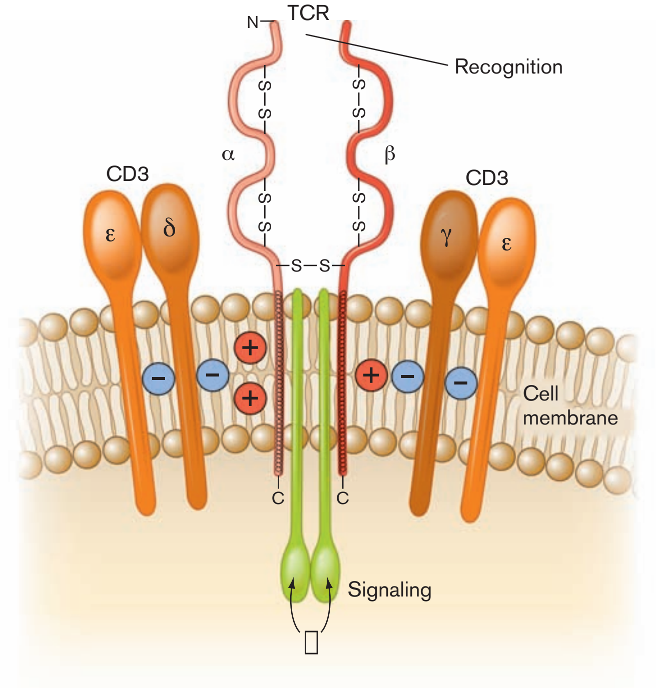

Figure 24.18 The T-cell receptor (TCR) and CD3 complex. The T-cell receptor proteins are associated with CD3 proteins at the cell surface. Antigen binds to the alpha and beta subunits. The positive and negative charges holding the complex together come from amino acids in the peptide sequences. Once bound to antigen, the complex transduces a signal into the cell. This signal triggers T-cell proliferation.

vated T cells influence the two arms of adaptive immunity: humoral and cellular. We will refer to **Figure 24.19** often within the next sections.

Two molecular signals are required to activate T cells. The first step, regardless of the T-cell type, involves the cross-linking of T-cell receptors by antigen-MHC proteins on antigen-presenting cells (**Fig. 24.19**, step 1). In the case of T_H0 cells, this involves class II MHC complexes. But this first step alone is not enough to activate a T cell. A second signal is required by T_H cells, which involves the binding of a CD28 molecule present on the T-cell surface to a molecule called B7 protein on the APC cell surface (**Fig. 24.19**, step 2). Different cytokines produced during infection will then convert activated T_H0 cells to T_H1 or T_H2 cells (**Fig. 24.19**, steps 3 and 4). Activation of cytotoxic T cells (T_C cells) will be examined later.

B-Cell Activation Revisited

As with T cells, B cells need two signals to become activated. The first signal, described earlier, occurs when antigen cross-links B-cell receptors on B-cell membranes (in the process called capping). But to become activated during a primary immune response, B cells usually require helper T cells. But not just any helper T cell can stimulate a B cell; specificity is involved. How does a B cell gain specific T-cell help? T cells (the T_H2 type) know which B cells to help via their T-cell receptors. As part of the B-cell capping mechanism, some antigen bound by B-cell receptors becomes internalized, to be processed and presented back on the B cell's surface MHC receptor (see **Fig. 24.17**, step 4). T_H2 cells that are activated by dendritic cells presenting antigen A, for instance, can use their T-cell receptor to bind to antigen A presented on the matched B cells. This contact allows CD40 on the B cell to bind CD154 on the T cell, an interaction that triggers the second intracellular signal needed for B-cell activation (**Fig. 24.19**, step 5).

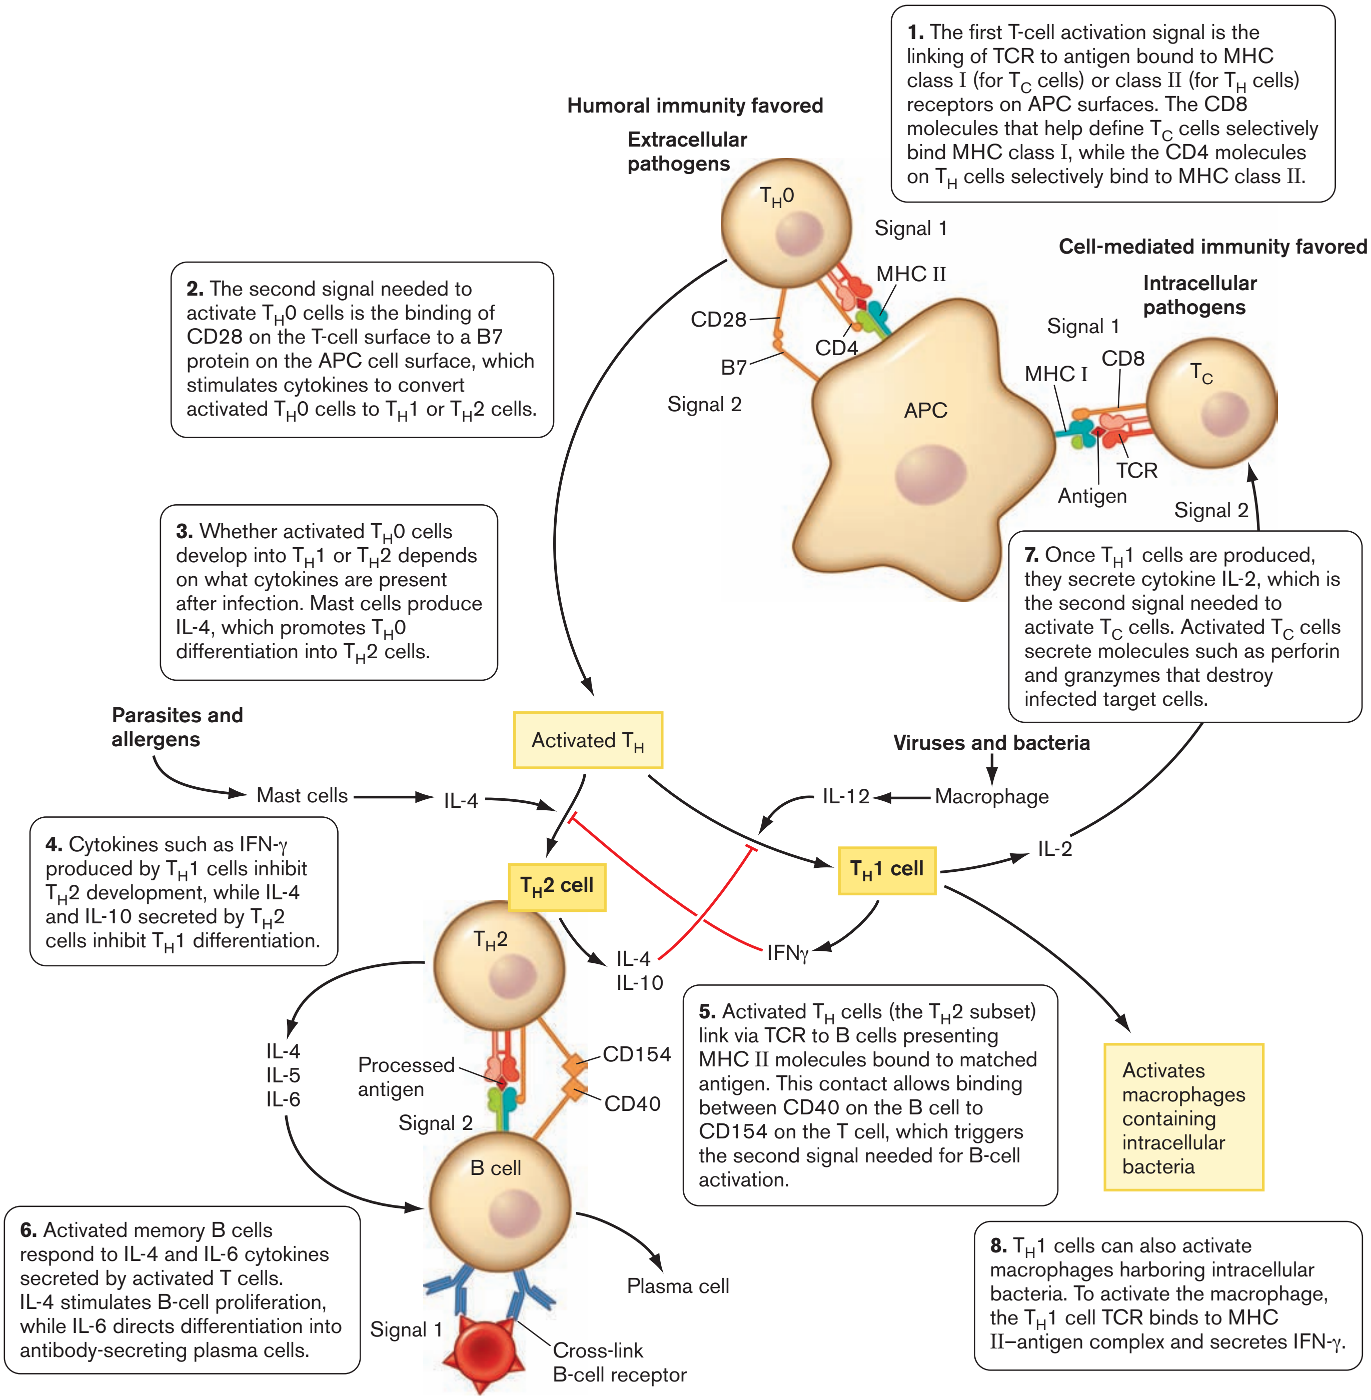
During the secondary response, B cells still need help to become plasma cells but do not need direct contact with helper T cells. Memory B cells that have antigen bound to their B-cell receptors can respond to the soluble IL-4 and IL-6 cytokines secreted by activated helper T cells without having direct contact with the T_H cell. IL-4 stimulates B-cell proliferation, while IL-6 directs differentiation into antibody-secreting plasma cells (**Fig. 24.19**, step 6).

Production of Cytotoxic T cells

As with helper T cells, the first signal needed to activate cytotoxic T cells is the binding of the TCR to an antigen-MHC complex (in this case, MHC class I) on an antigen-presenting cell (see **Fig. 24.19**, step 1). **Figure 24.20** shows a closer look at the interaction between an antigen-presenting cell and a CD8 cytotoxic T cell. This interaction occurs in a lymph node. As with the production of helper T cells, this interaction alone will not activate the cytotoxic T cell. The second signal needed here is actually a cytokine called IL-2 produced by the T_H1 class of helper T cells (**Fig. 24.19**, step 7). The first signal (the TCR–antigen–MHC I complex) initiates the synthesis of IL-2 receptors on the T_C cell surface. Upon subsequent binding of IL-2, the T_C cell gains cytotoxic activity, after which it can leave the lymph node, travel to the site of infection, and kill any cell bearing the same peptide–MHC class I complex (for example, cells infected with the same virus that triggered T_C production) (**Fig. 24.21**). The B7-CD28 interaction that was needed to activate helper T cells is not required for T_C cell activation but can help.

Superantigens Do Not Require Processing to Activate T Cells

Normal antigens require processing by antigen-presenting cells. Each peptide produced by antigen processing is ultimately recognized in the context of



1. The first T-cell activation signal is the linking of TCR to antigen bound to MHC class I (for T_C cells) or class II (for T_H cells) receptors on APC surfaces. The CD8 molecules that help define T_C cells selectively bind MHC class I, while the CD4 molecules on T_H cells selectively bind to MHC class II.

2. The second signal needed to activate T_H0 cells is the binding of CD28 on the T-cell surface to a B7 protein on the APC cell surface, which stimulates cytokines to convert activated T_H0 cells to T_H1 or T_H2 cells.

3. Whether activated T_H0 cells develop into T_H1 or T_H2 depends on what cytokines are present after infection. Mast cells produce IL-4, which promotes T_H0 differentiation into T_H2 cells.

4. Cytokines such as IFN-γ produced by T_H1 cells inhibit T_H2 development, while IL-4 and IL-10 secreted by T_H2 cells inhibit T_H1 differentiation.

5. Activated T_H cells (the T_H2 subset) link via TCR to B cells presenting MHC II molecules bound to matched antigen. This contact allows binding between CD40 on the B cell to CD154 on the T cell, which triggers the second signal needed for B-cell activation.

6. Activated memory B cells respond to IL-4 and IL-6 cytokines secreted by activated T cells. IL-4 stimulates B-cell proliferation, while IL-6 directs differentiation into antibody-secreting plasma cells.

7. Once T_H1 cells are produced, they secrete cytokine IL-2, which is the second signal needed to activate T_C cells. Activated T_C cells secrete molecules such as perforin and granzymes that destroy infected target cells.

8. T_H1 cells can also activate macrophages harboring intracellular bacteria. To activate the macrophage, the T_H1 cell TCR binds to MHC II–antigen complex and secretes IFN-γ.

Figure 24.19 Summary of the activation of humoral and cell-mediated pathways. Intracellular pathogens generally activate cell-mediated immunity by stimulating cytotoxic T cells. Extracellular pathogens tend to activate humoral immunity. The balance between cell-mediated and humoral immune responses to a given infection is regulated by the balance between the production of T_H1 (cell-mediated) versus T_H2 (antibody) helper cells. This balance is influenced by whether the foreign antigen was made by intracellular pathogens (T_H1-favored) or extracellular pathogens (T_H2-favored), and whether antigen presentation (APC) occurred through a macrophage (T_H1-favored) or a mast cell (T_H2-favored). T_H1 cells will encourage activation of cytotoxic T cells (cell-mediated immunity; best for killing intracellular pathogens), while T_H2 promotes antibody production (humoral immunity, best for attacking extracellular pathogens). See text for more details.

self MHC molecules by a specific cognate T-cell receptor. However, when an antigen is introduced into a host, there are only a few T cells with the proper TCR needed to recognize that antigen—in the range of 1–100 cells in a million. Proliferation of the T cells through antigen-dependent activation increases that number and increases the immune response to that antigen.

Some proteins, called **superantigens**, stimulate T cells much more rapidly by bypassing the normal route of antigen processing. In fact, recognition as an antigen is not even involved. Certain microbial toxins, such as staphylococcal toxic shock syndrome toxin (TSST), are actually superantigens. These proteins, as illustrated in **Figure 24.22**, simultaneously bind to the outside of T-cell receptors on T cells and to the MHC molecules on antigen-presenting cells (for example, macrophages). This joining of the T cell and macrophage activates more T cells than a typical immune reaction, and stimulates release of massive amounts of inflammatory cytokines from both cell types.

The effect of superantigens can be devastating because cytokines like tumor necrosis factor can overwhelm the host immune system regulatory network and cause severe damage to tissues and organs. The result is disease and sometimes death. Jim Henson, the creator of Kermit the frog and other Muppet characters, died in 1990 from complications of pneumonia caused by a potent superantigen produced by *Streptococcus pyogenes*. This example is but one of many ways that overreaction of the immune system causes morbidity (disease) and mortality (death), more so than the direct effects of the pathogen involved.

The CD4 and CD8 Surface Proteins Help T Cells Differentiate between MHC I and MHC II Surface Proteins

One question not yet addressed is how do the TCRs on T_C and T_H0 cells "know" to respectively bind MHC class I and class II antigen complexes? The answer is based on the different clusters of cellular differentiation (CD) molecules displayed on T_C and T_H0 cell surfaces. The surface CD proteins CD8 and CD4 help T cells distinguish between MHC class I and class II molecules on antigen-presenting cells. The CD8 molecules on T_C cells selectively bind MHC class I while CD4 molecules on T_H cells selectively bind to MHC class II (see **Fig. 24.19**, step 1). Antigens presented on class I MHC molecules generally arise from intracellular pathogens such as viruses and some bacteria, situations that will require cell-mediated immunity for resolution. In contrast, antigen peptides presented on class II MHC molecules originate from extracellular infections and are only recognized by CD4 T_H cells.

Once activated, cytotoxic CD8 T_C cells secrete molecules such as **perforin** and **granzymes** that destroy infected target cells (similar to natural killer cells; discussed in Section 23.7). Perforin forms a pore in target cells that is used to deliver toxic enzymes (granzymes).

Figure 24.21 Cytotoxic T-cell action. **A.** An antigen-presenting cell presenting viral peptide on MHC I surface molecules interacts with and activates a cytotoxic T cell in a lymph node. **B.** The activated T_C cell then leaves the lymph node and migrates to the site of infection where it can recognize the viral peptide presented on the MHC class I receptor on an infected cell. This interaction authorizes the cytotoxic T cell to kill the infected cell.

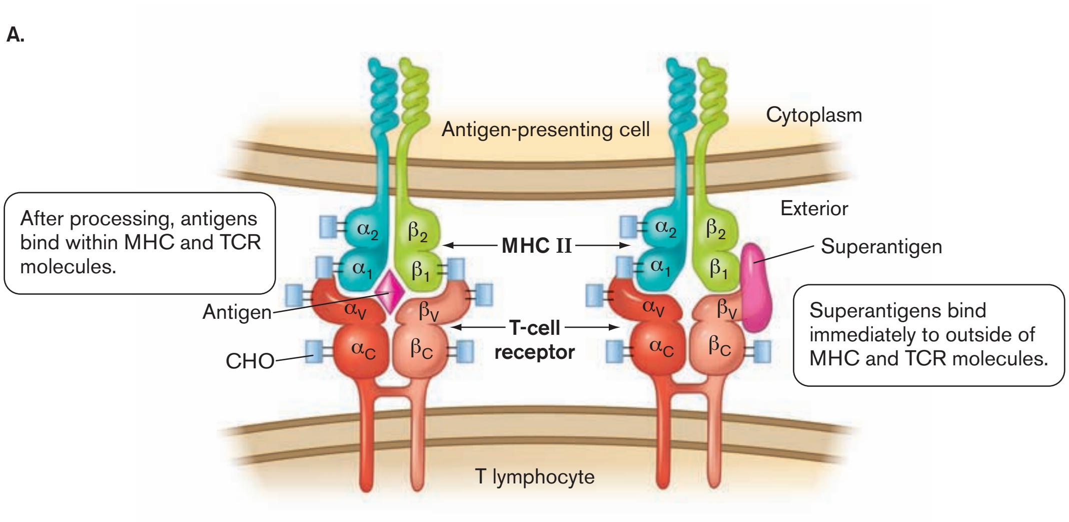

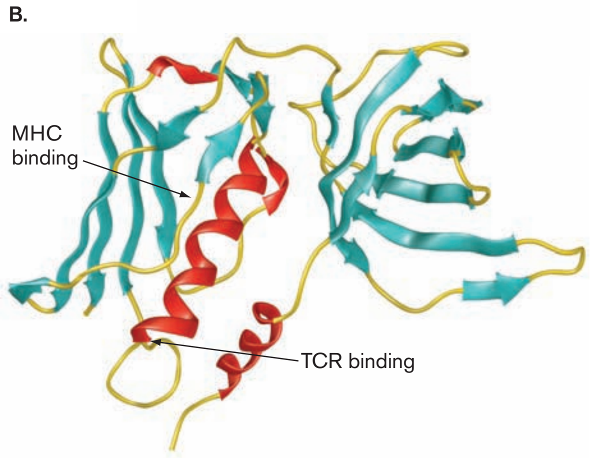

Figure 24.22 Superantigens. **A.** The difference between presentation of antigen and superantigen. Antigen presentation requires the antigen to bind within the binding pockets of MHC and TCR molecules. Superantigens do not require processing. They can bind directly to outer aspects of the TCR and MHC proteins, linking and activating the two cell types. **B.** Staphylococcal toxic shock syndrome toxin is one example of a potent superantigen. Alpha helices are shown as red ribbons, while sections of the beta sheet are shown as blue ribbons. (PDB code: 2qil)

Because they directly attack host cells, CD8 T_C cells are the major "enforcers" of the cellular immune system, along with macrophages and NK cells.

Why does the presentation of antigens on MHC I molecules activate cytotoxic T cells rather than B cells and antibody production? A major reason is that intracellular pathogens (for example, viruses) hide inside host cells, where they are protected from antibody. Consequently, these pathogens are best killed when the harboring host cell is also sacrificed (via cellular immunity). Because class I MHC molecules are found on all nucleated cells, any infected cell can potentially activate T_C cells, converting them to cytotoxic T cells that ultimately kill the infected cell (T_C cells are not actually cytotoxic until they are activated). The infected host cell is sacrificed for the good of the whole animal, human or otherwise.

Whereas antigens presented on class I MHC molecules elicit only cell-mediated immunity, antigens presented on class II molecules can actually stimulate either arm of the immune system. In contrast to CD8 T_C cells, CD4 helper T cells do not directly kill host cells. Instead, activated CD4 T_H cells release various cytokines called lymphokines that, among other things, attract additional white cells to the area. **Table 24.6** lists a fraction of the many different cytokines produced by various cell types and their influence over the immune system. Activated T_H1 cells secrete cytokines that stimulate the cytotoxic T_C cells of the cellular immune system (see **Fig. 24.19**, step 7), whereas activated T_H2 cells directly interact with the class II MHC–antigen peptide complexes on B cells, as described earlier, and stimulate those cells to differentiate and produce antibody (see **Fig. 24.19**, step 5).

AIDS (acquired immunodeficiency syndrome) provides a vivid and tragic illustration of the importance of CD4 T cells in immunity. The human immunodeficiency virus (HIV) binds to CD4 molecules and thus is able to invade and infect $CD4^+$ T cells. As the disease progresses, the number of CD4 T cells declines below its normal level of about 1,000 per microliter. When the number of CD4 T cells drops below 400 per microliter, the ability of the patient to mount an immune response declines dangerously. Not only does the patient become hypersusceptible to infections by pathogens, but the individual becomes susceptible to infection by commensal organisms as well. Most patients actually die from these opportunistic infections.

Table 24.6 Select cytokines that modulate the immune response.

Cytokine	Sample sources	General functions
IL-1	Many cell types, including endothelial cells, fibroblasts, neuronal cells, epithelial cells, macrophages	Affects differentiation and activity of cells in inflammatory response; central nervous system; acts as endogenous pyrogen
IL-2	T_H1 cells	Stimulates T-cell and B-cell proliferation
IL-3	T cells, mast cells, keratinocytes	Stimulates production of macrophages, neutrophils, mast cells, others.
IL-4	T_H2 cells, mast cells	Promotes differentiation of CD4 and T cells into T_H2 helper T cells; promotes proliferation of B cells
IL-5	T_H2 cells	Acts as a chemoattractant for eosinophils; activates B cells and eosinophils
IL-6	T_H2 cells, macrophages, fibroblasts, endothelial cells, hepatocytes, neuronal cells	Stimulates T-cell and B-cell growth; stimulates production of acute-phase proteins
IL-8	Monocytes, endothelial cells, T cells, keratinocytes, neutrophils	Chemoattracts PMNs; promotes migration of PMNs through endothelium
IL-10	T_H2 cells, B-cells, macrophages, keratinocytes	Inhibits production of IFN-γ, IL-1, TNF-α, IL-6 by macrophages
IFN-α/β	T cells, B cells, macrophages, fibroblasts	Promotes antiviral activity
IFN-γ	T_H2 cells, cytotoxic T cells, NK cells	Activates T cells, NK cells, macrophages
TNF-α	T cells, macrophages, NK cells	Exerts wide variety of immunomodulatory effects

The MHC Restriction Rule Limits T-Cell Reactivity

As noted previously, T cells can only recognize antigens complexed to an MHC molecule. Actually, it must be a self, MHC molecule. The MHC molecules of each person are unique. Thus, T cells from one individual normally do not recognize peptides placed on antigen-presenting cells from another individual, a property known as **MHC restriction**. CD4 T_H cells are class II MHC restricted, while CD8 T_C cells are class I restricted. Rolf Zinkernagel (University of Zurich) and Peter Doherty (St. Jude Children's Hospital, Memphis) discovered this phenomenon in 1976 with a simple yet profoundly insightful experiment. They demonstrated that mouse cytotoxic T cells would kill only virus-infected target cells that possessed the same MHC surface protein. If the infected target cell came from a different strain of mouse containing a different MHC protein, the infected target cell was spared. Thus, there are two components to T-cell recognition: self and nonself. The self component comes from the MHC receptor, while the nonself component comes from the pathogen. This concept won Zinkernagel and Doherty the 1996 Nobel Prize in Physiology or Medicine.

Cytokines Tip the Balance between Cell-Mediated Immunity and Antibody Production

We have already discussed how cytokines made from T_H1 cells help activate cells involved with cell-mediated immunity (the CD8 T_C cells, macrophages, and natural killer cells) and that other cytokines from T_H2 cells trigger B cells to class-switch their immunoglobulin. But what determines whether T_H1 or T_H2 cells predominate during an infection? Part of the answer is found in the contingent of cytokines generated by macrophages or mast cells during different types of infection. Infections by viruses and bacteria favor the production of T_H1 cells, whereas allergens and parasites favor differentiation to T_H2. Early in an infection, bacteria and viruses stimulate cells of the innate immune system (macrophages and natural killer cells) to produce cytokines that tilt development of T_H0 into T_H1 (one such cytokine is IL-12). During interactions with an allergen, on the other hand, mast cells produce IL-4, which promotes T_H0 differentiation into T_H2 cells (see **Fig. 24.19**, step 3).

There is also cross-inhibition of T_H1 and T_H2 development. Cytokines such as interferon-gamma (IFN-γ) produced by T_H1 cells inhibit T_H2 development, while interleukins IL-4 and IL-10 secreted by T_H2 cells inhibit T_H1 differentiation (**Fig. 24.19**, step 4). As a result, once the immune system starts to go down one pathway, the other pathway is held back. But this is not an all-or-none response. For instance, a viral infection will also result in T_H2 cells that stimulate antibody production. The tilt toward T_H1 or T_H2 predominance occurs because the body realizes which pathway, cell mediated (T_H1) or humoral (T_H2), will more effectively clear a particular infection.

Microbial Evasion of Adaptive Immunity

Efficient as our immune system is, numerous viral and bacterial pathogens have developed effective means for avoiding the adaptive immune response. Many viruses produce proteins that downregulate production of class I MHC on infected cell surfaces. This will limit antigen presentation, since MHC I is needed for that process. On the other hand, losing MHC I should expose the infected host cell to natural killer cells because NK cells attack peers that lack MHC I (discussed in Section 23.7). To surmount this obstacle, it appears that human cytomegalovirus places a decoy MHC I-like molecule on the surface of infected cells. These decoys are thought to bind inhibitory receptors on NK surfaces that block NK cell cytotoxicity.

Bacteria, like viruses, are masters of illusion when it comes to the immune system. A major cause of gastric ulcers, *Helicobacter pylori* expresses proteins from a cluster of pathogenicity genes that trigger apoptosis of T cells. (Apoptosis is a programmed cell death.) Other bacteria have evolved mechanisms that interfere with signal transduction pathways controlling the expression of cytokines. For example, YopP from *Yersinia enterocolitica*, one cause of gastroenteritis, inhibits a specific signal transduction pathway needed to produce TNF, IL-1, and IL-8. Thus, *Yersinia* avoids the detrimental effects of those pro-inflammatory cytokines. Another method of immune avoidance is employed by various mycobacteria, some of which cause tuberculosis and leprosy (**Fig. 24.23**). These bacteria induce the production of anti-inflammatory cytokines, which dampen the immune response. Mycobacterium-infected macrophages produce IL-6, which inhibits T-cell activation, and IL-10, which downregulates the production of MHC II molecules needed for specific activation of T cells. Fortunately for humans, in most cases the immune system catches on to these tricks and through redundant humoral and cellular mechanisms manages to resolve these infections.

Activated T_H1 Cells Can Also Activate Macrophages

Macrophages, too, must be activated to become highly effective killers of microbes. Activation of macrophages also requires two signals. One activation pathway involves interferon-gamma (IFN-γ) produced by nearby infected or damaged cells, followed by binding of the macrophage to lipopolysaccharide (LPS) or other microbial components. Once activated, the macrophage becomes highly aggressive in terms of phagocytosis and increases production of numerous antimicrobial reactive oxygen intermediates.

As noted earlier, some microorganisms such as mycobacteria, the causative agents of tuberculosis and leprosy, are intracellular pathogens that grow primarily in the phagolysosomes of macrophages. There they are shielded from the effects of both antibodies and cytotoxic T cells. These pathogens live in the usually hostile environment of the phagocyte either by inhibiting the fusion of lysosomes to the phagosomes in which they grow or by preventing the acidification of the vesicles needed to activate lysosomal proteases. However, macrophages can rid themselves of these pathogens if the macrophage is activated by a T_H1 cell (see **Fig. 24.19**, step 8). Macrophages, even unactivated, are able to process some of the intracellular bacteria and place antigen from them on their class II MHC molecules. T_H1 cells then activate these macrophages though binding of their TCR molecules to the macrophage MHC II–antigen complex and by secreting interferon-gamma. The activated macrophages can then kill any bacteria that may be growing within them.

Because activated macrophages are such effective assassins of microbial pathogens, why are macrophages not always kept in an active state? A major reason is that once activated, macrophages also damage nearby host tissue through the release of reactive oxygen radicals and proteases. Thus, effective killing of microbial pathogens comes at the expense of host tissue damage.

TO SUMMARIZE:

- **The major histocompatibility complex** consists of membrane proteins with variable regions that can bind antigens. Class I MHC molecules are on all nucleated cells, while antigen-presenting cells contain both class I and class II MHC molecules.
- **Antigen-presenting cells (APCs)** such as dendritic cells present antigens synthesized during an intra-

Right image is the same cell viewed by fluorescence microscopy. *M. bovis* is carrying green fluorescent protein. The macrophage was stained for F-actin (red) and nucleus (blue).

cellular infection on their surface class I MHC molecules, but place antigens from engulfed microbes or allergens on their class II MHC molecules.

- **Activation of a T_H0 cell** requires two signals: TCR/CD4 binding to an MHC II–antigen complex on an antigen-presenting cell, and CD20-B7 interaction.
- **T_H0 cell differentiation** to T_H1 or T_H2 cells is influenced by different cytokine "cocktails" secreted by macrophages and NK cells during an infection.
- **Activation of a B cell** into an antibody-producing plasma cell usually requires two signals: antigen binding to BCR and binding to a T_H2 cell activated by the same antigen.
- **Activation of cytotoxic T cells** requires two signals: TCR/CD8 molecules that recognize MHC I–antigen complexes and cytokines such as IL-2 made from activated T_H1 cells. The activated cytotoxic T cells in turn destroy infected host cells.
- **Superantigens** stimulate T cells by directly linking TCR on a T cell with MHC on an APC without undergoing APC processing and surface presentation.

THOUGHT QUESTION 24.8 Transplant rejection is a major consideration when transplanting most tissues because host T_C cells can recognize allotypic MHC on donor cells. So, why are corneas easily transplanted from a donor to just about any other person?

THOUGHT QUESTION 24.9 Why does attaching a hapten to a carrier protein allow production of anti-hapten antibodies?

24.7 Complement as Part of Adaptive Immunity

Chapter 23 describes how complement can attack invading microbes before a specific immune response is launched. In what is called the alternative pathway (see Section 23.8), C3b binding to LPS sets off a cascade of reactions resulting in the formation of a membrane attack complex (MAC) pore composed of C5b, C6, C7, C8, and C9 proteins (see **Fig. 23.29**). In addition to the alternative pathway, antibodies made during the humoral response to a pathogen offer another route to activate complement called the **classical complement pathway**. Called "classical" because it was the first complement pathway to be discovered, it requires a few additional proteins before reaching C3, the linchpin factor connecting the two pathways.

The classical cascade begins with the binding of the complement protein C1 complex to the Fc region of an antibody that is part of an antigen-antibody complex, as you would find when antibody binds to a bacterial or viral pathogen (**Fig. 24.24**). The bound C1 complex then cleaves two other complement factors, C2 and C4, not used in the alternative pathway. Two fragments, one each for C2 and C4, unite to form another protease called C3 convertase. This enzyme cleaves C3 into C3a and C3b. C3b, which in the alternative pathway is stabilized by interacting with LPS, combines in the classical pathway with the C3 convertase to make a C5 convertase (note that this C5 convertase is different from the C5 convertase formed in the alternative pathway; see **Fig. 23.31**). The subsequent steps leading to formation of a membrane attack complex are the same as in the alternative pathway. As before, C5b

binds to a target membrane and is joined by C6, C7, and C8. Multiple C9 proteins then assemble around the membrane attack complex and form a pore that compromises the integrity of the target cell.

One might wonder why we need complement with all the other immune responses at our disposal, but the need becomes evident in individuals with complement deficiencies. These patients are extremely susceptible to recurrent septicemic (blood) infections by organisms such as *Neisseria gonorrhoeae* (the cause of gonorrhea) that normally do not survive forays into the bloodstream because they are killed by complement. Why does reinfecting *Neisseria* not quickly succumb to all the other defenses, such as antibodies and cytotoxic T cells? Because key antigens on the bacterial surface undergo phase variations (see Sections 10.6 and 27.7), many antibodies made to cells of *N. gonorrhoeae* participating in the initial infection are useless during a second infection.

Regulation of Complement Activation

How do normal body cells prevent self-destruction following complement activation? The sequential assembly of the membrane attack complex provides several places where regulatory factors can intervene. One such factor is the host cell surface protein CD59. This protein will bind any C5b-C8 complex trying to form in the membrane and prevent C9 from polymerizing. Thus, no pore is formed and the host cell is spared. (Complement will not normally attack normal or infected host cells, since both contain CD59.)

Another regulatory mechanism hinges on a normal serum protein called **factor H**. This protein prevents the inadvertent activation of complement in the absence of infection. In the absence of factor H, the uncontrolled activation of complement could damage host cells despite the presence CD59. To short-circuit the cascade, factor H binds to C3bBb, displaces Bb from the complex, and acts as a cofactor for factor I protease that then cleaves C3b. Without C3b, the complement cascade stops. Some bacteria, such as some strains of *Neisseria gonorrhoeae,* have learned to protect themselves from complement by binding factor H.

Normal flora can also assist host cells in resisting complement. The intestinal microbe *Bacteroides thetaiotamicron* protects host cells from complement-mediated cytotoxicity by upregulating a **decay-accelerating factor** present in host cell membranes. Decay-accelerating factor stimulates decay of complement factors and prevents their deposition at the cell surface.

Other Roles for Complement Fragments

The C3a, C4a, and C5a cleavage fragments generated by the complement cascade do not participate in MAC formation but are important for amplifying the immune reaction. These peptides act as chemoattractants to lure more inflammatory cells into the area. C3b, which does participate in MAC formation, also can act as an opsonin when it is bound to a bacterial cell. An opsonin is a protein factor that can facilitate phagocytosis. Because phagocytes contain C3b receptors on their surfaces, it is easier for them to grab and engulf cells coated with C3b.

THOUGHT QUESTION 24.10 Do bone marrow transplants in a patient with severe combined immunodeficiency require immunosuppressive chemothereapy?

THOUGHT QUESTION 24.11 How can a stem cell be differentiated from a B cell at the level of DNA?

TO SUMMARIZE:

- **The classical pathway for complement activation** begins with an interaction between the Fc portion of an antibody bound to an antigen and C1 factor in blood. (The alternative pathway does not need antibody but begins when C3b binds to LPS on a bacterium.)
- **The Fc-C1 complex** reacts with C2 and C4, leading to production of C3b and a novel C5 convertase specific to the classical pathway.
- **After C5 convertase cleaves C5**, the classical pathway is the same as the alternative pathway, resulting in the formation of a membrane attack complex (MAC).
- **CD59 and/or factor H** prevent inappropriate MAC formation in host cells.

24.8 Failures of Immune System Regulation: Hypersensitivity and Autoimmunity

Sometimes the immune system overreacts to certain foreign antigens and causes more damage than the antigen (microbe) alone might cause. Furthermore, some foreign antigens possess structures similar in shape to host structures and can trick the immune system into reacting against self. These immune miscues are called allergic hypersensitivity reactions, and the antigen causing the reaction is called an **allergen**. There are four types of hypersensitivity reactions (**Table 24.7**). The first three types of hypersensitivity are antibody mediated; the fourth is cell mediated.

Case History: Type I Hypersensitivity

A bee stings a 9-year-old boy walking with his mother at the zoo. Within minutes the boy begins sweating and itching. His

Table 24.7 Summary of hypersensitivity reactions.

Type	Description	Time of onset	Mechanism	Manifestations
I	IgE-mediated hypersensitivity	2–30 min	Ag induces cross-linking of IgE bound to mast cells with release of vasoactive mediators	Systemic anaphylaxis, local anaphylaxis, hay fever, asthma, eczema
II	Antibody-mediated cytotoxic hypersensitivity	5–8h	Ab directed against cell surface antigens mediates cell destruction via ADCC or complement	Blood transfusion reactions, hemolytic disease of the newborn, autoimmune hemolytic anaemia
III	Immune complex–mediated hypersensitivity	2–8h	Ag-Ab complexes deposited at various sites induce mast cell degranulation via Fc receptor; PMN degranulation damages tissue (Arthus reaction, localized)	Systemic reactions, disseminated rash, arthritis, glomerulonephritis
IV	Cell-mediated hypersensitivity	24–72h	Memory T_H1 cells release cytokines that recruit and activate macrophages	Contact dermatitis, tubercular lesions

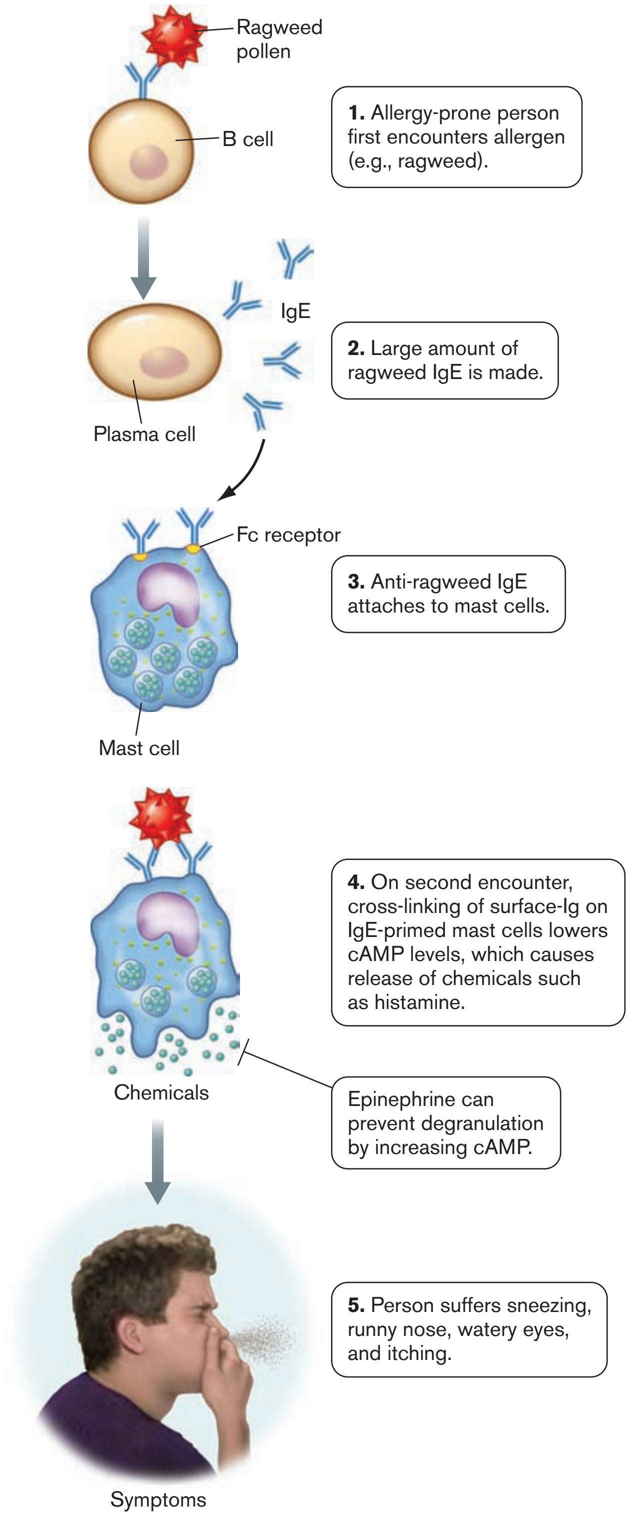
Ag = antigen; Ab = antibody; ADCC = antibody-dependent cell cytotoxicity; PMN = polymorphonuclear leukocyte

chest then starts to tighten and he has tremendous difficulty breathing. Terrified, he looks to his equally frightened mother for help.

This is a classic and severe example of **type I (immediate) hypersensitivity**, sometimes called **anaphylaxis**. (Anaphylaxis is defined as the contraction of smooth muscle and dilation of capillaries due to release of pharmacologically active substances.) Type I hypersensitivity occurs within minutes of a *second* exposure to an allergen when the allergen reacts with IgE-coated mast cells. Recall that the primary role of IgE is to amplify the body's response to invaders by causing mast cells to release inflammatory mediators (see Section 24.3). On initial exposure, an allergen elicits the production of IgE antibodies specific to the allergen (bee venom in this example). The Fc portions of these antibodies bind to Fc receptors on the surfaces of mast cells. IgE-coated mast cells are then said to be *sensitized*. Most allergen molecules contain several identical antigenic sites. Thus, a single allergen particle during a second exposure can bind to adjacent surface IgE molecules. The result is a bridge between adjoining binding sites (**Fig. 24.25**). This cross-linked complex inhibits the mast cell enzyme **adenylate cyclase**, so that intracellular levels of cyclic adenosine monophosphate (cAMP) fall. The lower levels of intracellular cAMP cause the mast cell granules to quickly migrate to the cell surface and release their contents in a process called degranulation. Understanding this process is clinically important because anaphylaxis inhibitors such as epinephrine (also known as adrenaline) stimulate adenylate cyclase activity, stopping the anaphylaxis cascade in its tracks.

Mast cell degranulation releases chemicals with potent pharmacological activities. The most important of these is histamine, which binds to histamine receptors (H1 receptors) present on most body cells. Antihistamines have a structure similar to histamine and work by binding H1 receptors to prevent histamine from binding. When histamine binds H1, it activates an enzyme (phospholipase A) that releases from the cell membrane a 20-carbon fatty acid called arachidonic acid. Arachidonic acid is then converted to leukotrienes by 5-lipooxygenase A and to prostaglandins by cyclooxygenase. Another important chemical released during degranulation is **tumor necrosis factor**. All of these mediators (leukotrienes, prostaglandins, and tumor necrosis factor) cause the smooth muscles nearby to contract. This constricts small blood vessels and expands capillary pores. Fluid is then forced from the circulation into the tissues. The immediate consequence is swelling (**edema**) in the joints and around the eyes and a rash (similar to hives), with burning and itching of the skin due to nerve involvement. In the clinical example involving the bee sting, the contraction of lung smooth muscles led to breathing difficulties.

What we described was a severe type I allergic reaction caused by a bee sting. Type I hypersensitivity reactions do not usually involve the whole body. Most type I reactions are more localized and cause what is called **atopic** ("out of place") disease. Hay fever, or allergic rhinitis, is a common manifestation of atopic disease that can be caused by the inhalation of dust mite feces (**Fig. 24.26**), animal skin or hair (dander), and certain types of grass or weed pollens. This disease affects the eyes, nose, and upper respiratory tract. Atopic asthma, another form of type I hypersensitivity resulting from inhaled



1. Allergy-prone person first encounters allergen (e.g., ragweed).

2. Large amount of ragweed IgE is made.

3. Anti-ragweed IgE attaches to mast cells.

4. On second encounter, cross-linking of surface-Ig on IgE-primed mast cells lowers cAMP levels, which causes release of chemicals such as histamine.

Epinephrine can prevent degranulation by increasing cAMP.

5. Person suffers sneezing, runny nose, watery eyes, and itching.

Andrew Syred

Figure 24.26 Inhaled allergen. Dust mite (200 to 600 micrometers) and dust mite feces (colorized SEM).

allergens, affects the lower respiratory track and is characterized by wheezing and difficulty breathing.

The administration of antihistamines is an effective treatment of allergic rhinitis, but the more important chemical mediators of asthma are the leukotrienes produced during what is called **late-phase anaphylaxis**. In late-phase anaphylaxis, mast cells release chemotactic factors that call in eosinophils. Eosinophils entering the affected area produce large amounts of leukotrienes that, like histamine, cause vasoconstriction and inflammation. At this point, antihistamines have little effect. Effective treatment includes inhaled steroids to minimize inflammation and bronchodilators (for example, albuterol) to widen bronchioles and facilitate breathing. A more recently developed medication, SINGULAIR™, works by blocking leukotriene receptors in the lung. During severe asthma attacks, injected epinephrine is critical. Epinephrine will open airways to ease breathing through direct hormonal action.

People sensitized to allergens are not necessarily doomed to suffer with the allergy their entire life. A clinical treatment called **desensitization** can sometimes be used to prevent anaphylaxis. Desensitization involves injecting small doses of allergen over a period of months. This process is thought to produce IgG molecules that circulate, bind, and neutralize allergens before they contact sensitized mast cells. Desensitization has been useful in cases of asthma, food allergies, and bee stings, although results are variable and by no means guaranteed.

There is a relatively new treatment for allergic asthma, omalizumab (Xolair), that can actually prevent sensitization. Omalizumab is a monoclonal antibody (an antibody preparation of one antibody type that only binds one epitope), administered by injection that selectively binds IgE. It prevents IgE from binding to Fc receptors on mast cells and, thus, prevents sensitization.

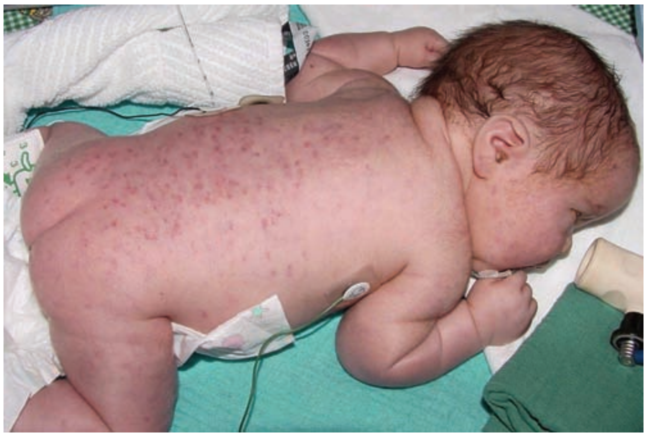
Why don't all antigens generate type I hypersensitivity? The answer is that most antigens do not elicit high levels of IgE antibodies. It is unclear what makes certain antigens capable of this and what makes different individuals prone to different allergies.

Case History: Type II Hypersensitivity

A hospitalized male patient with blood group B accidentally receives a transfusion with type A blood. Within hours, the individual experiences chills and lowered blood pressure and has blood in his urine, all symptoms of ABO blood group incompatibility.

This is a form of **type II hypersensitivity**. Type II hypersensitivity starts with antibody binding to cell surface antigens (donor blood cells, in this case). This differentiates it from type III hypersensitivity (considered next), which involves antibody binding to *soluble* antigens. The classic type II hypersensitivity reaction is illustrated by blood group incompatibilities resulting from transfusions. Destruction of the foreign red blood cells can occur by two routes. In the first route, antibody-dependent cell-mediated cytotoxicity is triggered when NK cells or macrophage surface Fc receptors bind to the Fc regions of antibodies bound to foreign red blood cell antigens. The second route involves complement activation, in which complement (C1) binds to the Fc regions of circulating antibodies affixed to foreign red blood cells. The complement cascade then creates a membrane attack complex (MAC) that destroys the RBC.

Another form of type II hypersensitivity is Rh incompatibility disease of the fetus and newborn (**Fig. 24.27**). Similar to ABO antigens, Rh antigens are chemical groups on red blood cells. Incompatibility between mother (Rh^-) and fetus (Rh^+) can lead to a hypersensitivity reaction in the fetus, especially in a second pregnancy. During birth of an Rh^+ child to an Rh^- mother, fetal red blood cells enter the mother's bloodstream. The Rh^- mother's immune system will make anti-Rh^+ IgG antibodies that can pass through the placenta. This is a problem during a subsequent pregnancy because these antibodies will attack an Rh^+ fetus. Rh disease can be prevented if the mother is passively given anti-Rh^+ immunoglobulin by intramuscular injection within a day after birth. This antibody binds the fetal Rh^+ antigen and prevents the mother's immune system from making Rh^+ antibody and the attendant memory B cells. Passive immunity only lasts four to six weeks, long enough to clear the fetal antigens from the mother's bloodstream.



Swiss Society of Neonatology

Figure 24.27 Type II hypersensitivity. Targeting foreign red blood cells in Rh disease of the newborn.

Case History: Type III Hypersensitivity

*A 16-year-old girl is treated for acne with minocycline (a tetracycline derivative). Two weeks later she develops a fever and a urticarial rash (***Fig. 24.28B***) and experiences muscle and joint pain. (Urticaria are hives, an itchy rash caused by tiny amounts of fluid that leak from blood vessels just under the skin surface.) Her symptoms resolve after five days of anti-inflammatory steroid treatment.*

This is an example of immune complex disease, also called **type III hypersensitivity**. In contrast to type II hypersensitivity, type III hypersensitivity is initiated by IgG antibody binding to *soluble* antigen, which in this case is minocycline. Penicillin sensitivity, usually associated with type I anaphylaxis, can also involve a type III hypersensitivity reaction. Normally, antigen-antibody complexes are readily cleared by macrophage engulfment, but an excessive amount of complexes may overwhelm the system and circulate in the blood, free to bind complement (C1 factor, classical pathway). The binding of C1 triggers a cascade in which complement fragments recruit and activate polymorphonuclear leukocytes (PMNs). The complement-activated PMNs release lysosomal proteases and reactive oxygen species that damage host cells in the area.

A more recent model for type III hypersensitivity is shown in **Figure 24.28A**. In this model, type III hypersensitivity is very similar to type I hypersensitivity in that mast cells are involved. The difference is that the immune complexes involve IgG molecules that are not prebound to mast cells. Once made, the soluble IgG-antigen complexes bind to Fc receptors on mast cells, causing degranulation and PMN recruitment. The PMNs use their Fc receptors to bind the complexes formed or deposited near tissues. The PMNs then release enzymes that damage cells in the area. Tissue deposition is important for disease because PMNs can more easily engage the deposited complex than if it is floating in blood, and the factors released will maintain a higher concentration in the local area. Because antigen-antibody complex deposition occurs throughout the body, the result is still a systemic disease. Systemic type III hypersensitivity will resolve once the immune complexes are cleared. In the case history described, steroid treatment was administered to minimize inflammation as the complexes were cleared.

In addition to systemic effects, there are also localized type III reactions. In 1903, a Frenchman named Maurice Arthus (1862–1945) discovered a phenomenon now

named for him—the Arthus reaction. Every few weeks, he would inject the same set of rabbits with horse serum. With each succeeding injection, he noted an increasingly severe reaction at the injection site. On early rounds only redness was noted, but after the fifth round, the lesions became necrotic and slow to heal. This is a *localized* type III reaction, where antigen-antibody complexes form at the vessel walls.

Case History: Type IV Hypersensitivity

The patient is a 19-year-old woman from Argentina. As a child she received the BCG vaccine for tuberculosis. Upon entering university in the United States, she is required to take a skin test for tuberculosis. She tries to refuse but is told it is a requirement and allows the nurse to apply the test to her arm. Three days later, the test site has a large red lesion and the skin is starting to slough (peel off).

Type IV hypersensitivity, also known as **delayed-type hypersensitivity (DTH)**, is the only class of hypersensitivity to be triggered by antigen-specific T cells. Because T cells have to react and proliferate to cause a response, it generally takes 24–48 hours before a reaction is noticed. This delay distinguishes type IV hypersensitivity from the more rapid antibody-mediated allergic reactions (types I–III). The woman in the case study was initially sensitized with BCG (an attenuated strain of *M. bovis*, a close relative of *M. tuberculosis*) as a result of childhood vaccination. Because the organism is intracellular, the vaccination produced a cell-mediated immunity, complete with preactivated memory T cells (similar to memory B cells). When she was reinoculated by the skin test, the memory T cells activated and elicited a localized reaction at the site of injection.

There are two stages to the development of type IV sensitivity. The first stage, sensitization, involves processing and presentation of antigen on cutaneous dendritic cells (called Langerhans cells). These APCs travel to the lymph nodes, where T_H0 cells can react to them as described earlier (see **Figure 24.19**), generating activated T cells and a subset of memory T cells. On second exposure, two routes leading to delayed-type hypersensitivity (DTH) are possible. In the first pathway, memory T_H1 cells, upon binding antigen that is complexed to class II MHC receptors (this happens at the site of infection), will release IFN-gamma, TNF-beta, and IL-2 (**Fig. 24.29A**). These cytokines recruit macrophages and PMNs to the site and will activate macrophages and natural killer cells to release a number of other inflammatory mediators that will damage innocent, uninfected bystander host cells. In the second pathway, memory T_C cells can recognize antigen on class I MHC receptors, become activated and directly kill the host cell presenting the antigen (**Fig. 24.29B**). A hallmark of type IV hypersensitivity is that transferring white blood cells, not serum, can transfer the sensitivity to a naive animal. This is because T cells, not serum antibody, are responsible for the reaction.

Forms of delayed-type hypersensitivity reactions include contact dermatitis (such as poison ivy) and

allograft rejection. The antigens involved with contact dermatitis are usually small haptens that have to bind and modify normal host proteins to become antigenic (**Fig. 24.30**). In this case, the hapten-modified protein is processed, and fragments containing the bound hapten are presented on the surfaces of antigen-presenting cells.

Autoimmunity Occurs When the Immune System Is Tricked into Recognizing Self as Nonself

The ability to distinguish between self antigens and foreign antigens is crucial to our survival; without this ability, our immune system would constantly attack us from within. Normally, the body develops tolerance to self; occasionally, however, an individual loses immune tolerance against some self antigens and mounts an abnormal immune attack against his or her own tissues. The attack can involve antibodies or T cells and is called an **autoimmune response**. Autoimmune responses may or may not be associated with pathological changes (autoimmune disease). Almost 30% of the population will have an autoimmune antibody by age 65, but many will not exhibit disease. The mechanisms that lead to autoimmune disease are essentially hypersensitivity reactions.

An autoimmune response results in autoimmune disease when an autoantibody or autoimmune lymphocyte causes damage to tissue components. Tissue damage can ensue when antibody to self activates antibody-dependent cell cytotoxicity (see Section 24.5). In this scenario, autoantibodies affixed to host cells can bind to NK cell Fc receptors and cause the NK cell to kill the tissue cell.

How might autoimmune antibodies be formed? One proposed mechanism starts with the occasional escape of self-reacting B cells from the negative selection process. The negative selection process normally kills autoreactive B cells. Self-reacting B cells that escape this process are usually not a problem because the specific helper T cells needed to activate them were deleted from the T-cell population. However, the self-reacting B cell can still be activated. The B cell can, of course, take up and process a self antigen (or a foreign antigen that mimics a self antigen). The problem comes if the antigen *also* contains a nonself epitope. This nonself epitope will also be presented on a B-cell receptor. When this happens, T cells specific to the nonself epitope will recognize the nonself peptide and activate that B cell. However, the B cell is programmed to make antibody to the self antigen, not the nonself antigen. Those antibodies will begin to attack the host antigen.

A good example of this is the M protein (pili) of *Streptococcus pyogenes*, a microbe that causes "strep throat" and the autoimmune disease rheumatic fever. M pili contain an epitope that resembles cardiac antigen, but the cardiac-like epitope is flanked by epitopes that are not related to the human host. The cardiac-like epitope can bind surface antibody on an escaped self-reacting B cell and be taken up. Because the nonself epitope and the heart-like epitope are contained within the same protein, the nonself epitope will "piggyback" its way into the B cell. The self epitope is processed and placed on the B-cell surface MHC. When this happens, T cells specific to the nonself epitope will recognize the non-self peptide and activate the B cell. Because the B cell is programmed to make antibody to the cardiac antigen, those self-reacting antibodies are made, begin to bind to cardiac tissue, and trigger autoimmune disease. In the case of *S. pyogenes*, cardiac tissue is damaged and rheumatic fever results. This similarity between the epitope in M protein and cardiac tissue is an example of antigenic mimicry.

Another type of autoimmune reaction involves cytotoxic T cells. Type 1 diabetes, also known as juvenile diabetes, is an autoimmune disease that usually occurs during childhood, when T cells attack and destroy the insulin-producing islet cells in the pancreas. (In contrast to type 1 diabetics, type 2 diabetics continue to produce insulin, but their cells no longer respond to it.) A theoretical series of events has been proposed that involves molecular mimicry and starts with a viral infection of some sort. In this unproven model, an infecting virus (one study suggests Coxsackie virus), possesses an antigen with a shape similar to the glutamic acid decarboxylase in pancreatic beta islet cells. The cytotoxic T cells produced in response to the viral infection will also attack the beta cells, destroying them and the ability to make insulin.

Other autoimmune diseases involve the production of autoantibodies that bind and block certain cell receptors. Graves' disease (hyperthyroidism), for example, occurs when an autoantibody is made that binds to the thyroid-stimulating hormone (TSH) receptor. This mimics TSH binding and continually stimulates the production of T3 and T4, which generally increases metabolic rate. The thyroid is not destroyed but in fact enlarges to form a goiter. Examples of other important autoimmune diseases are listed in **Table 24.8.**

Table 24.8 Examples of autoimmune diseases.

Autoimmune disease	Autoantigen	Pathology
Type II hypersensitivity—mediated by antibody to cell surface antigens		
Acute rheumatic fever	Streptococcal M protein, cardiomyocytes	Myocarditis, scarring of heart valves
Autoimmune hemolytic anemia	Rh blood group	Destruction of red blood cells by complement, phagocytosis
Goodpasture's syndrome	Basement membrane collagen	Pulmonary hemorrhage, glomerulonephritis
Graves' disease	Thyroid-stimulating hormone receptor	Ab stimulates T3, T4 production, hyperthyroidism
Myasthenia gravis	Acetylcholine receptor	Interrupts electrical transmission, progressive muscular weakness
Type III hypersensitivity—mediated by antibody complexes with small soluble antigens (immune complex)		
Systemic lupus erythematosus	DNA, histones, ribosomes	Arthritis, vasculitis, glomerulonephritis
Type IV hypersensitivity—mediated by antigen specific T cells		
Type I diabetes	Pancreatic β cell antigen	β cell destruction
Multiple sclerosis	Myelin protein	Demyelination of axons

Special Topic 24.3 Organ Donation and Transplantation Rejection

It is now possible to donate organs from one person to another because we can minimize the risk of the recipient's immune system rejecting the donated tissue. As a result of their "education" process, T cells that survive the selection process by and large do not have TCRs that "see" isogenic MHC proteins on other cells of the body. However, about 5% of the surviving T cells can recognize and bind to allotypic MHC proteins on cells from other individuals (donors). This is because the allotypic MHC resembles a self MHC-foreign antigen complex. For this reason, transplanting organs from a donor with one type of MHC protein into a recipient with a different type of MHC (called an **allograft**) typically ends badly, with the recipient rejecting the graft. The allotypic MHC proteins of the donor play a major role in this transplantation rejection process.

To understand transplant rejection, it is important to remember that during normal antigen presentation, the T-cell receptor actually recognizes part of the presenting MHC molecule (self) as well as the peptide (antigen) presented. Consequently, allograft rejection is initiated in one of two ways. TCR on a recipient's T cells can *directly* bind the allotypic MHC (that is, the nonself MHC) on donor target cells that are presenting peptides (**Fig. 1A**). Alternatively, T cells from the recipient can *indirectly* recognize *pieces* of the donor allotypic MHC presented on the recipient's host cell through normal antigen-processing pathways (**Fig. 1B**). In the direct route, it does not matter whether the donor's antigen-presenting cells are presenting self peptides (from the recipient) or foreign peptides (from the donor). The allotypic differences in MHC are sufficient to trigger a response. The indirect route, however, requires that foreign donor peptides be presented on recipient APCs. Once activated by one of these routes, cytotoxic T cells will destroy all the donor cells containing the allotypic MHC proteins. The tissue is rejected.

Transplant rejection due to allotypic differences in MHC proteins might appear to contradict the MHC restriction rule for T-cell responses that was noted earlier. By this rule preactivated T cells are restricted to act only on other host cells, that is, cells with compatible MHC proteins. Transplant rejection, however, is the result of T-cell action on foreign cells with incompatible MHC proteins and so appears to violate the MHC restriction rule. This paradox can be understood if we look at the time scales involved. In a typical laboratory experiment, when virus-infected cells of one MHC allotype are mixed with already activated T cells of a different MHC allotype, the in vitro cytotoxic reaction is monitored only for an hour. In this time period, activated cytotoxic T cells will not kill virus-infected cells of a different allotype but could kill virus-infected cells of the same isotype MHC. In transplant rejection, however, an unactivated T cell initially recognizes the donor cell allotypic MHC protein as nonself. The subsequent in vivo response to nonself will take days before rejection occurs. There are probably a few CD8 T_C cells in the in vitro experiment that could recognize the allotypic MHC antigen, but because they are so few in number, activation would take a long time.

MHC type matching is an important consideration for a successful transplant. Then how, you may ask, can we successfully carry out blood transfusions, which do not require MHC matching? Because human red blood cells, which are not nucleated, do not contain MHC proteins, tissue rejection via MHC incompatibility does not occur. However, the A or B antigens present on donor red blood cells can be recognized as foreign.

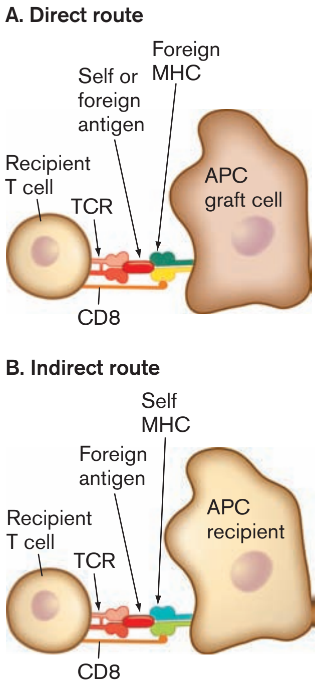

Figure 1 Transplantation rejection. A. In the direct route to tissue rejection, T cells from the recipient recognize the foreign MHC on a donor (graft) cell and become activated. **B.** The indirect route occurs when pieces of foreign donor MHC (allo-MHC) are presented on the surface of recipient APCs. Recipient T_C cells then respond and become activated.

TO SUMMARIZE:

- **Allergens** cause the host immune system to overrespond or react against self.
- **Type I hypersensitivity** involves IgE antibodies bound to mast cells by the antibody Fc region. Binding of antigen to the bound IgE causes mast cell degranulation. Can occur within minutes of an exposure.
- **Type II hypersensitivity** (for example, Rh incompatibility) involves antibodies binding to cell surface antigens. This can trigger cell-mediated cytotoxicity or activate the complement cascade. Can occur within hours of an exposure.
- **Type III hypersensitivity** is an immune complex disease involving antibody complexes with small, soluble antigens. The complexes can activate complement or bind to mast cells. The result is the recruitment of PMNs that damage host cells in the area. May take weeks to form.
- **Type IV hypersensitivity** (delayed-type hypersensitivity) involves antigen-specific T cells. T_H1 cells release cytokines that activate macrophages and NK cells. T_C cells can directly kill cells that present the antigen. Reaction seen within a few days of exposure.
- **Autoimmune disease** is caused by the presence of lymphocytes that can react to self.
- **Autoreactive B cells** (B cells that make antibody directed against self epitopes) are activated when they present a nonself epitope on their surface MHC. T cells that recognize the nonself epitope activate the B cell, which then secretes antibody against the self epitope.
- **Cytotoxic T cells can produce autoimmune disease** by killing host cells that make a self protein that closely resembles a foreign antigen.

Concluding Thoughts

Immunity is a remarkable feat of nature. The realization that any one person's immune system can recognize and respond to virtually any molecular structure and yet remain selectively "blind" to his or her own antigens is hard to comprehend. But even more remarkable is that pathogenic microbes have managed ways to outmaneuver the interconnected redundancies and safeguards of the immune system. In some cases, the pathogen evolves to become less harmful and coexists with the host; indeed, pathogens in nature are far outnumbered by closely related strains that are harmless or even beneficial to their hosts. In other cases, however, evolution generates a never-ending arms race between pathogen and host. The next chapter describes some of the microbial strategies that contribute to the success of a pathogen.

CHAPTER REVIEW

End of Chapter Questions

1. Define antigen, epitope, hapten, and antigenic determinant.
2. What is the basic difference between humoral immunity and cellular immunity?
3. Why are proteins better immunogens than nucleic acids?
4. What makes IgA antibody different from IgG?
5. What is immunoprecipitation and radial immunodiffusion?
6. Explain isotypic, allotypic, and idiotypic differences in antibodies.
7. How is IgE involved in allergic hypersensitivity?
8. Discuss differences in the primary and secondary antibody responses.
9. Outline the basic steps that turn a B cell into a plasma cell.
10. What is isotype switching, and how is antibody diversity achieved?
11. What signals are needed to activate helper T cells?
12. What signals activate cytotoxic T cells?
13. Discuss the differences between transplant rejections of nucleated cells and rejection of blood cells.
14. How do superantigens activate T cells?
15. Discuss the differences between the alternative and classical pathways of complement activation.
16. How does the host prevent membrane attack complexes from being formed in host cells?
17. Describe the differences between hypersensitivity types I, II, III, and IV.
18. How does a B cell programmed to make an antibody against self become activated in the absence of specific T-cell help?

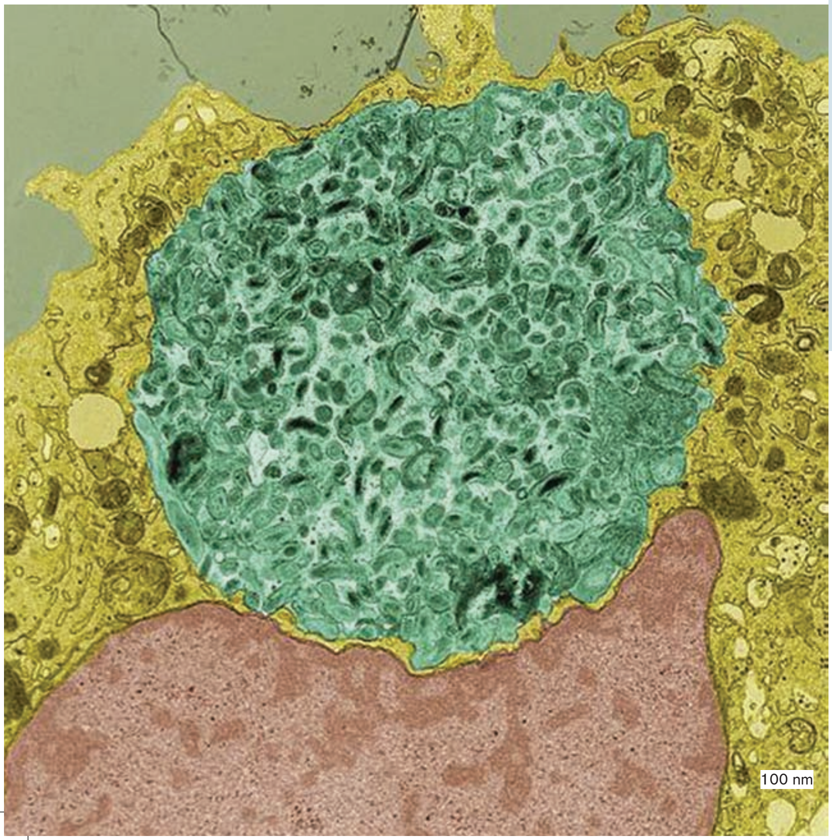
25.2 Virulence Factors and Pathogenicity Islands: The Tools and Toolkits of Microbial Pathogens
25.3 Virulence Factors: Microbial Attachment
25.4 Toxins: A Way to Subvert Host Cell Function
25.5 Protein Secretion and Pathogenesis
25.6 Finding Virulence Genes
25.7 Surviving within the Host
25.8 Viral Pathogenesis

Mammals have developed elaborate physical, chemical, and immunological defenses that protect against disease-causing microbes, or pathogens. Yet every fortress has its weakness. Pathogenic microbes have identified those weaknesses and exploit them to gain entry. The result is disease.

What makes a pathogen different from a commensal organism? The answer varies, depending on the pathogen. Some bacterial pathogens can avoid being phagocytosed by host cells, whereas others actively encourage it. Why do some microbes prefer to live intracellularly? Even more mysterious are those bacterial pathogens that develop a latent stage in the host, where they are undetectable, but still emerge and cause disease. Pathogens also differ widely with respect to their effects on a host. Some pathogens efficiently slay their hosts. Others persist for many years without killing. Which is the more successful pathogen?

The fundamental question of microbial pathogenesis is how an organism too small to be seen with the naked eye can kill a human that is 1 million times larger. This chapter will explore the varied methods that different bacterial and viral pathogens use to accomplish this feat.



Pseudocolored transmission electron micrograph (magnification ×4,000) showing a Vero cell infected for 8 days with *Coxiella burnetii*, an obligate intracellular bacterium and the agent of human Q fever. *C. burnetii* multiplies within a large vacuole, called a parasitophorous vacuole (green). The organism directs development of this vacuole, a process presumably aided by the potent antiapoptotic properties of the organism, which keeps the host cell from killing itself. *Source*: Elizabeth Fischer of the Research Technologies Branch, Rocky Mountain Laboratories Microscopy Unit. From Daniel E. Voth, et al. 2007. *Infection and Immunity* 75:4263.

A 23-year-old Hispanic mother brought her 3-year-old daughter into the emergency room. The child was lethargic, had a fever of 40°C (104°F), and was having difficulty breathing. The mother explained that the family arrived in the United States from El Salvador the previous week. The attending physician noted an extreme swelling of the child's cervical lymph nodes, giving the girl a thick, "bull-neck" appearance. She also noticed the beginnings of a membranous growth at the back of the child's throat that was beginning to obstruct the trachea. It was grayish in color and bled when scraped. When asked, the distraught mother admitted that the child had not received any vaccinations before arriving in New Mexico. Suspecting the nature of the child's illness, the physician granted immediate admission to the hospital and ordered administration of penicillin and a specific antitoxin. The results of a throat swab sent to the microbiology lab confirmed the physician's suspicion. The root of the child's disease was *Corynebacterium diphtheriae*, which causes diphtheria.

Corynebacterium diphtheriae is a deadly pathogen able to kill humans by attacking the respiratory and cardiac systems. When untreated, death often comes by suffocation when the gray membrane completely covers the trachea. This pathogen is a gram-positive, nonspore-forming rod identical in appearance to many common commensal throat microbes, such as the more docile *C. striatum*. So, two gram-positive rods, identical in appearance, are both found in the human throat. Why is one a killer and the other not? The child in the case history most likely came in contact with the pathogen before leaving El Salvador, where vaccinations in some areas are difficult to obtain. The result was diphtheria. The question we want to ask in this chapter is *not* how this could have been prevented, but what genetic distinctions separate closely related disease-causing pathogens from innocuous nonpathogens. In this instance, the difference between friend and foe is a bacteriophage genome embedded in the genome of the organism. This phage carries the gene for diphtheria toxin, whose properties will be described later.

Pathogens, such as *C. diphtheriae*, that kill their hosts or only transiently reside there must also be prepared for life outside the host. These microbes possess an alternate physiology that allows survival in nonhost environments such as a lake or soil. However, some pathogens are not as versatile and die when separated from their host. They must be passed directly from person to person. If the host dies before transmission, the pathogen dies with it. Thus, to kill or not to kill is an important question each pathogen must address. This chapter will discuss the various relationships that occur between pathogens and their hosts and the factors that contribute to **pathogenesis**, the processes by which microbes cause disease in a host. The degree of harm that is caused depends on the mechanisms the pathogen has at its disposal.

25.1 Host-Pathogen Interactions

Parasites, in the broadest sense, include bacteria, viruses, fungi, and protozoa that colonize and harm their hosts. However, the term **pathogen** is typically used to refer to bacterial, viral, and fungal agents of disease. Disease-causing protozoans and worms, on the other hand, are normally called parasites. Pathogens and parasites infect their animal and plant hosts in a variety of ways and enter into different host pathogen relationships, depending on the site of colonization. For example, organisms that live on the surface of a host are called **ectoparasites**. The fungus *Trichophyton rubrum*, one cause of athlete's foot, is an ectoparasite (**Fig. 25.1**). *Wuchereria bancrofti*, the worm parasite that causes elephantiasis, is an **endoparasite** because it lives inside the body (**Fig. 25.2**).

Before examining the mechanisms microbes use to cause disease, it is helpful to know the terminology of pathogenesis. An **infection** occurs when a pathogen or parasite enters or begins to grow on a host. Be aware that

CDC

Figure 25.2 An endoparasite. The disease filariasis, commonly known as "elephantiasis" for obvious reasons, is caused by the worm *Wuchereria bancrofti* (blowup), which enters the lymphatics and blocks lymphatic circulation. Adult worms are threadlike and measure 4–10 cm in length. The young microfilaria (shown) are approximately 0.5 mm in length. Though not a problem in the United States, it is found throughout middle Africa, Asia, and New Zealand.

the term *infection* does not necessarily imply overt disease. Any potential pathogen growing in or on a host is said to cause an infection, but that infection may be only transient because immune defenses kill the pathogen before noticeable disease results. Indeed, most infections go unnoticed. For example, every time you have your teeth cleaned by a dentist your gums bleed and your oral flora transiently enter the bloodstream, but you rarely suffer any consequences.

Primary pathogens, also called **frank pathogens**, are disease-causing microbes possessing the means to breach the defenses of a healthy host. For example, *Shigella flexneri*, the cause of bacillary dysentery, is a frank pathogen. When ingested, it can survive the natural barrier of an acidic (pH 2) stomach, enter the intestine, and begin to replicate. **Opportunistic pathogens**, on the other hand, only cause disease in a compromised host. *Pneumocystis jiroveci* (previously *P. carinii*) is an opportunistic pathogen that causes life-threatening infections in AIDS patients, whose immune systems have been eroded (**Fig. 25.3A**). Some microbes even enter into a **latent state** during infection, where the organism cannot be found by culture. Herpes virus, for instance, can enter the peripheral nerves and remain dormant for years, then suddenly emerge to cause cold sores (**Fig. 25.3B**). The bacterium *Rickettsia prowazekii* causes epidemic typhus, but it can also enter a latent phase and months or years later cause a disease relapse called recrudescent typhus.

The term **pathogenicity** refers to an organism's ability to cause disease. It is defined in terms of how easily an organism causes disease (infectivity) and how severe that disease is (virulence). Pathogenicity, overall, is shaped by the genetic makeup of the pathogen. In other words, an organism is more—or less—pathogenic depending upon the tools at its disposal (such as toxins), and their effectiveness.

Virulence is a measure of the degree or severity of disease. For instance, Ebola virus and the closely related Marbury virus have case fatality rates near 70%. This means that they are highly virulent (**Fig. 25.4**). On the other hand, rhinovirus, the cause of the common cold, is very effective at causing disease but never kills its victims. So it is highly infective but has a low virulence. Both organisms are pathogenic, but with one you live and the other you die.

One way to measure virulence is to determine how many bacteria or virions are required to kill 50% of an experimental group of animal hosts. This is called the **LD_{50}** (lethal dose 50%). An organism with a low LD_{50}, in which very few organisms are required to kill 50% of the hosts, is more virulent than one with a high LD_{50} (**Fig. 25.5**). For organisms that colonize but do not kill the host, the **infectious dose** needed to colonize 50% of the experimental hosts (ID_{50}) can be measured. Infectious dose is measured by determining how many microbes are required to cause disease symptoms in half of an experimental group of hosts.

Although one might be able to measure the infectious dose, rather than lethal dose, for a lethal pathogen, it is not typically done. Because it gives a clear end point, LD_{50} is much easier to use when trying to determine the effectiveness of a given treatment (an antibiotic, for example) or quantitate the role of a given gene in pathogenesis.

THOUGHT QUESTION 25.1 Is a microbe with an LD_{50} of 5×10^4 more or less virulent than a microbe with an LD_{50} of 5×10^7?

Figure 25.4 Highly virulent Ebola virus. A. Ebola virus (approx. 1 µm long, TEM). **B.** The body of a victim of Marburg virus is placed in a coffin for safe burial in Angola. Marburg and Ebola cause hemorrhagic infections in which patients bleed from the mouth, nose, eyes, and other orifices. They have a 70–80% mortality rate.

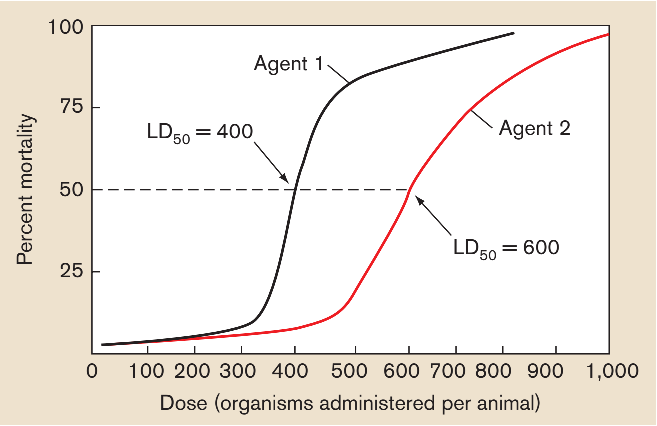

Figure 25.5 Measurement of virulence. Each LD_{50} measurement requires infecting small groups of animals with increasing numbers of infectious agent and viewing how many animals die. The number of microbes that kill half the animals is called the LD_{50} dose. In this example, agent 1 is more virulent than agent 2.

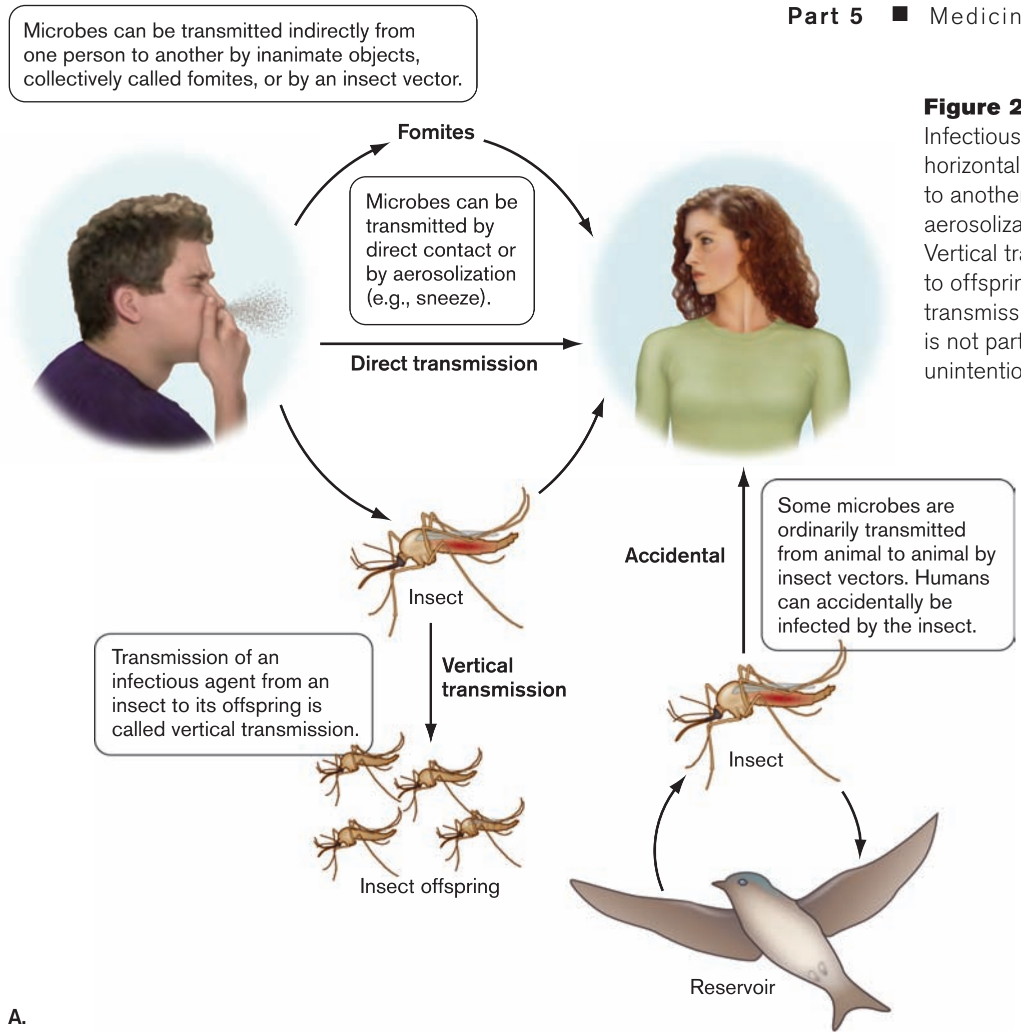
Infection Cycles Can Be Direct or Indirect

Somehow, pathogens must pass from one person or animal to another if a disease is to spread. The route an organism takes to accomplish this is called the **infection cycle**. A cycle of infection can be simple or complex (**Fig. 25.6**). Organisms that spread directly from person to person, such as the rhinovirus or *Shigella*, have simple infection cycles. Inanimate objects through which pathogens can be relayed to hosts are called **fomites**. More complex cycles often involve **vectors**, usually insects, as intermediaries. Vectors serve to carry infectious agents from one animal to another. A mosquito vector, for example, transfers the virus causing yellow fever from infected to uninfected individuals (**Fig. 25.7**) in what is called **horizontal transmission**. The mosquito can also bequeath this particular virus to its offspring via infected eggs in a form of **vertical transmission** called **transovarial transmission**. Although yellow fever is not a problem in the United States today, West Nile virus, a flavivirus closely related to yellow fever, currently claims several victims each year in this country.

Because insects are instrumental in transmitting pathogens, killing insect vectors is an important way to halt the spread of disease. Interventions include spraying insecticide in a community during egg-hatching season or using other microbes as assassins “trained” to kill the vector. For example, *Bacillus thuringiensis* will kill many types of insects that carry infectious agents. More recently, an insect virus called baculovirus has been developed that kills the *Culex* mosquito vectors carrying the West Nile virus. The advantage of these vector-targeting microbes is that they do not kill other insects or animals, as do many chemical insecticides.

Another critical factor in an infection cycle is the **reservoir** of infection. A reservoir is an animal, bird, or insect that normally harbors the pathogen. In the case of yellow fever, the mosquito is not only the vector, but the reservoir as well, because the insect can pass the virus to future generations of mosquitoes through vertical transmission. The virus causing eastern equine encephalitis (EEE), however, uses birds as a reservoir. The microbe is normally a bird pathogen and is transmitted from bird to bird via a mosquito vector. The virus does not persist in the insect, but transmission by the insect vector keeps the virus alive by passing it to new avian hosts. Humans or horses entering geographic areas harboring the disease (called **endemic areas**) can also be bitten by the mosquito. When this happens, they become accidental hosts and contract disease. The virus does not replicate to high titers in mammals, which means that horses and humans are poor reservoirs for the virus. However, the virus does replicate to high numbers in the avian host. Reservoirs are critically important for the survival of a pathogen and as a source of infection. If the eastern equine encephalitis virus had to rely on humans to survive, the virus would cease to exist because of limited replication potential and limited access to mosquitoes. It is important to note that the reservoir of a given pathogen might not exhibit disease.



Microbes can be transmitted indirectly from one person to another by inanimate objects, collectively called fomites, or by an insect vector.
Fomites
Microbes can be transmitted by direct contact or by aerosolization (e.g., sneeze).
Direct transmission
Accidental
Some microbes are ordinarily transmitted from animal to animal by insect vectors. Humans can accidentally be infected by the insect.
Insect
Vertical transmission
Transmission of an infectious agent from an insect to its offspring is called vertical transmission.
Insect
Insect offspring
Reservoir

Figure 25.6 Infection cycles. Infectious agents can be transmitted horizontally from one member of a species to another by a variety of means: fomites, aerosolization, direct contact, or insect vector. Vertical transmission is passage from parent to offspring during birth, while accidental transmission happens when a host that is not part of the normal infectious cycle unintentionally encounters that cycle.

CDC

Figure 25.7 Insect vector and yellow fever. A. Walter Reed, a member of the University of Virginia Medical School class of 1869, proved in 1901 that the mosquito *Aedes aegypti* was the vector of transmission for yellow fever, a disease named for the jaundice produced by liver damage. **B.** *Aedes aegypti*. Yellow fever is caused by a flavivirus (inset, TEM) carried by this mosquito. The virus varies in size from 50 to 90 nm. Yellow fever remains endemic in the northern part of South America and in central Africa.

Even a simple infectious cycle can become more complex. For example, rhinovirus can be spread person-to-person by a sneeze (airborne) or through the sharing of inanimate objects (fomites) such as contaminated utensils (fork, pen), towels, cloth handkerchiefs, and doorknobs. Handshaking is also an efficient means of transferring some pathogens. Imagine that one person in a city of 100,000 people has a cold and sneezes on her hands. Then, without washing her hands, she goes through the day shaking hands with 10 people, and each of those people shake hands with another 10 people per day, and so on. If there were no repeat handshakes, and if none of the contacts washed their hands, it would take only four days to spread the virus throughout the population.

In this example, eventually the entire populace of the city would come in contact with the virus, but not everyone would actually contract disease. Additional factors influence whether the virus successfully replicates in a given individual.

Portals of Entry

How do infectious agents gain access to the body? Each organism is adapted to enter the body in different ways. Food-borne pathogens (for example, *Salmonella*, *E. coli*, *Shigella*, and rotavirus) are ingested by mouth and ultimately colonize the intestine. They have an oral portal of entry. Airborne organisms, in contrast, infect through the respiratory tract. Some microbes enter through the conjunctiva of the eye, others through the mucosal surfaces of the genital and urinary tracts. Agents that are only transmitted by mosquitoes or other insects enter their human hosts via the parenteral route, meaning injection into the bloodstream. Wounds and needle punctures can also serve as portals of entry for many microbes. For instance, shared needle use between drug addicts has been an important factor in the spread of HIV.

TO SUMMARIZE:

- **Infection** with a microbe does not always lead to disease.
- **Primary pathogens** have mechanisms that help the organism circumvent host defenses.
- **Opportunistic pathogens** cause disease only in a compromised host.
- **Pathogenicity** refers to the mechanisms a pathogen uses to produce disease and how efficient the organism is at causing disease, whereas virulence is a measure of disease severity.
- **Diseases can be spread** by direct or indirect contact between infected and uninfected persons/animals or by insect vectors.
- **Pathogens use portals of entry** best suited to their mechanisms of pathogenesis.

25.2 Virulence Factors and Pathogenicity Islands: The Tools and Toolkits of Microbial Pathogens

Pathogens can be distinguished from their avirulent counterparts by the presence of **virulence factors** that help establish the organism in the host and that alter host functions to cause disease. Virulence factors, which are encoded by virulence genes, include toxins, attachment proteins, capsules, and other devices used to avoid host innate and adaptive immune systems. All of these factors enhance the disease-producing capability, or pathogenicity, of the pathogen.

Extensive sequencing efforts have allowed us to compare genomes of many pathogens and expose some "footprints" of their evolution. For example, in bacterial pathogens, most chromosomes are dotted with clusters of pathogenicity genes that encode virulence functions. These gene clusters, called **pathogenicity islands**, can be considered the toolboxes of pathogens (originally discussed in Section 9.7). Many virulence genes reside in pathogenicity islands, although many others do not. Some virulence genes reside on plasmids (for example, the genes for the diarrhea-producing labile toxin of certain *E. coli* strains) or in phage genomes (such as the genes encoding the diphtheria toxin of *Corynebacterium diphtheriae*).

Many of the genes in pathogenicity islands were originally inherited through horizontal transmission from other organisms by, for example, conjugation or transduction (discussed in Section 9.2). But what do the pathogenicity genes do? Some genes encode molecular "grappling hooks," such as pili that attach to host cells. Once attached, microbes can secrete toxins that injure the host cell. Other bacteria wall themselves off to prevent damage by host inflammatory responses. Some bacterial pathogens are even capable of what could be called "host cell reprogramming." These organisms inject proteins directly into the host cell to disrupt normal signaling pathways. This reprogramming causes the target cell to either engulf the bacterium, commit suicide (undergo apoptosis), or provide an even more intimate attachment platform at the cell surface.

Pathogenicity Islands Are Different from the Rest of the Genome

How do new pathogens evolve? DNA sequencing efforts suggest that gene swapping followed by divergent evolution is a major force in the development of emerging pathogens. Horizontal gene transfers move whole blocks of DNA (more than 10 kbp) from one organism to another, placing the blocks directly in the chromosome in what is called a **genomic island**. If the island increases the "fitness" of a microorganism (pathogen) that interacts with a host, it is called a pathogenicity island. Genomic islands generally reveal themselves by several anomalies that they possess with respect to the rest of the host genome:

- They are often linked to a tRNA gene and generally have a GC/AT ratio very different from the rest of the chromosome (**Fig. 25.8**). For example, a plot of GC content along the length of a chromosome may reveal that most of the genome has a 50% GC content. But somewhere in the middle, a 50-kbp region sticks out on the graph, showing a content of 40%. This probably reflects the GC content of the microbe that donated the island. The reason tRNA genes are often the targets for insertion of pathogenicity islands is not known. One hypothesis is that the conserved secondary structure of tRNA genes provides a structural motif that facilitates integration by an integrase.
- They are typically flanked by genes with homology to phage or plasmid genes. This is thought to reflect the transfer vector used to move the island from one organism to another.
- They carry gene clusters with specific functions, such as protein export systems that secrete toxins (for example, type III secretion systems that inject toxic proteins directly into target host cells; see Section 25.5). These are the operons that contribute to the fitness of the organism in pathogenic circumstances.

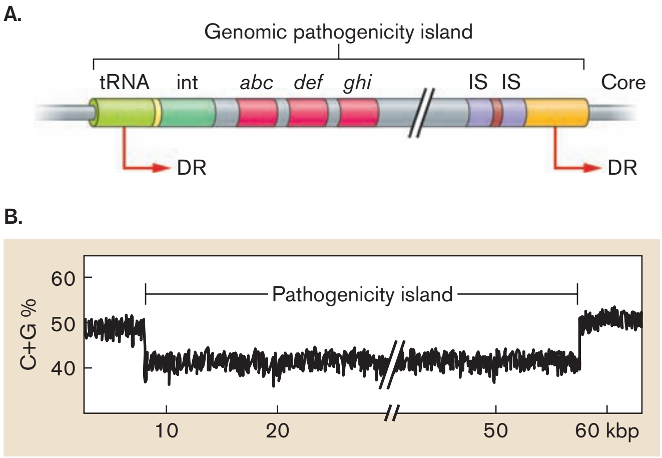

Figure 25.8 Model pathogenicity island. A. Schematic model of a pathogenicity island. The DNA block is linked to a tRNA gene and flanked by direct repeats (DR) that may be "footprints" of a transposon or viral-mediated transfer. The integrase gene (int) and insertion sequences (IS) may also be remnants of transposition. **B.** The guanine + cytosine (GC) content of the island is different from that of the core genome.

Table 25.1 lists several pathogenicity islands and their functions. It provides examples of pathogenicity islands present in different bacteria, names a key function of the products of the island, and gives the disease caused. Various pathogenicity island functions will be described as the chapter proceeds.

Shigella and *Escherichia* Are Examples of Evolution through Horizontal Transmission

Figure 25.9 shows a schematic comparison of the circular *Shigella flexneri* genome with those of *E. coli* K-12 (a commonly used avirulent lab strain) and *E. coli* O157:H7 (a virulent strain of enterohemorrhagic *E. coli*). All three gram-negative rods are closely related but differ greatly in terms of pathogenic potential and mechanisms. *S. flexneri* and *E. coli* O157:H7 cause bloody diarrhea, while *E. coli* K-12 has a commensal origin. DNA sequence analysis has revealed chromosome regions that are common among these organisms, as well as genomic islands specific to individual species and strains (Fig. 25.9). The core genes needed for sustaining growth (that is, for transcription, translation, replication, and so on) are common to all

Table 25.1 Examples of pathogenicity islands.

Pathogenicity island	Function	Organism	Disease
HPI (high pathogenicity island)	Iron uptake	*Yersinia* spp.	Plague, enterocolitis
VPI (*Vibrio* pathogenicity island)	Toxin production	*Vibrio cholerae*	Cholera
PAI III (pathogenicity island III)	Encodes adhesins	Uropathogenic *E. coli*	Urinary tract infection
SPI-1 and SPI-2 (*Salmonella* pathogenicity islands)	Type III secretion	*Salmonella enterica*	Gastroenteritis
SHI-1 and SHI-2 (*Shigella* islands)	Type III secretion	*Shigella flexneri*	Bloody diarrhea
YSA (*Yersinia* secretion apparatus)	Type III secretion	*Yersinia* spp.	Plague, enterocolitis
Cag PI (cytotoxin-associated gene)	Type IV secretion	*Helicobacter pylori*	Gastric ulcers, gastric cancer
icm/dot (intracellular multiplication)	Type IV secretion	*Legionella pneumophila*	Legionnaires' disease

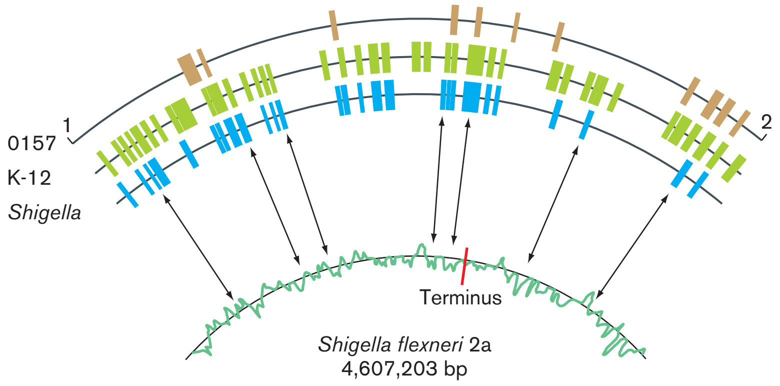

Figure 25.9 Comparison of the *Shigella flexneri* 2a chromosome with those of *E. coli* K-12 and O157:H7 (EDL933). Segments of the three genomes between 1 MB and 2 MB are shown. Gray line indicates DNA sequences shared among the organisms (O157, top arc; K-12, second arc; *Shigella*, third arc). Colored boxes depict genomic islands (including pathogenicity islands) present in each organism. The bottom arc illustrates the GC content of the *Shigella* genome. Each data point along the graph indicates GC content relative to AT content as averaged over a sliding 10 kbp window. Note how major differences in *Shigella* GC content shown above or below the center line (indicating 50% GC content) often correlate with the genomic islands depicted in the third arc. Arrows indicate some islands with obvious correlation to GC content.

three organisms, whereas other genes may be present in only one. These unique genes and islands are thought to be the result of horizontal gene transfers originating from widely different genera. Within the unique DNA segments of *S. flexneri* and *E. coli* O157:H7 are genes encoding host cell attachment, toxin secretion, and the toxins themselves—all of which are absent from K-12. The degree of gene shuffling that was required to separate these otherwise similar bacteria is remarkable.

The following sections describe some of the specific tools pathogens use to undermine the integrity of the body. From attachment, to toxins, to intracellular invasion, the infection process is like a chess match, with each side, human and microbe, trying to outmaneuver the other.

TO SUMMARIZE:

- **Pathogenicity islands** are DNA sequences within a species that are acquired by horizontal gene transfer from a different species.
- **Virulence genes** encode genes whose products enhance the disease-causing ability of the organism. Many virulence genes can be found within pathogenicity islands, but some are located outside of an obvious genomic island or reside in plasmids.
- **Pathogenicity islands** contain distinct features, such as GC content and the remnants of phage or plasmids, that mark them as being different from the rest of the genome.

25.3 Virulence Factors: Microbial Attachment

Regardless of the disease, pathogens must reach a colonization site either through their own motility or by hitchhiking with a vector. Once at the site, attachment mechanisms are needed to stay there.

The human body has many ways to exclude pathogens. The lungs use a mucociliary elevator (see **Fig. 23.5**) to rid themselves of foreign bodies, the intestine uses peristaltic action to ensure that its contents are constantly flowing, and the bladder uses contraction to propel urine through the urethra with tremendous force. How do bacteria ever manage to stay around long enough to cause problems? Like a person grasping a telephone pole during a hurricane, successful pathogens moving through the body manage to grab onto host cells and tenaciously hold on. Thus, the first step toward infection is attachment, also called adhesion. An **adhesin** is the general term for any microbial factor that promotes attachment.

Viruses attach to the host through their capsid or envelope proteins, which bind to specific host cell receptors discussed in Chapters 6 and 11. Bacteria have a variety of similar strategies. They can use hairlike appendages called **pili** (also called **fimbriae**), whose tips contain receptors for mammalian cell surface structures. Or they can use a variety of adherence proteins or other molecules (adhesins) that are not part of a pilus. Sometimes they use both. **Table 25.2** summarizes bacterial attachment strategies.

Types of Pili

Different pili from different bacterial species have been classified historically based on phenotype. In some cases the phenotype classes have turned out to be inconsistent with sequence-based homologies. We will consider three groups in this chapter.

Table 25.2 Specific attachments of bacteria to cell or tissue surfaces.

Bacterium	Adhesin	Host receptor	Attachment site	Disease
Streptococcus pyogenes	Protein F	Amino terminus of fibronectin	Pharyngeal epithelium	Sore throat
Streptococcus mutans	Glucan	Salivary glycoprotein	Pellicle of tooth	Dental caries
Streptococcus salivarius	Lipoteichoic acid	Unknown	Buccal epithelium of tongue	None
Streptococcus pneumoniae	Cell-bound protein	*N*-acetylhexosamine galactose disaccharide	Mucosal epithelium	Pneumonia
Staphylococcus aureus	Cell-bound protein	Amino terminus of fibronectin	Mucosal epithelium	Various
Neisseria gonorrhoeae	*N*-methylphenylalanine pili	Glucosamine galactose carbohydrate	Urethral/cervical epithelium	Gonorrhea
Enterotoxigenic *E. coli*	Type I fimbriae (pili)	Species-specific carbohydrate(s)	Intestinal epithelium	Diarrhea
Uropathogenic *E. coli*	Type I fimbriae (pili)	Complex carbohydrate	Urethral epithelium	Urethritis
Uropathogenic *E. coli*	P pili (pyelonephritis-associated pili)	P-blood group	Upper urinary tract	Pyelonephritis
Bordetella pertussis	Pili (“filamentous hemagglutinin”)	Galactose on sulfated glycolipids	Respiratory epithelium	Whooping cough
Vibrio cholerae	*N*-methylphenylalanine pili	Fucose and mannose carbohydrate	Intestinal epithelium	Cholera
Treponema pallidum	Peptide in outer membrane	Surface protein (fibronectin)	Mucosal epithelium	Syphilis
Mycoplasma	Membrane protein	Sialic acid	Respiratory epithelium	Pneumonia
Chlamydia	Unknown	Sialic acid	Conjunctival or urethral epithelium	Conjunctivitis or urethritis

Type I pili are a group that, in general, adhere to mannose residues on host cell surfaces. Because adding free mannose will inhibit attachment of most type I pili, this binding is called mannose sensitive. Another group of pili is called mannose resistant because the pili do not bind to mannose residues. There are at least two types of mannose-resistant pili. Members of one type, sometimes called **type III pili**, bind to red blood cells treated with tannic acid. The other more commonly studied type is called **type IV pili**. Unlike type I pili, which simply stick out from the cell surface, type IV pili are more dynamic and are assembled on the cell surface through a very different pathway.

There are other types of attachment pili that do not fall neatly into one of these three groups. For clarity, it is important to note that the primary classification of pili is now based largely on protein sequence information (deduced from DNA sequence) and may contradict earlier phenotype-based schemes. For instance, the pyelonephritis adhesion pili (Pap) of the uropathogenic *E. coli* are mannose resistant, since they bind to a digalactoside on host surfaces (called the P blood group antigen). However, Pap is very similar to type I pili based on amino acid sequence homology.

Pilus Assembly

How bacteria assemble pili on their cell surfaces is an engineering marvel. The shafts of pili are cylindrical structures composed of identical pilin protein subunits. Several different proteins adorn the tip, including one at the very apex that binds to host receptors (**Fig. 25.10A**). In addition to these structural components, numerous other proteins work together as a machine to assemble the structure. Genes encoding a given pilin protein and the associated assembly apparatus are typically arranged on the chromosome as an operon (**Fig. 25.10B**).

In **Figure 25.11**, the assembly of a type I pilus is shown, using uropathogenic *E. coli* Pap pili as a model. The mechanism is representative of other type I pili; only the names of the proteins will differ for each system. Protein components are secreted into the periplasm by the SecA-

A. FimH adhesion tip (TEM)

B. Type I pilus gene cluster

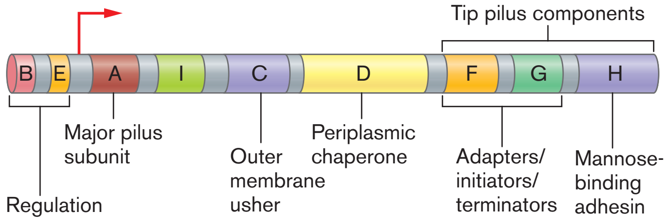

Figure 25.10 Attachment pili and encoding operon. A. High-resolution micrograph showing a type I pilus (TEM). The FimH adhesin at the tip is the protein that binds to the cell receptor. **B.** Genetic organization of the type I gene cluster, which includes genes involved in pilus assembly. The genes are designated *fim A-H*.

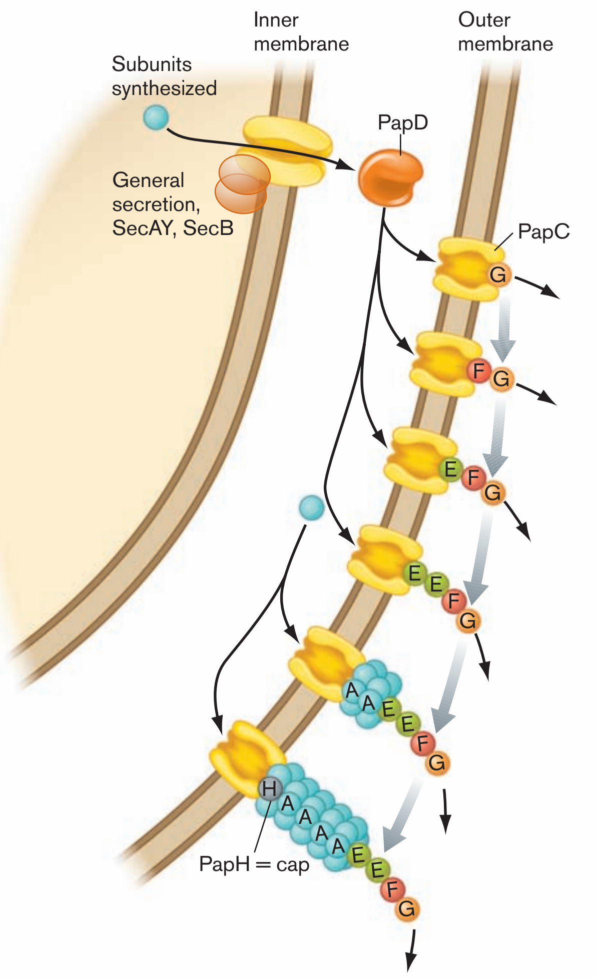

Figure 25.11 Assembly of type I pili. The figure illustrates pyelonephritis-associated pilus (Pap) assembly but is representative of other type I pili. Only the names of the proteins will differ. Proteins are secreted by the Sec system to the periplasm, where they are chaperoned by PapD to the site of assembly. PapC, also called the usher, assembles the individual proteins in the proper order. Assembly starts with the tip protein, PapG, marked at the far right, which ultimately binds to carbohydrates on host membranes. The subunits fit together like pieces of a jigsaw puzzle. The arrow at the head of the elongating pilus indicates direction of pilus growth.

dependent general secretory system (discussed in Section 8.4). Once in the periplasm, the subunits are chaperoned by PapD to the membrane site of assembly, which is marked by the presence of the usher protein PapC. PapC proteins form channels in the outer membrane large enough to accommodate individual pilus subunits and, like an usher in a theater, direct the subunits to their proper places. Chaperoning of the pilin building blocks by PapD is necessary to prevent pilin subunits from inadvertently assembling in the periplasm. As illustrated in Figure 25.11, appropriate assembly of pili at the usher site starts with the tip protein, PapG, which will ultimately bind to carbohydrates on host membranes after the pilus is complete. After PapG, the ushers add PapF and PapE, forcing PapG farther away from the surface. Then a series of identical PapA pilin subunits are strung together to form the shaft. The PapA subunits assemble by swapping domains, essentially linking themselves together like pieces of a jigsaw puzzle.

Interestingly, shear forces generated by fast-moving urine in the urethra may actually tighten bacterial adhesion to target cells. The tip protein, FimH, which is analogous to PapG but for a different type I pilus, contains two domains, the pilin domain (pale yellow) and the lectin domain (blue), as shown in **Figure 25.12.** The pilin domain integrates FimH into the tip of the pilus. The lectin domain binds the host receptor. Scientists have described a mechanism whereby a shear force, such as might be experienced by uropathogenic *E. coli* bound to bladder cells during urination, extends the interdomain linker between the FimH lectin and pilin domains and *strengthens* the hold of the lectin domain on the mannose receptor. It is not clear whether shear ends up changing the existing site from a low-affinity to a high-affinity binding site or if the conformational shift exposes a second, hidden, mannose-binding site. Regardless, it becomes harder to pry *E. coli* from its target host cell. Thus, fluid forces in the human body, as occur with salivating, swallowing, sneezing, urinating, and weeping, may in some cases strengthen bacterial adhesion instead of detaching and flushing away the infectious agents.

Figure 25.12 **Structure of type I pili tip protein.** FimH contains two domains, the pilin domain (yellow) and the lectin domain (blue). The pilin domain integrates FimH into the tip of the pilus. The lectin domain binds the host receptor. When shear is created, the receptor-binding site on the lectin domain is pulled in one direction (yellow arrows), and residue T158 (orange arrow) is pulled in the opposite direction. (PDB codes: 2co4, 1tr7)

Other pili with an important role in pathogenesis are the type IV pili. Type IV pili are found in a broad spectrum of gram-negative bacteria and share amino acid homology in their major pilin structure (**Fig. 25.13**). Species with type IV pili include *V. cholerae, Pseudomonas aeruginosa* (**Fig. 25.13B**), certain pathogenic strains of *E. coli, Neisseria meningitidis,* and *N. gonorrhoeae.* All type IV pili use similar secretion and assembly machinery involving at least a dozen proteins. One major difference between the assembly of type IV and type I pili is that type IV pilus proteins are never free in the periplasm; they are transported directly from the cytoplasm through a channel in the outer membrane (**Fig. 25.13A**). Thus, type IV pilus assembly is SecA independent. As described here, the blueprints for this mechanism were adapted and modified through evolution to secrete other proteins via what is generally called type II protein secretion (discussed in Section 25.5).

Type IV pili can actually make cells move because the assembly process involves the reiterative elongation and retraction of the pili. The process, called "twitching motility," occurs when the pilus elongates, attaches to a surface, then depolymerizes from the base, which shortens the pilus and pulls the cell forward. This mechanism is akin to using a grappling hook to scale a building. The gliding motility of the slime mold *Myxococcus xanthas* is also due to type IV pili. The type IV pili of *Neisseria meningitidis*, shown in **Figure 25.13C**, are essential for crossing the blood-brain barrier and causing bacterial meningitis.

Bacteria also carry afimbriate adhesins (proteins that aid in attachment but do not form pili) that mediate binding to host tissues (**Fig. 25.14**). Some examples include *Bordetella* pertactin (which binds to integrin), *Streptococcus* protein F (binds to fibronectin), *Streptococcus* M protein (binds to fibronectin and complement regulatory factor H), and intimin of enteropathogenic *E. coli* (binds to Tir; discussed in Section 25.5). Fimbriae (pili) often mediate the initial binding between bacterium and host, after which a more intimate attachment is created by an afimbriate attachment protein. In the case of *Neisseria gonorrhoeae*, once the type IV pilus has attached to the surface of the mucosal epithelial cell, the filamentous pilus contracts, pulling the bacterium down onto the host cell membrane. Tight secondary interactions are then mediated by the neisserial Opa membrane proteins, another example of an afimbriate adhesin (Opa is named because of the *opa*city it adds to colony appearance).

TO SUMMARIZE:

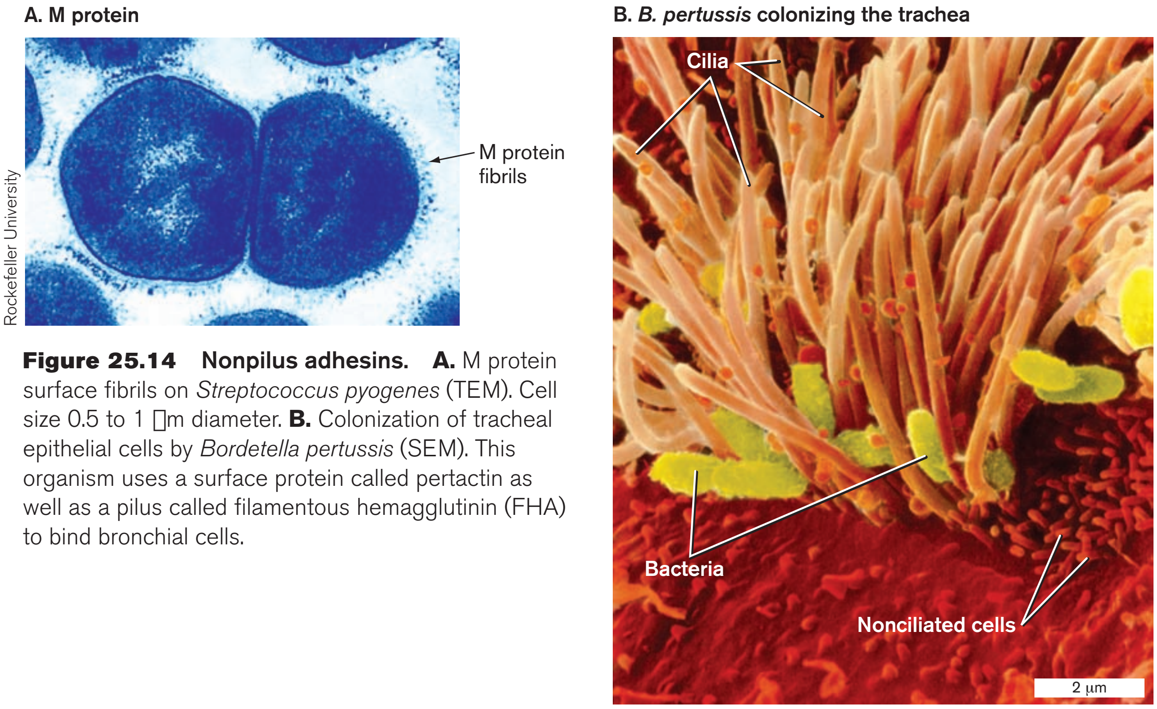
- **Bacteria use pili and nonpilus adhesins** to attach to host cells.
- **Type I pili** produce a static attachment to the host cell, whereas type IV pili continually assemble and disassemble.
- **Nonpilus adhesins** are bacterial surface proteins, or other molecules, that can tighten interactions between bacteria and target cells.

25.4 Toxins: A Way to Subvert Host Cell Function

Following attachment, many microbes secrete protein toxins (called **exotoxins**) that kill host cells and unlock their nutrients (because dead host cells ultimately lyse). Bacterial pathogens have developed an impressive array of toxins that take advantage of different key host proteins, or structures. All gram-negative bacteria also possess a nonprotein yet toxic compound called **endotoxin** that can hyper-activate host immune systems to harmful levels.

Microbial Exotoxins Have Many Modes of Action

Microbial exotoxins fall into five broad categories based on their mechanisms of action (**Table 25.3**). Three of these classes are illustrated in **Figure 25.15**.



A. M protein

B. *B. pertussis* colonizing the trachea

Figure 25.14 Nonpilus adhesins. A. M protein surface fibrils on *Streptococcus pyogenes* (TEM). Cell size 0.5 to 1 μm diameter. **B.** Colonization of tracheal epithelial cells by *Bordetella pertussis* (SEM). This organism uses a surface protein called pertactin as well as a pilus called filamentous hemagglutinin (FHA) to bind bronchial cells.

- **Cell membrane disruption.** Members of the first class, exemplified by the alpha (α) toxin of *Staphylococcus aureus*, disrupt the cell membrane and cause leakage of cell constituents (**Fig. 25.15A**).
- **Protein synthesis disruption.** A second class, exemplified by diphtheria and Shiga toxins, targets eukaryotic ribosomes and destroys protein synthesis (**Fig. 25.15B**).
- **Second messenger pathway disruption.** The third broad mechanism of action involves the toxin subverting host cell secondary messenger pathways. Cholera toxin and *E. coli* ST (stable toxin), for instance, cause runaway synthesis of cAMP (described later) and cGMP (**Fig. 25.15C**), respectively, in target cells. Elevated cAMP or cGMP levels, in turn, trigger critical changes in ion transport and fluid movement.
- **Superantigens.** The fourth class includes toxins that act as superantigens and activate the immune system without being processed by antigen-presenting cells (discussed in Section 24.6). The pyrogenic toxins of *Staphylococcus aureus* (toxic shock syndrome toxin) and *Streptococcus pyogenes* are examples of superantigenic toxins.
- **Proteases.** The fifth class of toxins consists of proteases. One example is tetanus toxin, a protease that cleaves host components involved in nerve signal transmission.

This section focuses on the key concepts of microbial toxin activity. Section 25.5 discusses how bacteria secrete these toxins.

A common structural theme among many, but not all, bacterial toxins is that they have two subunits, usually called A and B. These two-subunit complexes are termed **AB toxins**. The actual toxic activity in AB toxins resides within the A subunit. The role of the B subunit is limited to binding host cell receptors. Thus, the B subunit for each toxin delivers the A subunit to the host cell. Many AB toxins have five B subunits arranged as a ring, in the center of which is nestled a single A subunit (**Fig. 25.16A**).

A major AB toxin subclass comprises toxins that have an **ADP-ribosyltransferase** enzymatic activity. These enzyme toxins transfer the ADP-ribose group from an NAD molecule to a target protein (**Fig. 25.16B**). The ADP-ribosylated protein has an altered function. Sometimes the function is destroyed (for example, protein synthesis is destroyed by diphtheria toxin); other times, the protein is locked into an active form insensitive to regulatory feedback control (for example, cAMP synthesis continues unchecked in the presence of cholera toxin).

Mechanisms of selected toxins representing the various classes are described in this section.

Alpha toxin. The hemolytic alpha toxin is produced by *Staphylococcus aureus*, an organism that causes boils and blood infections. Alpha toxin forms a transmembrane, oligomeric (seven member) beta barrel pore in target cell membranes. It is easy to see how the resulting leakage of cell constituents and influx of fluid cause the target cell to burst. To form the pore, hydrophobic areas of each monomer face the lipids of the membrane and hydrophilic residues face the channel interior.

Figure 25.15 Three classes of microbial toxins. These classes are defined by mode of action. **A.** Pore-forming toxins assemble in target membranes and cause leakage of compounds into and out of cells. **B.** Shiga toxin attaches to ganglioside Gb3, enters the cell, and cleaves 28S rRNA in eukaryotic ribosomes to stop translation. **C.** Enterotoxigenic *E. coli* heat-stable toxin affects cGMP production. The result is altered electrolyte transport: inhibition of Na^+ uptake and stimulation of Cl^- transport. Water follows the resulting electrolyte imbalance and leaves the cell.

Table 25.3 Characteristics of bacterial toxins.[a]

Toxin	Organism	Mode of action	Host target	Disease	Toxin implicated in disease[b]
Damage membranes					
Aerolysin	*Aeromonas hydrophila*	Pore former	Glycophorin	Diarrhea	(Yes)
Perfringolysin O	*Clostridium perfringens*	Pore former	Cholesterol	Gas gangrene[c]	Unknown
Hemolysin[d]	*Escherichia coli*	Pore former	Plasma membrane	UTIs	(Yes)
Listeriolysin O	*Listeria monocytogenes*	Pore former	Cholesterol	Food-borne systemic illness, meningitis	Yes
Alpha toxin	*Staphyloccocus aureus*	Pore former	Plasma membrane	Abcesses[c]	(Yes)
Pneumolysin	*Streptococcus pneumoniae*	Pore former	Cholesterol	Pneumonia[c]	(Yes)
Streptolysin O	*Streptococcus pyogenes*	Pore former	Cholesterol	Strep throat Scarlet fever	Unknown
Inhibit protein synthesis					
Diphtheria toxin	*Corynebacterium diphtheriae*	ADP-ribosyltransferase	Elongation factor 2	Diphtheria	Yes
Shiga toxins	*E. coli/Shigella dysenteriae*	*N*-glycosidase	28S rRNA	HC and HUS	Yes
Exotoxin A	*Pseudomonas aeruginosa*	ADP-ribosyltransferase	Elongation factor 2	Pneumonia[c]	(Yes)
Activate second messenger pathways					
CNF	*E. coli*	Deamidase	Rho G proteins	UTIs	Unknown
LT	*E. coli*	ADP-ribosyltransferase	G proteins	Diarrhea	Yes
ST[d]	*E. coli*	Stimulates guanylate cyclase	Guanylate cyclase receptor	Diarrhea	Yes
EAST	*E. coli*	ST-like?	Unknown	Diarrhea	Unknown
Edema factor	*Bacillus anthracis*	Adenylate cyclase	ATP	Anthrax	Yes
Dermonecrotic toxin	*Bordetella pertussis*	Deamidase	Rho G proteins	Rhinitis	(Yes)
Pertussis toxin	*B. pertussis*	ADP-ribosyltransferase	G protein(s)	Pertussis (whooping cough)	Yes
C2 toxin	*Clostridium botulinum*	ADP-ribosyltransferase	Monomeric G-actin	Botulism	Unknown
C3 toxin	*C. botulinum*	ADP-ribosyltransferase	Rho G protein	Botulism	Unknown
Toxin A	*Clostridium difficile*	Glucosyltransferase	Rho G protein(s)	Diarrhea/PC	(Yes)
Toxin B	*C. difficile*	Glucosyltransferase	Rho G protein(s)	Diarrhea/PC	Unknown
Cholera toxin	*Vibrio cholerae*	ADP-ribosyltransferase	G protein(s)	Cholera	Yes
Activate immune response					
Enterotoxins	*S. aureus*	Superantigen	TCR and MHC II	Food poisoning[c]	Yes
Exfoliative toxins	*S. aureus*	Superantigen (and serine protease?)	TCR and MHC II	Scalded skin syndrome[c]	Yes
Toxic shock toxin	*S. aureus*	Superantigen	TCR and MHC II	Toxic shock syndrome[c]	Yes
Pyrogenic exotoxins	*S. pyogenes*	Superantigens	TCR and MHC II	Toxic shock syndrome Scarlet fever	Yes Yes

Lethal factor	*B. anthracis*	Metalloprotease	MAPKK1/MAPKK2	Anthrax	Yes
Neurotoxins A–G	*C. botulinum*	Zinc metalloprotease	VAMP/synaptobrevin SNAP-25 syntaxin	Botulism	Yes
Tetanus toxin	*Clostridium tetani*	Zinc metalloprotease	VAMP/synaptobrevin	Tetanus	Yes

[a] **Abbreviations:** CNF, cytotoxic necrotizing factor; LT, heat-labile toxin; ST, heat-stable toxin; CLDT, cytolethal distending toxin; EAST, enteroaggregative *E. coli* heat-stable toxin; TCR, T-cell receptor; MHC II, major histocompatibility complex class II; MAPKK, mitogen-activated protein kinase kinase; VAMP, vesicle-associated membrane protein; SNAP-25, synaptosomal-associated protein; UTI, urinary tract infection; HC, hemorrhagic colitis; HUS, hemolytic uremic syndrome; PC, antibiotic-associated pseudomembranous colitis.

[b] Yes, strong causal relationship between toxin and disease; (yes), role in pathogenesis has been shown in animal model or appropriate cell culture.

[c] Other diseases are also associated with the organism.

[d] Toxin is also produced by other genera of bacteria.

Source: C. K. Schmidt, K. C. Meysick, and A. O'Brien. 1999. Bacterial toxins: Friends or foes? *Emerging Infectious Diseases* 5:224–234.

A completed pore and a cutaway view exposing the channel are illustrated in **Figure 25.17A** and **B**. Diagnostic microbiology laboratories visualize hemolysins (proteins that lyse red blood cells) such as alpha toxin by inoculating bacteria onto agar plates containing sheep red blood cells (**Fig. 25.17C**). The clear, yellow zones around the *S. aureus* colonies growing on blood agar indicate that the microbe secretes a hemolysin.

Cholera and *E. coli* labile toxins. *Vibrio cholerae* (**Fig. 25.18A**) produces a severe diarrheal disease called cholera that generally afflicts malnourished people populating poor countries like Bangladesh, or countries in which access to clean water has been disrupted by war or natural disasters. This microbe produces a gastrointestinal enterotoxin nearly identical to one produced by some strains of *E. coli* associated with what is known as "traveler's diarrhea." Enterotoxins specifically affect the intestine. The *E. coli* enterotoxin is called **labile toxin (LT)** because it is easily destroyed by heat. Cholera toxin (CT) and labile toxin are both AB toxins with identical modes of action, which is to increase the level of cAMP made inside the host cell.

After the bacteria attach to the cells lining the intestinal villa (**Figs. 25.18C** and **D**), they secrete these AB toxins, the structure of which is shown in **Figure 25.18B**. Both toxins have five B subunits arranged as a ring around a single A subunit. The B subunits bind to ganglioside GM1 on eukaryotic cell membranes and deliver the A subunit to the target cell (**Fig. 25.19A**, steps 1 to 4). The A subunit possesses the toxic part of the molecule, an ADP-ribosyltransferase, which must be activated by the host.

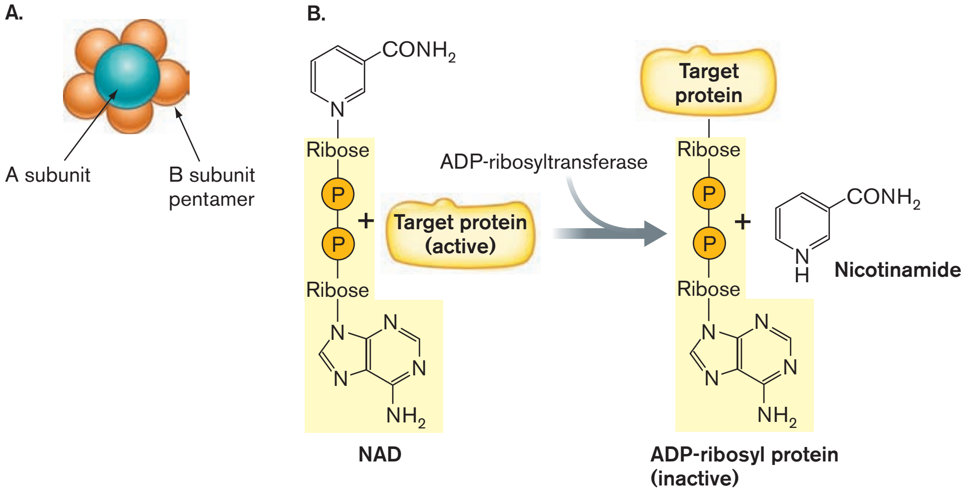

Figure 25.16 AB toxins. **A.** A typical AB toxin consists of an A subunit and a pentameric B subunit joined noncovalently. **B.** Many AB toxins are ADP-ribosyltransferase enzymes that modify protein structure and function.

(PDB code: 7ahl) **B.** Cross section showing the channel. **C.** A blood agar plate inoculated with *S. aureus*. The alpha toxin is secreted by the organism and diffuses away from the producing colony. It forms pores in the red blood cells embedded in the agar, causing them to lyse. This is visible as a clear area surrounding each colony.

The binding of CT or LT to GM1 triggers endocytosis and the formation of a toxin-containing vacuole. The phagosome is then transported to the endoplasmic reticulum. During this time, the A subunit is cleaved by a host protease into two fragments called A1 and A2, which are still held together by a disulfide bond. The reducing environment at the cell surface reduces that bond and frees the A1 peptide containing active ADP-ribosylase into the endoplasmic reticulum, which exports the toxin into the cytoplasm.

The mission of A1 peptide is to modify (ADP-ribosylate) a membrane-associated GTPase (called a G protein) that binds to adenylate cyclase and controls its activity (**Fig. 25.19A**, step 5). To understand how the toxin produces diarrhea, it is helpful to observe what happens in the absence of toxin (**Fig. 25.19B**).

1. G-factor complex (α, β, γ) bound to hormone receptor. When bound to hormone, GTP exchanges for GDP on Gα.

2. Gα-GTP disengages from receptor, interacts with adenylate cyclase, and either stimulates (if G$_s$α) or inhibits (if G$_i$α) cAMP production.

3. An intrinsic GTPase activity within Gα inactivates the G factor.

4. Gα factor with GDP returns to receptor complex to await stimulation.

Figure 25.19 Cholera toxin mode of action. **A.** Delivery of cholera toxin into target cells and deregulation of adenylate cylase activity. **B.** Normal regulation of human cell adenylate cyclase. Human cells have two G-factor complexes, G$_s$ and G$_i$, that stimulate and inhibit adenylate cyclase, respectively. ⏯

The intestinal epithelium has both absorptive and secretory functions. Transport is characterized by a net absorption of NaCl, short-chain fatty acids (SCFA), and water, allowing extrusion of a feces with very little water and salt content. In addition, the epithelium secretes mucus, bicarbonate, and KCl. A major player in the secretion of Cl^- is the cystic fibrosis transmembrane conductance regulator (CFTR). Chloride export via CFTR is activated indirectly by cAMP. (CFTR is so named because a genetically based defect in the CFTR transporter/regulator manifests as the lung disease cystic fibrosis.)

Human cells have two types of G-factor complexes called G_s and G_i that stimulate and inhibit adenylate cyclase, respectively. The G-factor complexes share beta and gamma subunits but have distinct alpha subunits (G_s-alpha and G_i-alpha). The complexes are normally bound to specific membrane hormone receptors (**Fig. 29.19B**). Stimulation of the hormone receptor allows GTP to bind the associated G-alpha subunit (replacing a bound GDP). Subsequently, the G-alpha–GTP protein leaves the receptor complex and binds adenylate cyclase, either stimulating cAMP production (if G_s-alpha) or inhibiting it (if G_i-alpha).

Normally, an intrinsic GTPase activity within the G-alpha protein degrades GTP to GDP. G-alpha protein bound to GDP is inactive and cannot control adenylate cyclase. G-factor-associated GTP turnover controls cAMP levels and thus CFTR activity in normal cells.

In the disease state (**Fig. 25.19A**, step 5), G-alpha protein is ADP-ribosylated by cholera or labile toxin. Modified G-alpha protein can still activate adenylate cyclase, but it has a defective GTPase. Because the altered G factor cannot degrade GTP, the protein continually stimulates cAMP production. This increases the levels of cAMP tremendously. Elevated levels of cAMP stimulate a host enzyme called protein kinase A that activates various ion transport channels (**Fig. 25.19**, step 6). One of these channels is the cystic fibrosis transmembrane conductance regulator that controls chloride transport (discussed in Section 24.4). As a result, chloride, sodium, and other ions leave the cell and, in an attempt to equilibrate osmolarity, water leaves as well. Because the affected cells line the intestine, the escaping water enters the intestinal lumen, leading to watery stools, or diarrhea.

How is diarrhea a benefit to the microorganism? A major benefit to the organism is to propagate the species. The more diarrhea that is produced and expelled, the greater the number of organisms are made and disseminated throughout the environment. This increases the chance that another host will ingest the organism, ensuring survival of the species. Diarrhea can also benefit a pathogen by decreasing competition with other organisms as they are swept away. In fact, the vast majority of organisms found in the diarrheal fluids of cholera patients are *V. cholerae* bacteria.

Different pathogens have discovered alternative ways to alter host cAMP levels. The gram-negative pathogen *Bordetella pertussis* causes a childhood respiratory infection called whooping cough, so named for the whooping sound made as a child tries to take a breath after a fit of coughing. This microbe also secretes an ADP-ribosylating toxin, but one that modifies G_i-alpha (the inhibitory factor that normally downregulates adenylate cyclase activity). ADP-ribosylation in this instance prevents that inhibition, with the result (again) of runaway cAMP synthesis. Pertussis toxin, however, is structurally different from cholera toxin. In addition, the organism makes a “stealth” adenylate cyclase that is secreted from the bacterium but remains inactive until it enters host cells, where it becomes active by binding the calcium-binding protein calmodulin. The resulting increase in cAMP levels causes inappropriate triggering of certain host cell signaling pathways.

THOUGHT QUESTION 25.2 Antibodies to which subunit of cholera toxin will best protect a person from the toxin's effects?

Diphtheria toxin. Other exotoxins can affect host protein synthesis. The microbe *Corynebacterium diphtheriae* produces a potent toxin that causes the disease diphtheria by inhibiting protein synthesis in eukaryotic cells (**Fig. 25.20A**). The organism remains in the pharynx while the toxin spreads throughout the body. Symptoms of diphtheria include the formation of an airway-obstructing pseudomembrane that forms over the trachea (**Fig. 25.20B**) and enlarged lymph nodes that give the patient a bull-neck appearance (**Fig. 25.20C**). The pseudomembrane consists of fibrin, bacteria, and inflammatory cells; it adheres firmly to underlying tissue. The toxin, not growth of the organism, is solely responsible for these symptoms. The gene encoding the toxin actually resides in the genome of a bacteriophage that lysogenizes *C. diphtheriae* (lysogeny is discussed in Section 10.7). The phage is called Beta phage and is a prime example of how a phage genome may, over generations, degenerate to become a pathogenicity island, losing its former identity as a phage genome.

Diphtheria toxin is also an ADP-ribosylase and another example of an AB toxin. But unlike cholera toxin, whose A and B subunits are synthesized as separate peptides from separate genes, diphtheria toxin is synthesized as a single polypeptide. **Figure 25.21A** illustrates the monomeric and natural dimeric forms of diphtheria toxin. There are three domains within the peptide. A

central **receptor-binding domain** (the B subunit of the toxin) binds to the target cell receptor on the membrane. There is also a C-terminal **transmembrane domain** that allows the protein to embed in the host membrane. The third domain, located at the amino terminus, carries the ADP-ribosylase activity and is the A subunit of the peptide toxin.

As with cholera toxin, diphtheria toxin must be cleaved to become active. As illustrated in **Figure 25.22**, the receptor-binding domain (B) binds the host membrane, and the toxin (A + B) then enters the cell by endocytosis. Once the toxin enters the cell, its peptide backbone is cleaved, but the halves are held together by disulfide bonds. When the inside of the endosome vesicle acidifies (by H^+-pumping ATPases), the disulfide bonds are reduced (cleaved), allowing the transmembrane domain of subunit A to embed in the host endosome membrane and then to pass through the vesicle membrane. The transmembrane domain then facilitates passage of the A peptide (that is, the catalytic domain) through the vesicle membrane. Once inside the cytoplasm, the catalytic domain (A subunit) ADP-ribosylates an important protein synthesis factor called elongation factor 2 (EF2). This effectively halts protein synthesis and kills the cell.

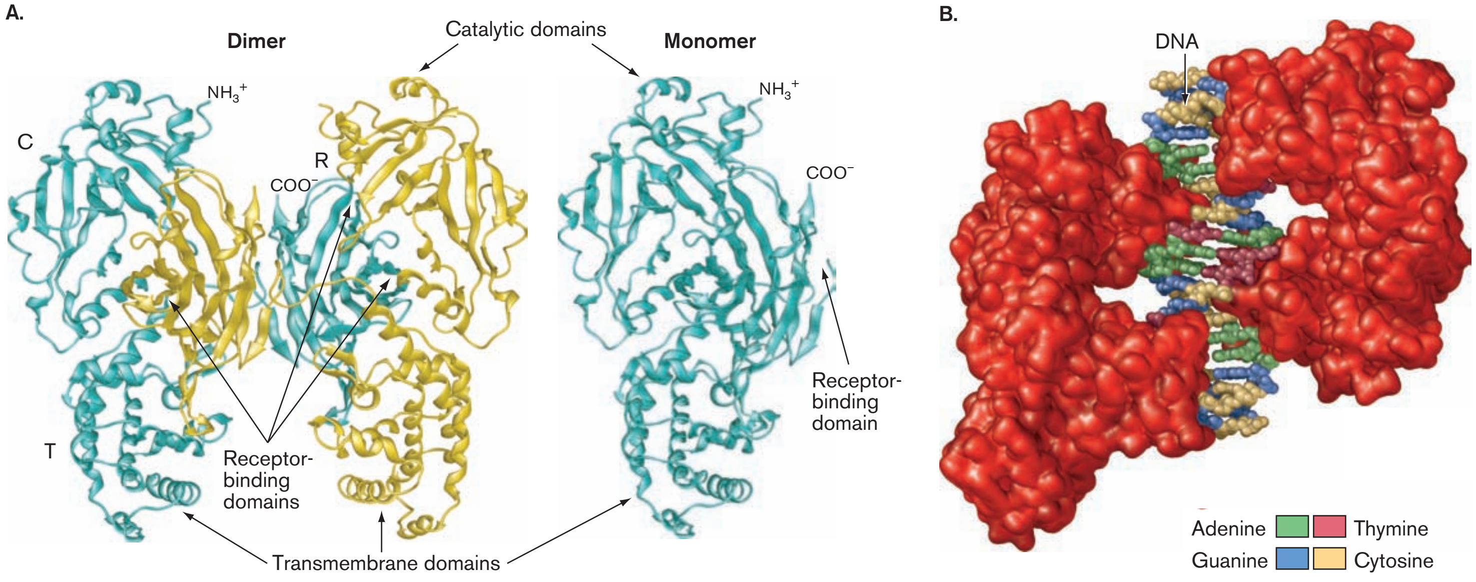

Figure 25.21 Diphtheria toxin and the diphtheria toxin repressor. A. View of diphtheria toxin showing swapped domains of a dimer and a monomer of the toxin. To form a dimer, the receptor-binding domains of two monomers swap to produce a stable structure. (PDB code: 1SGK) **B.** Diphtheria toxin repressor (DtxR) bound to the *dtx* promoter DNA. When bound to iron, the repressor binds to the *dtx* gene in the beta phage to prevent toxin synthesis. (PDB code: 1C0W)

2. Membrane-bound toxin (A + B) enters by endocytosis.

3. Catalytic subunit A is cleaved but held to the B subunit by disulfide bonds. Endosome vesicle acidifies; the disulfide bonds are reduced.

4. The transmembrane domain facilitates passage of the catalytic A peptide through the vesicle membrane.

5. The catalytic A domain ADP-ribosylates elongation factor 2 (EF2). This halts protein synthesis and kills the cell.

Figure 25.22 Diphtheria toxin mode of action. ADP-ribose, ADPR.

Today, thanks to intense vaccination efforts using inactivated toxin (called a toxoid), the disease diphtheria is rarely seen in this country. However, scientists are now learning to modify diphtheria toxin to serve new therapeutic purposes. Some experimental anticancer therapies have used gene-splicing techniques to replace the receptor-binding domain of diphtheria toxin with protein domains that bind unique receptors on cancer cells. The catalytic (toxic) and transmembrane domains of the toxin are left intact, but the new receptor domain targets the toxin to cancer cells. The toxin then enters and kills the cancer cell without harming innocent (noncancerous) bystander cells. Though showing promise, recombinant diphtheria toxin has not yet been proven effective in clinical trials.

Why is diphtheria toxin made? Iron availability appears to be a key factor. The body holds its iron very tightly in proteins such as lactoferrin and ferritin. So to an invading microbe, the body seems to be a very iron-poor environment. This makes it difficult for the pathogen to grow. Diphtheria toxin offers the organism a way to rob the host's iron stores.

Diphtheria toxin genes (*dtx*) are controlled by a repressor (DtxR) that binds iron (see **Fig. 25.21B**). When iron is plentiful, the repressor binds as a dimer to the promoter region of the *dtx* gene and prevents transcription. However, when free iron is scarce, as is the case in the body, there is not enough iron to activate the repressor and the *dtx* gene is expressed. As a result, diphtheria toxin is made, target cells are killed, and iron is released for bacterial use. This quest for iron is another common theme used by many pathogens to control pathogenic mechanisms.

THOUGHT QUESTION 25.3 Would patients with iron overload (excess free iron in the blood) be more susceptible to infection?

Shiga toxin: *Shigella* and *E. coli* O157:H7. *S. flexneri* and *E. coli* O157:H7 (also known as enterohemorrhagic *E. coli*) cause food-borne diseases whose symptoms include bloody diarrhea. These organisms produce an important toxin known as Shiga toxin (or Shiga-like toxin). The toxin has five B subunits for binding and one A subunit imbued with toxic activity. The A subunit, upon entry, destroys protein synthesis by cleaving 28S rRNA in eukaryotic ribosomes. Strains that produce high levels of this toxin are associated with acute kidney failure known as hemolytic uremic syndrome.

E. coli O157:H7 is a recently emerged pathogen. The organism can colonize cattle intestines without causing bovine disease; as a result, undetected bacteria can easily contaminate meat products following slaughter. The organism is sometimes referred to as the "Jack-in-the Box" microbe, a reference to the first large U.S. outbreak associated with fast-food hamburgers at a Washington state Jack-in-the-Box restaurant in 1993. Both *E. coli* and *Shigella* have remarkable acid resistance mechanisms that rival that of the gastric pathogen *Helicobacter pylori.* This acid resistance makes these pathogens infectious at a very low infectious dose.

THOUGHT QUESTION 25.4 How might you experimentally determine if a pathogen secretes an exotoxin?

and sheep. Humans only acquired the disease accidentally. Today we fear the deliberate shipment of *B. anthracis* through the mail or its dispersion from the air ducts of heavily populated buildings. What makes this gram-positive, spore-forming microbe so dangerous? In large part, its lethality is due to the secretion of a plasmid-encoded tripartite toxin. The core subunit of the toxin is called **protective antigen (PA)** because immunity to this protein *protects* hosts from disease. Protective antigen is made as a single peptide but then binds to the host cell surface, where a human protease cleaves off a fragment (**Fig. 25.23B**). The remaining part of PA can autoassemble in the membrane to form a heptameric (seven-membered) pore. The other two components of anthrax toxin, **edema factor (EF)** and **lethal factor (LF)**, bind to separate rings and are carried into the cell (see **Fig. 25.23C**). The complex is endocytosed, and the two proteins carried in are passed through the pore into the host cytoplasm.

Edema factor and lethal factor are the toxic parts of anthrax toxin. Both are enzymes that attack the signaling functions of the cell. Edema factor is an adenylate cyclase that remains inactive until entering the cytoplasm, where it binds calmodulin. This binding activates adenylate cyclase, resulting in a huge production of cAMP, and inactivates calmodulin from its normal function in the cell.

Lethal factor is actually a protease that cleaves several host protein kinase kinases, each of which is part of a critical regulatory cascade affecting cell growth and proliferation. A protein kinase kinase is an enzyme that phosphorylates, and thereby activates, another protein kinase that can then phosphorylate one or more subsequent target proteins. One consequence of subverting these phosphorylation cascades is a failure to produce signals that recruit immune cells to fight the infection.

We have examined only a few of the many toxins employed by pathogens. Some of the others, including tetanus and botulism toxins, will be described in the next chapter. What should be apparent from our brief sampling is the evolutionary ingenuity that pathogens have used to try to tame the human host.

THOUGHT QUESTION 25.5 Internet problem: What other toxins are related to the cholera enterotoxin A subunit? B subunit?

WWW | Anthrax tutorial

Identifying New Protein Toxins

How does one identify and characterize the toxin of a new pathogen? In part that depends on whether there is an animal model for the disease (that is, whether the organism will infect a laboratory animal like the guinea pig or mouse and cause disease similar to that of humans). If there is a suitable animal model, one can grow the pathogen in laboratory media and harvest cell-free growth media into which the suspected exotoxin was secreted. The supernatant can be injected directly into a small number of mice, and effects on the health of the animals can be monitored over time. It is important to also use control mice that have received only fresh laboratory media (no toxin). If an effect is noted in the test mice, the exotoxin-containing supernatant can be treated with proteinase. If the toxin is protein, the treatment will destroy toxic activity. Subsequently, a variety of protein purification techniques, such as ion-exchange and molecular sieve chromatography, can be used to purify the protein.

One can also utilize tissue culture cells to test for the presence of a cell-free toxin in growth media. In using this method, one thing to keep in mind is that the effect may be tissue specific: The toxin may work on one tissue but not another. Another concern is whether the laboratory medium used to grow the bacterial cells is sufficient to elicit toxin production. A high-iron medium, for example, will prevent synthesis of diphtheria toxin. Thus, it is important to mimic the host environment as closely as possible when coaxing a pathogen to make exotoxin in vitro.

Endotoxin (LPS) Is Made Only by Gram-Negative Bacteria

Another important virulence factor common to all gram-negative microorganisms is endotoxin present in the outer membrane (discussed in Chapter 3). Not to be confused with secreted exotoxins, endotoxin is an embedded part of the bacterial cell surface and an important contributor to disease. Endotoxin, otherwise called lipopolysaccharide (LPS), is composed of lipid A, core glycolipid, and a repeating polysaccharide chain (**Fig. 25.24**). LPS molecules form the outer leaflet of the gram-negative outer membrane. As bacteria die, they release endotoxin. Endotoxin can then bind macrophages or B cells and trigger

the release of TNF-alpha, interferon, IL-1, and other cytokines. The release of these active agents causes a variety of symptoms, such as:

- Fever
- Activation of clotting factors, leading to disseminated intravascular coagulation
- Activation of the alternate complement pathway
- Vasodilation, leading to hypotension (low blood pressure)
- Shock due to hypotension
- Death when other symptoms are severe

The lipid A moiety of LPS possesses endotoxic activity (**Fig. 25.24**).

NOTE: Lipopolysaccharides are also the outer membrane structures called O antigens that are used to classify different strains of *E. coli* as well as other gram-negative organisms (for example, *E. coli* O157 versus *E. coli* O111).

The role of endotoxins can be seen in infections with the gram-negative diplococcus *Neisseria meningitidis* (**Fig. 25.25A**), a major cause of bacterial meningitis. *N. meningitidis* has, as part of its pathogenesis, a septicemic phase where the organism can replicate to high numbers in the bloodstream. The large amount of endotoxin present causes a massive depletion of clotting factors that leads to internal bleeding, most prominently displayed to a physician as small pinpoint hemorrhages called **petechiae** on the patient's hands and feet. (**Fig. 25.25B**). Capillary bleeding near the surface of the skin causes petechiae. One danger of treating massive gram-negative sepsis with antibiotics is that the enormous release of endotoxin from dead bacteria could well kill the patient. Untreated gram-negative sepsis is, however, almost always fatal, so its treatment, albeit risky, is imperative.

TO SUMMARIZE:

- **There are five categories of protein exotoxins** based on mode of action. These include toxins that cause membrane disruption, inhibition of protein synthesis, or alteration of host cell signal molecule synthesis, as well as superantigens and target-specific proteases.
- **AB subunit toxins** are common. The B subunit promotes penetration through host cell membranes, and the A subunit has toxic activity.
- ***S. aureus* alpha-toxin** forms pores in host cell membranes.
- **Cholera toxin, *E. coli* labile toxin, and pertussis toxin** are AB toxins that alter host cAMP production by adding ADP-ribose groups to different G-factor proteins.

Figure 25.25 **Effect of *Neisseria meningitidis* endotoxin.** **A.** *Neisseria meningitidis* (cell 0.8 to 1 μm diameter, SEM). **B.** Petechial rash caused by *N. meningitidis*.

- **Diphtheria toxin** is an AB toxin that adds an ADP-ribosyl group to eukaryotic elongation factor 2—a modification that stops protein synthesis.
- **Shiga toxin** is an AB toxin that cleaves host cell 28S rRNA in host cell ribosomes.
- **Anthrax toxin** is a three-part AB toxin with one B subunit (protective antigen) and two different A subunits that affect cAMP levels (edema factor) and cleave host protein kinases (lethal factor).
- **Lipopolysaccharide**, known as endotoxin, is an integral component of gram-negative outer membranes and an important virulence factor that triggers massive release of cytokines from host cells. The indiscriminate release of cytokines can trigger fever, shock, and death.

25.5 Protein Secretion and Pathogenesis

A recurring theme among bacterial pathogens is the secretion of proteins that destroy, cripple, or subvert host target cells. The bacterial toxins described in Section 25.4 are secreted into the surrounding environment, where they float randomly until chance intervenes and they hit a membrane-binding site. However, many pathogens attach to a tissue and inject bacterial proteins directly into the host cell cytoplasm. The proteins may not kill the cell but redirect host signaling pathways in ways that benefit the microbe.

Protein secretion pathways were introduced in Section 8.5, focusing on ATP-binding cassette (ABC) proteins as a model. Additional secretion models are described here in their critical role of delivering pathogenicity proteins such as toxins. A particularly interesting aspect of these secretory systems is that many of them evolved from, and bear structural resemblance to, other more innocuous systems. Other molecular processes that are evolutionarily related to secretion include:

- Type IV pilus biogenesis (homologous to type II protein secretion)
- Flagellar synthesis (homologous to type III protein secretion)
- Conjugation (homologous to type IV protein secretion)

Table 25.4 gives examples of virulence proteins associated with these export systems.

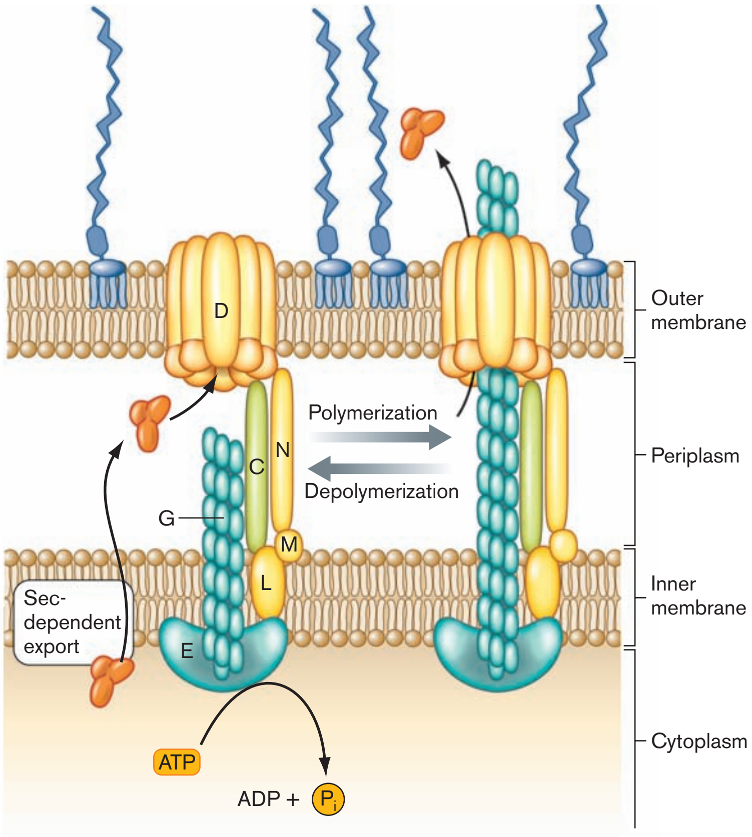

Figure 25.26 Type II secretion. C, D, E, G, L, M, and N are protein components of the secretion system. *Source*: Modified from Moat, Foster, and Spector. 2002. *Microbial Physiology*, 4th ed.

Type II Secretion Systems Resemble Pilus Assembly

Type II secretion offers a clear example of how nature has modified the blueprints of one system to do a very different task. DNA sequence analysis has revealed that the genes used for type IV pilus biogenesis (see Section 25.3) were duplicated at some point during evolution and redesigned to serve as a protein secretion mechanism. Type IV pili have the unusual ability to extend and retract from the outer membrane, a property that produces the gliding motility of *Myxococcus* (see Section 4.7) and the twitching motility of *Neisseria* and *Pseudomonas*. As you might guess, assembly/disassembly of these appendages is quite complex. Type II protein secretion mechanisms mirror this complexity. Proteins to be secreted first make their way, via the Sec-dependent general secretion pathway, to the periplasm, where they then encounter the appropriate type II secretion system. Because of this periplasmic "layover," the proteins are folded *before* secretion. Type II secretion systems use the pilus-like structure as a piston to ram the folded proteins through an outer membrane pore structure and into the surrounding void (**Fig. 25.26**). Piston action occurs via cyclic assembly and disassembly of pilus-like proteins, driving the pilus-like structure through an outer membrane pore and then retracting. Cholera toxin is a well-known example of a protein expelled by a type II secretion mechanism.

Table 25.4 Secretion systems for bacterial toxins.

Secretion type	Features	Examples
I	SecA dependent	*E. coli* alpha-hemolysin, *Bordetella pertussis* adenyl cyclase
II	SecA dependent, similar to type IV pili	*Pseudomonas aeruginosa* exotoxin A, elastase
Autotransporters	SecA dependent to periplasm, self-transport through outer membrane	Gonococcal and *Haemophilus influenzae* IgA proteases
III	SecA independent, syringe	*Yersinia* Yop proteins, *Salmonella* Sip proteins, EPEC EspA proteins, TirA
IV	Related to conjugational DNA transfers	*B. pertussis* toxin, *Helicobacter* CagA

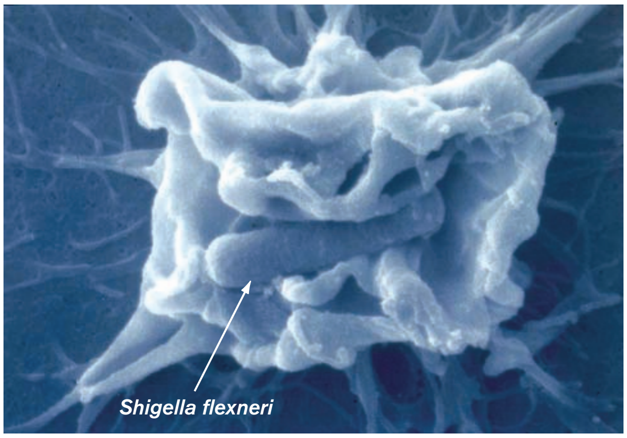
Type III Secretion Injects Protein into Host Cells

In the last decade of the previous century, it was discovered that the etiological agents of Black Death and various forms of diarrhea (caused by species of *Yersinia*, *Salmonella*, and *Shigella*) could somehow take their bacterial virulence proteins made in the cytoplasm and drive them directly into the eukaryotic cell cytoplasm without the protein ever getting into the extracellular environment. Direct delivery is a good idea because it eliminates the dilution that happens when a toxin is secreted into media. Another advantage of this strategy is that it avoids the need to tailor the toxin to fit a preexisting host receptor.

What kind of molecular machine can directly deliver cytoplasmic bacterial proteins into target cells? Research has shown that some microbes use tiny molecular syringes embedded in their membranes to inject proteins directly into the host cytoplasm; this mechanism of delivery is called **type III secretion**. **Figure 25.27** shows electron micrographs of actual type III secretion needles and a model of the complex. Genes encoding type III systems are actually related to flagellar genes, whose products export the flagellin proteins through the center of a growing flagellum (discussed in Chapter 3). It appears that flagella genes were evolutionarily reengineered to act more like molecular syringes (see **Fig. 25.27C**). The bacterial virulence proteins secreted by type III systems subvert normal host cell signaling pathways and cause dramatic rearrangements of host membranes that often lead to engulfment of the microbe (**Fig. 25.28**). The genes encoding type III systems are usually located within pathogenicity islands inherited from other microbial sources.



Roger Wepf, Philippe Sansonetti, and Ariel Blocker, EMBL, Heidelberg

Figure 25.28 *Shigella* invades a host cell ruffle produced as a result of type III secretion. *Shigella flexneri* entering a HeLa cell (scanning transmission microscopy). The bacterium (small diameter approx. 1 µm) interacts with the host cell surface and injects (via its type III secretion apparatus) its invasin proteins, which act to choreograph a local actin-rich membrane ruffle at the host cell. The ruffle engulfs the bacterium and eventually disassembles, internalizing the bacterium.

Many bacterial pathogens use this type of secretion system, including plant pathogens such as *Pseudomonas syringae* (the cause of blight, a disease of many plants in which leaves or stems develop brown spots). Secretion is normally triggered by cell-cell contact between host and bacterium.

The use of type III secretion will be examined during our discussion of *Salmonella* and *E. coli* pathogenesis (**Special Topic 25.1**). Because of their importance to virulence, type III secretion systems are the subject of intensive research designed to exploit them as potential drug targets.

***Salmonella* pathogenesis.** The enteric pathogen *S. enterica* uses type III secretion systems to invade the eukaryotic host cell and become an intracellular parasite. Following ingestion of contaminated food or water, this bacterium attaches to and invades M cells that are interspersed along the intestinal wall. M cells are specialized intestinal epithelial cells (see Figure 23.17) that sample the intestinal flora and transfer pathogens across the epithelial barrier for recognition by the immune system. *Salmonella* subverts the normal function of M cells and causes an inflammatory response that leads to diarrhea. During its evolutionary journey toward becoming a pathogen, *Salmonella* has acquired at least five and as many as ten pathogenicity islands that are absent from related, but harmless, *E. coli* strains. Only two will be discussed here. ***Salmonella* pathogenicity island 1 (SPI-1)** encodes a type III protein secretion system that delivers a cocktail of at least 13 different protein toxins (called effector proteins) directly into the cytosol of host epithelial cells in the gut (**Fig. 25.29**). Inside epithelial cells, these effector proteins interfere with signal transduction cascades and modulate the host response. One mission of these effectors is to induce cytoskeletal rearrangements that cause ruffling of the eukaryotic membrane around the microbe (see **Fig. 25.28**). The membrane ruffling starts the process of engulfment. *Salmonella* induces this response as a way to avoid the normal endocytic process.

Once *Salmonella* enters an epithelial cell or a macrophage, it finds itself in a vacuole. In the normal course of events, an enzyme-packed lysosome would then fuse with the phagosome and release its contents in an effort to kill the invader. *Salmonella,* however, possesses a second pathogenicity island called **SPI-2** that subverts this host response. SPI-2 uses another type III secretion system to inject proteins that alter vesicle trafficking, thereby reducing phagosome-lysosome fusion so that the intracellular bacteria are spared. The pathogenesis of *Salmonella* is even more complex than just outlined. There are 12 recognized pathogenicity islands present in the genome.

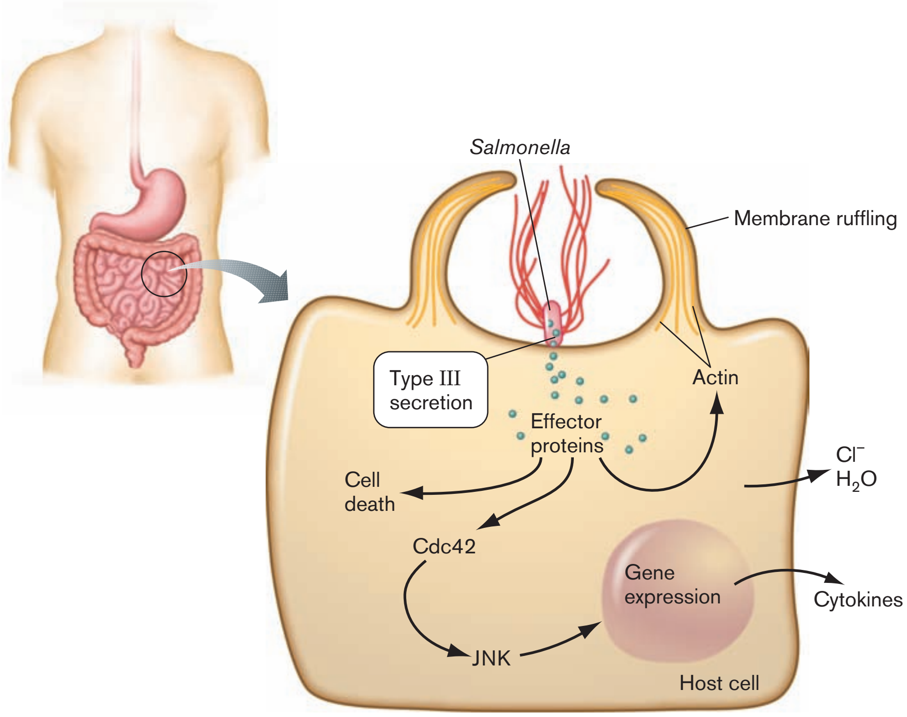


Figure 25.29 Schematic overview of *Salmonella* pathogenesis. Effector proteins injected by *Salmonella* into a host M cell affects the activity of host proteins that trigger cell death (apoptosis), influence gene expression (Cdc42 and JNK), influence electrolyte movements, and induce actin rearrangement. Actin rearrangement produces the ruffling of host membrane to engulf the organism.

Special Topic 25.1 The Bacterial Trojan Horse: Bacteria That Deliver Their Own Receptor

Many pathogens rely on key host surface structures such as gangliosides to recognize and attach to the correct host cell. But the host species can evolve to become resistant to infection when the gene encoding the receptor (or receptor synthesis) mutates. The mutation could lead to complete loss of the protein or a change in its shape to prevent recognition or alter its function. An example is the T-cell surface protein CCR5, which acts as a receptor for HIV virus (see Section 11.5). Individuals with a genetic defect that eliminates CCR5 are immune to HIV infection, so absent methods for preventing and curing HIV infection, humans would evolve a level of resistance to HIV.

Some microbes circumvent possible loss of a host receptor by not relying on the natural array of host receptors in the first place. Instead, these bacterial pathogens use a type III secretion system to insert their own receptors into target cells (**Fig. 1A**). One such group of enterprising pathogens is enteropathogenic *E. coli* (EPEC). The adhesion molecule on the bacterial cell is called **intimin**. Intimin is a 94-kDa integral outer membrane bacterial protein needed for intimate adherence to host cells. However, there is no natural receptor for intimin on host membranes. As discovered by Brett Finley and his colleagues in Vancouver, British Columbia, EPEC must deliver its own intimin receptor, a 57-kDa bacterial protein called Tir (for translocated intimin receptor) that the bacteria inject into the host cell. The genes that encode intimin, Tir, and the secretion apparatus are all part of an EPEC pathogenicity island.

Once injected and placed in the host membrane, Tir binds intimin on the bacterial surface (**Fig. 1B**). The result is the more intimate adherence between the bacterium and host cell surface required for infection to proceed. In addition, host protein kinases phosphorylate Tir at tyrosine residue 474. Phosphorylated Tir directly triggers a remarkable reorganization of host cellular cytoskeletal components (actin, alpha-actinin, ezrin, talin, and myosin light chain) such that a membrane "pedestal" is formed, raising the microbe up (**Fig. 1C**). The result of this attachment is the characteristic attaching and effacing (A/E) lesion, characterized by destruction of the microvilli and pedestal formation.

Figure 1 ***E. coli*** **type III secretion and cell-cell interaction.** **A.** EspA filaments form a bridge between enteropathogenic *E. coli* (EPEC) and an epithelial cell during the early stages of attaching and effacing lesion formation (SEM). These filaments are part of the type III secretion apparatus, functioning as a molecular syringe to inject proteins from pathogenic *E. coli* into the host cell. **B.** Model of cytoskeletal components within the EPEC pedestal. EPEC injects Tir protein into the host cell, where it moves to the membrane and acts as a receptor for intimin. Tir also communicates through phosphorylation with other host proteins to cause a change in actin cytoskeleton, which leads to pedestal formation. **C.** Pedestal formation (SEM).

Type IV Secretion Resembles Conjugation Systems

As Chapter 9 describes, many bacteria can transfer DNA from donor to recipient cells via a cell-cell contact system known as conjugation (discussed in Section 9.2). The conjugation systems of some pathogens have, through evolution, been modified into new systems that transport proteins, or proteins plus DNA, directly into target cells. *Agrobacterium tumefaciens,* for example, uses its Vir system to transfer the tumor-producing Ti plasmid and some effector proteins into plant cells. The result is a plant cancer called crown gall disease. The bacterium responsible for whooping cough in humans, *Bordetella pertussis,* also uses a type IV secretion system to export pertussis toxin, but simply exports the toxin without injecting it into the host (**Fig. 25.30**). Type IV systems also differ with respect to whether the protein is taken directly from the cytoplasm, like CagA from *Helicobacter,* or from the periplasm, as with pertussis toxin. In the latter case, the SecA-dependent general secretory system first delivers the toxin to the periplasmic space.

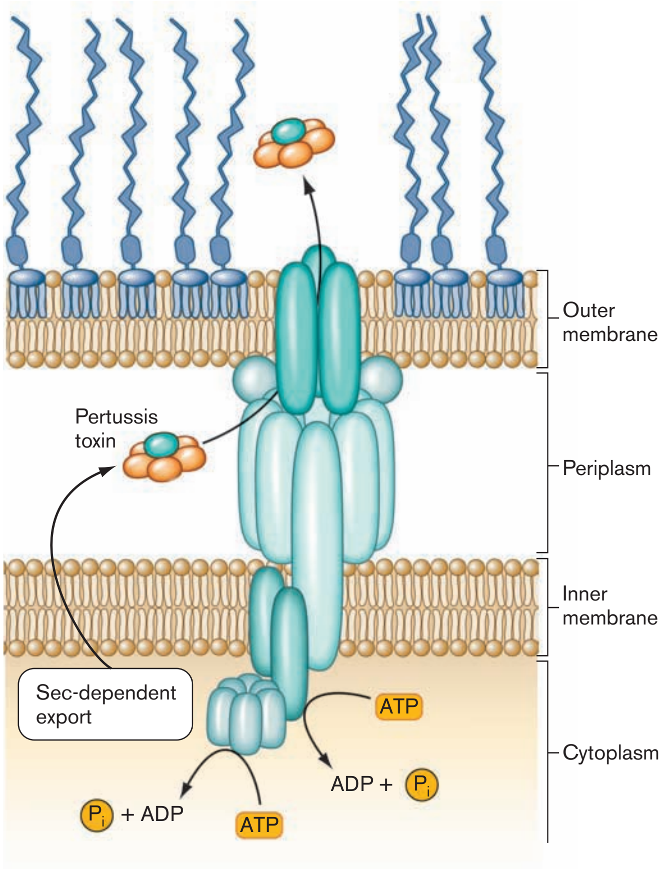

Figure 25.30 Type IV secretion of pertussis toxin. Evolutionarily related to conjugation systems, this type IV system in *Bordetella pertussis* takes pertussis toxin from the periplasm (moved there by SecA-dependent transport) across the outer membrane.

THOUGHT QUESTION 25.6 Protein and DNA have very different structures. Why would a protein secretion system be derived from a DNA-pumping system?

TO SUMMARIZE:

- **Many pathogens** use specific protein secretion pathways to deliver toxins.
- **Type II secretion** systems use a pilus-like extraction/retraction mechanism to push proteins out of the cell.
- **Type III secretion** uses a molecular syringe to inject proteins from the bacterial cytoplasm into the host cytoplasm.
- **Type IV secretion** utilizes an entourage of proteins that resemble conjugation machinery to secrete proteins from either the cytoplasm or periplasm.

25.6 Finding Virulence Genes

All pathogens must enter a host; find their unique niche; avoid, circumvent, or subvert normal host defenses; multiply; and eventually be transmitted to a new susceptible host. Although certain common pathogenic tactics have come to be appreciated, each microbe has a unique "pathogenic signature" that permits survival and leads to its freedom to multiply. When an emerging pathogen causes disease, how do we figure out its mechanisms of virulence? Virulence constitutes a measurable phenotype of an organism. Genes encoding virulence factors are expressed just like those for other traits (for example, expression of the *lac* operon confers the ability to metabolize lactose; discussed in Section 10.2). For metabolic or biosynthetic pathways, identifying the requisite genes is relatively straightforward. For instance, mutations in genes for amino acid biosynthesis produce a clear phenotype that can be observed on an agar plate. If the pathway is defective, the amino acid is not made and must be added to the medium or the mutant will not grow. Because virulence is a consequence of growth in a host, there is no way to identify a phenotype for virulence gene mutants in vitro. Virulence mutants fail to survive or fail to cause disease in animals. So how are these genes identified?

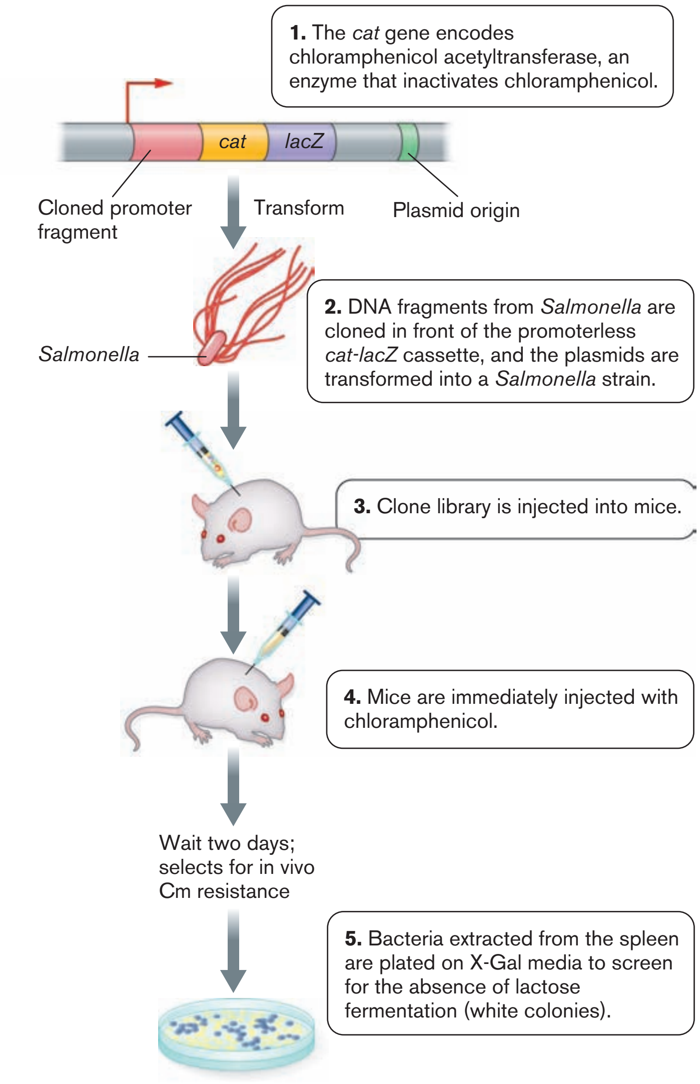
If the genome has been sequenced and a gene bears similarity to a known virulence gene present in another organism, that gene can be selectively mutated and the resulting mutant strain tested for virulence, usually by measuring LD_{50}. But what of genes not assigned an annotated function? They, too, could encode virulence factors. And what of genes that are expressed only during an infection? How do we find those?

In Vivo Expression Technologies Can Identify Virulence Genes

Bacterial genes that are exclusively expressed by the pathogen only during growth within an animal host can now be discovered using what is called **in vivo expression technology (IVET)**. The first step in IVET is to cripple a pathogen so that it cannot grow in the host animal unless a "rescue" gene that produces the missing factor is expressed. Next, the rescue gene is placed without its promoter into a plasmid to make what is called a promoter trap plasmid. The promoter of the plasmid-borne rescue gene is then replaced with random promoters cloned from the microbial genome. If one of the cloned promoters drives expression of the bacterial rescue gene after the organism is injected into the animal, the organism will flourish and kill the host. The trick is to find the promoters that express in vivo but that do not express, or that very poorly express, in laboratory media. Promoters that fit these criteria respond only to unknown in vivo conditions within the host and can be used to determine what those in vivo conditions are.

The IVET procedure was first described in 1995 by J. Mekalanos and colleagues at Harvard University using a promoter trap plasmid in which random fragments of *Salmonella* DNA were inserted (that is, cloned) upstream of a promoterless *cat-lacZ* fusion in the plasmid (**Fig. 25.31**). The *cat* gene encodes chloramphenicol acetyltransferase, an enzyme that inactivates chloramphenicol, making the strain resistant to the drug. The collection of random clones was then injected into mice that were immediately injected with chloramphenicol. When a promoter allowed in vivo expression of the *cat* gene, the microbe became resistant to the drug, grew in the animal, and traveled to the spleen.

The researchers knew that some of the in vivo expressed promoters would also be expressed in vitro (for example, promoters that drive genes encoding ribosome proteins). However, the goal was to identify promoters *only* expressed in the host, a characteristic that would indicate the presence of a downstream gene dedicated to virulence. So, the next task was to identify which of the in vivo expressed promoters was *not* expressed in vitro. To do this, the bacteria extracted from the spleen were plated on artificial media containing X-gal (an indicator of beta-galactosidase enzyme made from the *lacZ* gene). A colony that was blue indicated that the promoter was expressed in vitro. A white colony indicated that the promoter was *not* expressed in vitro, but since the strain grew in the mouse, that same promoter must be exclusively expressed in vivo. DNA sequence analysis of the insert identified the promoter and, based on the promoter's location on the bacterial genome, led to the conclusion that downstream genes were expressed specifically in vivo. This approach has now been used to identify potential virulence genes in several pathogens.



1. The *cat* gene encodes chloramphenicol acetyltransferase, an enzyme that inactivates chloramphenicol.
cat
lacZ
Cloned promoter fragment
Transform
Plasmid origin

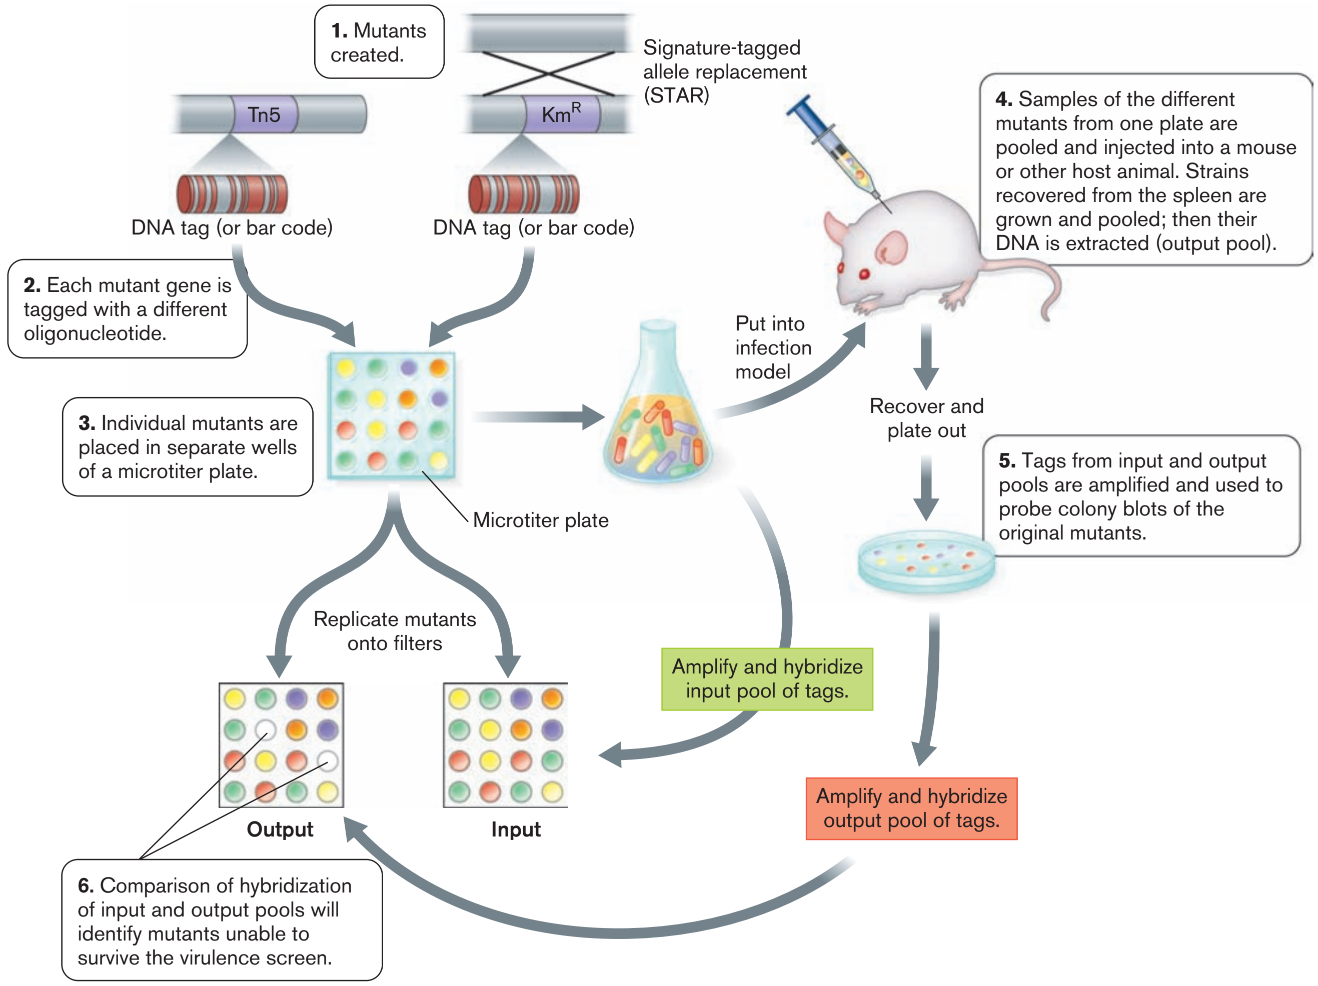
2. DNA fragments from *Salmonella* are cloned in front of the promoterless *cat-lacZ* cassette, and the plasmids are transformed into a *Salmonella* strain.
3. Clone library is injected into mice.
4. Mice are immediately injected with chloramphenicol.
Wait two days; selects for in vivo Cm resistance
5. Bacteria extracted from the spleen are plated on X-Gal media to screen for the absence of lactose fermentation (white colonies).

Figure 25.31 In vivo expression technology. A library of promoter trap plasmids containing randomly cloned fragments of *Salmonella* DNA is transferred into *Salmonella* by transformation. The cloned pool is fed or injected into mice that have themselves been injected with chloramphenicol. Plasmids containing promoters expressed in vivo will yield Cm-resistant bacteria that can survive for two days and travel to the spleen. Bacteria recovered from the spleen are tested for an inability of the promoter fragment to drive *lacZ* expression in vitro. Lactose-fermenting colonies will turn blue when grown on X-Gal medium.

You could ask why these virulence or pathogenicity genes are needed for in vivo growth of pathogens if commensal microbes, which also grow in vivo, do not need them. The reason is that commensal microbes exist in distinct niches within or on the body. Pathogens have mechanisms to subvert or bypass host defenses to gain entrance and grow in privileged sites normally unassailable by commensal bacteria. Finding these genes is the goal of IVET and other gene selection technologies (**Special Topic 25.2**).

Special Topic 25.2 Signature-Tagged Mutagenesis

An especially elegant approach to identifying virulence genes is signature-tagged mutagenesis. Signature-tagged mutagenesis is a negative selection procedure that will allow the researcher to find mutants that do *not* replicate in hosts. The process, as applied to *Salmonella*, starts with a pool of mutants (**Fig. 1**, step 1). Each member of the pool is mutated (randomly) in a different gene and each mutant gene is tagged with a different oligonucleotide (like a bar code)



1. Mutants created.
Tn5
Km^R
Signature-tagged allele replacement (STAR)
DNA tag (or bar code)
DNA tag (or bar code)
2. Each mutant gene is tagged with a different oligonucleotide.
3. Individual mutants are placed in separate wells of a microtiter plate.
Microtiter plate
Put into infection model
4. Samples of the different mutants from one plate are pooled and injected into a mouse or other host animal. Strains recovered from the spleen are grown and pooled; then their DNA is extracted (output pool).
Recover and plate out
5. Tags from input and output pools are amplified and used to probe colony blots of the original mutants.
Replicate mutants onto filters
Amplify and hybridize input pool of tags.
Amplify and hybridize output pool of tags.
Output
Input
6. Comparison of hybridization of input and output pools will identify mutants unable to survive the virulence screen.

Figure 1 Signature-tagged mutagenesis. DNA on the filter from mutants unable to survive in mouse will not hybridize to anything amplified from the output pool.

Using Modern Tools to Define Pathogenesis

***Helicobacter pylori* and gastric ulcers.** *Helicobacter pylori* is a gram-negative microbe, transmitted orally, that causes a variety of stomach diseases, including ulcers and cancer (**Fig. 25.32**). *H. pylori* has a genome size of 1.6 megabases (Mb) encoding 1,590 genes. The organism, however, is extremely difficult to grow in vitro and does not easily exchange genetic material. Because of this, classical approaches for studying its pathogenicity that rely on mutagenesis, clonal selection, and gene transfer are nearly impossible.

However, cutting-edge gene array technology, which can identify the repertoire of genes expressed under any condition (see Section 10.9), and signature-tagged mutagenesis have successfully identified numerous genes involved in the virulence of *Helicobacter*. A basic scheme of (step 2). Each individual mutant with its unique sequence tag is placed in a separate well in a 96-well microtiter plate (step 3). Samples of the 96 different mutants from one plate are pooled and injected into a mouse or other host animal. Strains with mutations in pathogenicity genes will not grow in the mouse and will not be recovered from the spleen. These defective virulence mutants are identified using what is called a colony blot.

For the colony blot, strains recovered from the spleen are grown and pooled, and then their DNA is extracted (step 4). The various tagged genes in this pool of DNA are then amplified and radiolabeled using PCR (all of the unique tag sequences are flanked by common sequences to which PCR primers are made). The individual clones originally arrayed in the microtiter dish are blotted onto a nitrocellulose membrane (step 5). This colony blot membrane is treated to separate DNA strands and submerged into a solution containing the pooled radioactive PCR tag fragments made from the bacteria that survived in the mice and made it to the spleen (see step 4). Hybridization is spotted when a colony spot becomes radioactive. The conclusion is that representative bacteria from that colony survived in vivo. In contrast, a colony on the nitrocellulose membrane that does *not* hybridize to any of the probes in the mix (and thus is not radioactive) represents an *attenuated* strain that did not make it through the mouse selection (step 6). This strain contains a mutation (with a linked unique tag) within a virulence gene needed for in vivo survival of the bacterium. The gene can then be identified through various DNA-sequencing strategies. The SPI-2 pathogenicity island of *Salmonella enterica* was discovered using this technique (**Fig. 2**).

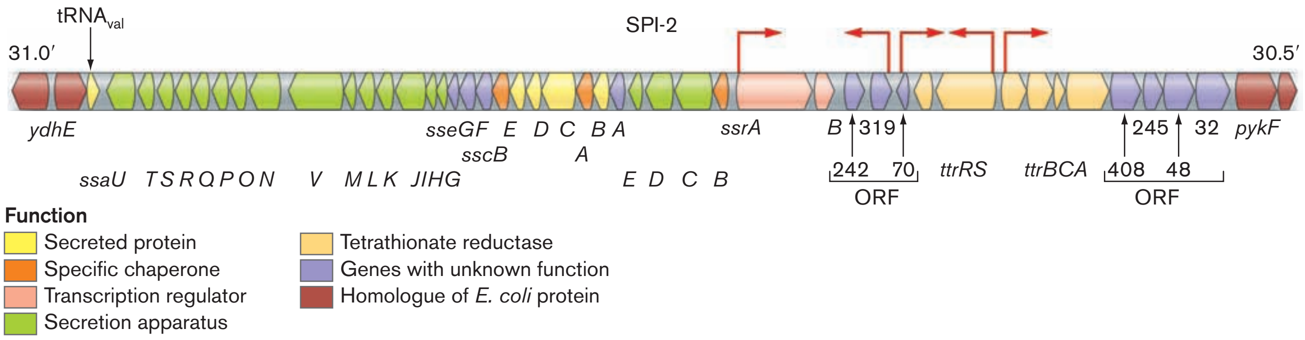


Figure 2 The *Salmonella* pathogenicity island SPI-2 was identified using signature-tagged mutagenesis. The island is located between 30.5 and 31 centisomes. ORFs are indicated by colored block arrows pointing in the direction of transcription. Gene designations are positioned below each ORF. The functional classes of SPI-2 genes are represented by different colors.

pathogenesis has been suggested as a result (**Fig. 25.33**). As with most microbial diseases the first step is colonization. Following ingestion of the pathogen, *H. pylori* flagella propel the organism toward the mucosa (step 1). As it approaches the mucosa, the pathogen produces intracellular and perhaps extracellular urease, which converts urea to CO_2 and ammonia, locally reducing the acidic pH of the stomach (step 2). Two other enzymes, collagenase and mucinase, soften the mucus lining, which allows the bacteria to reach the stomach's epithelial lining (step 3). The epithelial lining is much less acidic than the lumen, permitting the organism to grow and divide. Once at the epithelium, *Helicobacter* produces various adhesins, such as BapA or HpaA, to bind host cells (step 4). Once the organism has adhered, tissue damage occurs following the release of vacuolating cytotoxin (VacA) and neutrophil-activating protein (NAP), which activates neutrophils and mast cells that further damage local tissue (step 5).

CagA
6. CagA injected into host epithelial cells activates host signal transduction pathways that can stimulate growth, possibly leading to cancer.

Figure 25.33 **Summary of steps involved in *Helicobacter* colonization.**

VacA forms a hexameric pore in the host membrane and induces apoptosis (programmed cell death). Another protein, CagA, is injected into host epithelial cells, where it is phosphorylated; CagA then interacts with host signaling proteins and activates host signal transduction pathways that can stimulate growth, possibly leading to cancer (step 6).

As you can see, genomics has been a powerful tool in the study of *Helicobacter*. From DNA sequence alone, a fairly detailed picture of *Helicobacter* physiology and pathogenesis was proposed based on homologies to known enzymes from other organisms (see **Fig. 8.42**). Several aspects of these models have been confirmed experimentally.

Whipple's disease. It is difficult to characterize a pathogen if you cannot even grow it in culture. The microorganism *Tropheryma whipplei* causes a gastrointestinal illness called Whipple's disease, whose symptoms include diarrhea, intestinal bleeding, abdominal pain, loss of appetite, weight loss, fatigue, and weakness. Though identified, the causative agent had never been grown outside of fibroblast cells. This made it nearly impossible to study its physiology. Once the complete genome sequence of two strains of *T. whipplei* became available, however, Didier Raoult and his colleagues at the Marseille School of Medicine discovered how to feed this fastidious bacterium. The genome (less than 1 Mb) contained a great deal of functional information. Computer modeling studies used this information to discover that the organism lacks the machinery to make several amino acids. With this knowledge, the investigators were able to design a cell-free culture medium that supported the growth of three different strains of *T. whipplei* as well as a new strain isolated from a heart valve. Similar applications of modern genomic techniques should lead to other successes in growing previously unculturable intracellular pathogens.

TO SUMMARIZE:

- **In vivo expression technology (IVET)** is a positive selection tool to identify genes required for a pathogen to grow in vivo.
- **Signature-tagged mutagenesis** is a technique that uses negative selection to identify genes required for in vivo growth.
- **Genomic tools** were used to predict mechanisms of *Helicobacter pylori* pathogenesis and the growth requirements for the Whipple's disease microbe.

25.7 Surviving within the Host

Once inside a host, a successful pathogen must avoid detection and destruction for as long as possible. Many products of the virulence factor arsenal help the microbe escape or resist innate immune mechanisms. Others are dedicated to stealth, that is, hiding from the immune system.

Intracellular Pathogens

In an effort to escape both nonspecific and humoral immune mechanisms (see Chapter 24), many pathogens, called **intracellular pathogens**, seek refuge by invading host cells. Antibodies and phagocytic cells will not penetrate live host cells, so hiding there provides temporary safe harbor for the pathogen. Some bacteria dedicate their entire lifestyle to intracellular parasitism. *Rickettsia*, for example, for reasons unknown, will not grow outside a living eukaryotic cell. Other microbes, such as *Salmonella* and *Shigella*, are considered facultative intracellular pathogens. **Facultative intracellular pathogens** can live either inside host cells or free. We have discussed how intracellular parasites get into cells, but how do they withstand intracellular attempts to kill them?

Once inside the phagosome, intracellular pathogens have three options to avoid being killed by the phagolysosome. They can escape the phagosome, prevent phagosome-lysosome fusion, or survive the result.

Escape from the phagosome. The gram-negative bacillus *Shigella dysenteriae* and the gram-positive bacillus *Listeria monocytogenes*, both of which cause food-borne gastrointestinal disease, use hemolysins to break out of the phagosome vacuole before fusion. In this way, they completely avoid lysozymal enzymes. Once free in the cytoplasm, they are thought to enjoy unrestricted growth. Yet even in the cytoplasm, these microbes have found a way to redirect host cell function to their own ends.

A fascinating aspect of escaping the phagosome involves motility. *Shigella* and *Listeria* are both nonmotile at 37°C in vitro; however, they both move around inside the host cell, even though they have no flagella. How do they move? These species are equipped with a special device at one end of the cell that mediates host cell actin polymerization. The polymerizing actin, called a "rocket tail," propels the organism forward through the cell (**Fig. 25.34A**) until it reaches a membrane. The membrane is then pushed into an adjacent cell, where the organism once again ends up in a vacuole. This strategy allows the microbe to spread from cell to cell without ever encountering the extracellular environment, where it would be vulnerable to attack.

Inhibit phagosome-lysosome fusion. Other intracellular pathogens avoid the hazard of lysosomal enzymes by preventing lysosomal fusion with the phagosome. *Salmonella*, *Mycobacterium*, *Legionella*, and *Chlamydia* are good examples. For example, *Legionella pneumophila* grows inside alveolar macrophage phagosomes and produces the potentially fatal Legionnaires' disease, so named for the veterans group that suffered the first recognized outbreak in 1976. The organism, once inside a phagosome, secretes proteins through the vesicle membrane and into the cytoplasm. These bacterial proteins interfere with the cell-signaling pathways that cause phagosome-lysosome fusion. The result is that *L. pneumophila* can grow in a friendlier vesicle.

Thrive under stress. In what could be called the "grin and bear it" strategy, some intracellular pathogens prefer the harsh environment of the phagolysosome. *Coxiella burnetii*, for example, grows well in the very acidic phagolysosome environment (**Fig. 25.34B**). This obligate intracellular organism causes a flu-like illness called Q fever (Query fever). The symptoms of Q fever include sore throat, muscle aches, headache, and high fever. It has a mortality rate of about 1%, so most people recover to good health. The organism allows phagosome-lysosome fusion because the acidic environment that results is needed for it to survive and grow.

THOUGHT QUESTION 25.7 How can one determine if a bacterium is an intracellular parasite?

Why some bacteria are obligate intracellular pathogens is unclear. One intracellular bacterium, *Rickettsia prowazekii,* a cause of epidemic typhus, appears to be an "energy parasite" that can transport ATP from the host

A. *Shigella flexneri* (red) and actin tails (green)

The organism, which prefers to live in the acidified vacuole, undergoes a form of differentiation that changes its shape and alters its interactions with the host cell.

cytoplasm and exchange it for spent ADP in the bacterium's cytoplasm. But this does not explain its obligate intracellular status, since giving rickettsia ATP outside a host does not allow the bacterium to grow. Other factors remain to be discovered.

THOUGHT QUESTION 25.8 Why would killing a host be a bad strategy for a pathogen?

Extracellular Immune Avoidance

This topic was first discussed in the chapters on host defense (Chapter 23) and immunology (Chapter 24). Many bacteria, such as *Streptococcus pneumoniae* and *Neisseria meningitidis*, produce a thick polysaccharide capsule that envelopes the cell. Capsules help organisms resist phagocytosis in several ways. Recall that phagocytes must recognize bacterial cell surface structures or surface-bound C3b complement factor to begin phagocytosis (see Section 23.6). Capsules cover bacterial cell wall components and mannose-containing carbohydrates that phagocytes normally use for attachment. The uniformity and slippery nature of capsule composition makes it difficult for phagocytes to lock onto the bacterial cell. But what about complement factor C3b, which can bind to the bacterial cell? Phagocytes have surface C3b receptors that latch onto C3b molecules. Capsules will envelop any C3b complement factor that binds to the bacterial surface, thereby hiding it from the phagocyte. Fortunately, immune defense mechanisms can circumvent this avoidance strategy by producing opsonizing antibodies (IgG) against the capsule itself (see Section 24.3). The Fc regions of antibodies that bind to the capsule stick out away from the bacterium, where they can be recognized by the Fc receptors on phagocyte membranes. Binding of the Fc region to the phagocyte's Fc receptor can then trigger phagocytosis.

Pathogens can also use proteins on the cell surface to avoid phagocytosis. *Staphylococcus aureus* has a cell wall protein called **protein A** that binds to the Fc region of antibodies, hiding the bacteria from phagocytes. This works in two ways. Protein A can bind to the Fc region of an antibody before the antibody binding site ever finds its bacterial target. Thus, the business end of the antibody—that is, the part with antigen-binding sites—is pointing *away* from the microbe. However, even if the antibody finds its antigen target on one bacterium, protein A from a second bacterium can bind to that Fc region, once again blocking phagocyte recognition.

Other microbes can trigger apoptosis in target host cells. Proteins made by the pathogen enter the host cell and trigger this programmed cell death. If a macrophage is targeted for self-destruction, it cannot destroy the microbe.

Another immune avoidance strategy used by microorganisms is to shift their antigenic structure. Genes encoding flagella, pili, and other surface proteins often use, as part of their regulatory features, site-specific inversions to express alternative proteins (for example, *Salmonella* phase variation) or slipped-strand mispairing to add or remove amino acids from a sequence (see Section 10.6).

Many bacteria and viruses also use mimicry to confuse the immune system (discussed in Section 24.6). In some cases, microbial proteins are made that look like cytokines.

These factors manipulate the balance of T helper cells and send immunity down the wrong path for combating the microbe. All of these strategies are designed to buy the microbe more time to overwhelm the host.

Chapter 26 presents additional mechanisms bacteria use to survive in vivo.

Regulating Virulence: How Do Pathogenic Bacteria Know Where They Are?

Many pathogens can grow either outside or inside a host. To accommodate the needs imposed by these different environments, microbes will employ alternate physiologies appropriate to each. Why make a type III secretion system if there are no host cells around? So how do microbial pathogens know whether they are in a host or in a pond? And what bacterial genes are exclusively expressed while in a host?

The same types of regulatory mechanisms that sense environmental conditions in a pond are used by the microbe to intuit its whereabouts in a host. That is, various sensing systems act in concert to recognize any specific environmental niche. Two-component signal transduction systems, discussed in Section 10.1, are used to monitor magnesium concentrations, which are characteristically low in a host cell vacuole. Other regulators measure pH, which will be acidic in the same vacuole. There are many other examples. The point is that there is no one in vivo sensor system. The various regulators collaborate to trigger the expression of virulence genes. As one example, the concentration of free iron, which is typically very low in the host, is an important signal used to induce the synthesis of virulence proteins whose purpose is to liberate iron bound up in host proteins. However, regulators sensitive to other in vivo signals must also be activated to achieve a successful infection.

Cell-cell communication is also important during infections. *Pseudomonas aeruginosa*, for example, has at least two quorum-sensing systems that detect secreted autoinducers. As the number of bacteria in a given space increases, so, too, does the concentration of the chemical autoinducer. When the autoinducer reaches a critical concentration, it diffuses back into the bacterium or binds to a surface receptor and triggers the expression of bacterial target genes. Genes included in the *P. aeruginosa* quorum-sensing regulons encode *Pseudomonas* exotoxin A and other secreted proteins, such as elastase, phospholipase, and alkaline protease. Why would a pathogen employ quorum sensing to regulate virulence factors? One reason may be to prevent alerting the host that it is under attack before enough microbes can accumulate through replication. Tripping the host's alarms too early would make eliminating infection easy. However, releasing toxins and proteases once a large number of bacteria have amassed could overwhelm the host.

Knowledge of quorum sensing has also provided an opportunity for treating disease. We know that bacteria can communicate with each other by secreting, and sensing, autoinducer chemicals. We also know that these molecules will accumulate in the growth environment and trigger collaborative responses, such as biofilm formation, among members of the population. A new chemical has been developed that interferes with quorum sensing and could serve as a new type of antibiotic. The compound, *N*-(2-oxocyclohexyl)-3-oxododecanamide, is an analog of the homoserine lactone autoinducers used by *P. aeruginosa.* The compound can bind, but not activate, the regulatory proteins LasR and RhlR. When tested in vitro, this compound reduced biofilm formation and decreased production of virulence factors.

TO SUMMARIZE:

- **Intracellular bacterial pathogens** attempt to avoid the immune system by growing inside host cells. Different mechanisms are used to avoid intracellular death.
- **Hemolysins** are used by certain pathogens to escape from the phagosome and grow in the host cytoplasm.
- **Actin tails** are used by some microbes to move within and between host cells.
- **Inhibiting phagosome-lysosome fusion** is one way pathogens can survive in phagosomes.
- **Specialized physiologies** enable some organisms to survive in the normally hostile environment of fused phagolysosomes.
- **Extracellularly, pathogens** evade the immune system by hiding in capsules, by changing their surface proteins, by triggering apoptosis, or by using molecular mimicry.
- **Two-component signal transduction systems** can regulate virulence gene expression in response to the environment.
- **Quorum sensing** may prevent pathogens from releasing toxic compounds too early during infection.

25.8 Viral Pathogenesis

The pathogenic strategies of viruses are at once similar to and yet distinctly different from those of bacteria. On their own, viruses are inert objects, lacking motility and unable to replicate. Like tiny molecular mines, they float in the environment until bumping into a suitable target cell. There is no need to transport food, expel waste, or generate energy, because the host does all that. But each virus must still attach to a host cell and subvert its biochemistry, directing it to make more virus. Because of the differences between bacteria and viruses, important insights into pathogenicity can be derived by comparing infection strategies used by different viruses.

The Common Cold Versus Influenza

You have probably wondered why you repeatedly get colds if the immune system is so effective. Why are you not protected from recurring infections after having one cold? The common cold is caused by over 100 known serotypes of rhinovirus, a small (30 nm), nonenveloped single-strand RNA virus. Serotypes of a given organism differ from one another in the antigenic makeup of a specific protein.

The host receptor for these viruses is ICAM-1 (see **Fig. 24.3**), which is also important for the extravasation of leukocytes through blood vessels (see Section 23.5). Many of the differences among the rhinovirus strains can be traced to the structure of one of the capsid proteins, VP1, which is thought to bind ICAM-1. Because of these differences, neutralizing antibodies to one strain of rhinovirus will not neutralize a different strain. Thus, we repeatedly contract a cold because we are infected with a different strain.

Unlike many viruses, rhinoviruses prefer to replicate at 33°C. As a result, they grow in the cooler regions of the respiratory tract, such as nasal passages. The reason these viruses cause a runny nose is that virus-infected cells release bradykinin and histamine, both of which affect fluid loss from local blood vessels (discussed in Section 24.5).

Certain strains of coronavirus also cause common cold symptoms. It is significant to note, however, that a recent variant of coronavirus is also responsible for the newer, more deadly disease known as severe acute respiratory syndrome (SARS).

THOUGHT QUESTION 25.9 Why do rhinovirus infections fail to progress beyond the nasopharynx?

Influenza infection proceeds very differently from rhinovirus infections, even though the two are often confused by the public. Influenza virus first establishes a local upper respiratory tract infection, where it targets and kills mucus-secreting, ciliated epithelial cells, destroying this primary defense. If the virus spreads down to the lower respiratory tract, it can cause shedding of bronchial and alveolar epithelium down to the basement membrane. As a result, oxygen and CO_2 exchange is compromised and breathing becomes difficult. Systemic symptoms, such as muscle aches, are due to the release of interferon and lymphokines in response to the infection. Because natural defenses are compromised, persons infected with flu are very susceptible to superinfection with bacterial pathogens such as *Haemophilus influenzae*. In fact, these bacterial infections are so prevalent in persons infected with influenza virus that *Haemophilus influenzae* was originally suspected as the causative agent of flu.

What makes flu so dangerous is that every 10 to 15 years the virus undergoes a major genetic alteration called an **antigenic shift** that results in a new pandemic strain. The change takes place in the gene encoding hemagglutinin and produces a change in the protein's antigenic form. (Hemagglutinin binds to and agglutinates red blood cells. It is used by the virus for attachment to host cells.) As a result of the change in form, antibodies that recognized the old hemagglutinin will not recognize and neutralize the new one. Antigenic shift occurs when two different strains of influenza infect the same cell, usually in animals like pigs or chickens. Recall that influenza has a segmented RNA genome. Thus, as the two viruses disgorge their eight nucleic acid segments, recombinations can occur between them, generating a chimeric, and thus new, form of the hemagglutinin gene (see Section 11.4). This new influenza virus can then jump to humans, and a new pandemic begins. During the time between major shifts, minor changes in antigen structure also occur. Because they are minor, the process is called antigenic drift. Antigenic shifts and drifts are the reasons why a new vaccine (the flu shot) is required each year. These shots are highly recommended for the elderly, who are very susceptible to the disease, and are a good idea for everyone else.

An estimated 21 million people worldwide died of the flu in the pandemic of 1918 (**Fig. 25.35**). No one then knew what caused the disease. Influenza was originally thought to be of bacterial etiology, and not until 1933 was it established that a virus was at fault. Many flu epidemics have taken place since then, but none have been so deadly. Though different from influenza, what was so frightening about the SARS outbreak that began in 2003 is that it had a fatality rate of greater that 10%, making it more deadly than the 1918 influenza strain, which had a fatality rate of 2–4%.

The 1918 influenza virus was thought lost, and with it the opportunity to learn why it was so deadly. Such knowledge could prove important as we face the threat of another deadly strain, which, as of this writing, is the avian flu. However, we now have a new opportunity to learn about this deadly strain. In February 1997, Ann Reid, Jeffery Taubenberger, and their colleagues at the Armed Forces Institute of Pathology reported the partial sequences of five influenza genes recovered from the preserved lung tissue of a U.S. soldier who died from influenza in 1918. Additional sequences of this virus were obtained from an Alaskan influenza victim who was buried in the permafrost in November 1918. The freezing helped preserve the integrity, if not the viability, of the flu genome. In 2005, a group of scientists at the CDC, using these sequences, actually regenerated a live version of the 1918 pandemic virus, which is kept under tight security and containment. Its resurrection is expected to reveal secrets of its pathogenesis that may help us combat the inevitable emergence of a new, equally deadly flu virus.

Notice the dramatic dip in 1918, the result of deaths from influenza.

Human Immunodeficiency Virus

Acquired immunodeficiency syndrome (AIDS) became an enormously important disease in the late twentieth century and continues to grip us today. There are between 30 to 40 million cases worldwide. As a result of infection by the retrovirus HIV (human immunodeficiency virus), the patient becomes severely immunocompromised and susceptible to a wide variety of infectious diseases. Death in patients with AIDS is usually the result of these secondary infections. Chapter 11 discusses the detailed molecular biology of HIV; here we will deal with the pathogenesis of the disease.

In contrast to rhinovirus, which exclusively binds to one cell receptor, ICAM-1, HIV binds multiple cell receptors via its glycoprotein 120 (gp120, also called the spike protein; see Section 11.5 and **Fig. 25.36A**). For HIV, the basic receptor unit on host cells is CD4 (meaning T cells are the usual targets), in combination with a chemokine receptor CCR-5 (see Fig 11.29A). By binding to the chemokine receptor, HIV can block chemokine binding and disconnect communication between the target cell and the immune system. You might still expect that the infection would be stopped because another aspect of the viral infection should, on its own, trigger apoptosis of the infected cell. Viral protein gp120 cross-links CD4 surface molecules on T cells, which, coupled with *antigen* binding to the T-cell receptor, should trigger apoptosis. The ensuing programmed cell death would simultaneously kill the infecting virus. However, the virus makes a protein (negative factor, NEF) that hinders apoptosis. NEF is one of several HIV proteins that affect pathogenesis (**Table 25.5**). As a result, the virus can replicate and bud from these lymphocytes (**Fig. 25.36B**).

Despite the presence of NEF, however, the lymphocytes eventually do die. Because $CD4^+$ T cells are the primary target of HIV, the levels of these T cells decline dramatically in an infected patient and cause an immunodeficiency, particularly in immune regulation. Monitoring T-cell numbers, therefore, is a critical diagnostic tool.

Comparing HIV infection and AIDS, the disease it causes, underscores the difference between infection and disease. Detection of HIV in an individual does not equate with that person having overt disease. The individual can go for years without developing symptoms. But even if infected individuals are not showing signs of disease, they are fully able to transmit the virus to another person sexually, through blood transfusion, or through the use of shared hypodermic needles.

As with many viral diseases, AIDS begins with flu-like symptoms—fever, headache, fatigue, sore throat, and sometimes a rash. Consequently, symptomology is never a reliable way to diagnose HIV infection. The detection of antibodies is a good initial screen to gauge whether a person has been exposed to the virus. Once exposure has been confirmed by a serum test (a change in test result

from negative to positive is called seroconversion), it is important to use PCR techniques to measure actual HIV viral load in a patient's blood. The higher the viral load the faster the disease will progress. Thus, for proper disease management, it is important to know viral load in addition to monitoring T-cell numbers.

The symptoms of AIDS itself begin to manifest once T-cell numbers fall to around 300 per microliter of blood (the normal range is 500–1,500). It can often take four or five years (or more) before a patient starts to experience this decline. With this immunocompromised state come secondary infections such as shingles (herpes zoster virus), Pneumocystis pneumonia, tuberculosis, and oral thrush (a fungal infection of the mouth caused by the yeast *Candida albicans*). Late-stage AIDS is defined by CD4$^+$ counts below 200, at which point a malignancy called **Kaposi's sarcoma** can develop (**Fig. 25.36C**). Kaposi's sarcoma is a malignancy originating in endothelial or lymphatic cells, and tumors can arise anywhere—gastrointestinal tract, mouth, lungs, skin, or brain.

An important cause of AIDS symptoms is the HIV Tat protein (trans activator of the HIV promoter). A transactivator is a protein that can diffuse through the cytoplasm to bind and regulate a target gene sequence. The Tat protein is needed for viral replication. In addition, it is released from infected monocytes and enters other cells, where it alters host regulatory cascades and gene expression. The result is an increase in the production of nuclear factor kappa beta (NF κβ), which helps further disassemble the

Table 25.5 HIV proteins that affect pathogenesis.

Proteins	Role in pathogenesis
TAT (transcriptional trans-activator)	Secreted from infected cells; accelerates HIV gene transcription by host polymerase, has chemokine-like properties, acts as growth factor for endothelial cells, alters gene expression in target cells
VPR (viral protein R)	Induces G_2 cell cycle arrest and nuclear import of the preintegration complex
NEF (negative factor)	Downregulates cell surface CD4 and MHC class I (important for virus release); enhances virion infectivity by inhibiting apoptosis.
VIF (virion infectivity factor)	Counteracts a host cellular protein that naturally inhibits HIV replication
VPU (viral protein U)	Enhances HIV release from infected cells and CD4 degradation by targeting CD4 to the proteasome

Protein p53 normally helps limit cell division by inactivating EF2. Virus E6 protein, however, removes p53, so the cell will begin to divide uncontrollably and become cancerous.

immune system, and activation of endothelial cell growth, which can lead to Kaposi's sarcoma. Some believe that a vaccine using inactivated Tat will be useful in preventing AIDS. Other HIV proteins important to the pathogenesis of HIV and AIDS are presented in **Table 25.5**.

The relative incidence of AIDS by race since 1986 is examined in **Figure 25.36D**. Since 1990, the overall incidence, approximately 40,000 annual cases, has declined in the United States, mainly as a result of improvements in antiviral therapies. However, the decrease is also due to a drop in the numbers of white males afflicted. The numbers for women, African Americans, and Hispanic minorities continue to rise.

Human Papillomavirus

Human papillomavirus (HPV) is a very common virus that causes warts, an abnormal growth of skin tissue (**Figs. 25.37A** and **B**). HPV can produce warts on the feet, hands, vocal cords, mouth, and genital organs. Over 60 types of HPV have been identified so far. Each type infects different parts of the body. Some strains of HPV have also been associated with cervical and penile cancer. Genital HPV is one of the most common sexually transmitted diseases among college students.

How does this virus cause excessive growth of tissues? Once inside host cells, HPV synthesizes a protein called E6 (**Fig. 25.37C**). E6 binds to a host protein, p53, that normally prevents cells from completing a cell cycle if their DNA is not properly replicated. Protein p53 inhibits cell division by binding to a transcription factor called EF2, preventing it from activating two oncogenes *c-myc* and *c-fos*. Transcription of *c-myc* and *c-fos* is needed for mitosis, so blocking their transcription prevents cell division and controls growth. The HPV protein E6 targets p53 for destruction by the cell proteosome (discussed in Section 8.6). With p53 thus removed, *c-myc* and *c-fos* proteins are made continually. As a result, cell division proceeds unabated to produce warts or, in the worst-case scenario, cervical cancer. After the initial infection has resolved, the virus may remain latent in tissues and can reactivate if immune system function is impaired.

An effective HPV vaccine that will protect against cervical cancer has been developed, although guidelines for its use remain controversial. The problem is that it must be administered before a girl becomes sexually active (and potentially exposed) in order to work. The FDA and CDC have recommended its use in women and girls between ages 9 and 26.

TO SUMMARIZE:

- **Multiple reinfection** of the same person by a virus can occur because different strains of the virus have minor sequence differences in attachment proteins (for example, capsid). Because of these differences, neutralizing antibodies made during a previous infection are ineffective against the new strain.

- **Viral infection** can increase a patient's susceptibility to other, less virulent microbes.
- **Antigenic shifts** in a viral antigen (as in the hemagglutinin of influenza) can lead to a new pandemic of the disease.
- **Animals coinfected with two viruses** can serve as incubators for antigenic shifts or the evolution of new viruses.
- **Binding to host cells** can involve a single host receptor (as in rhinovirus) or multiple receptors (as in HIV).
- **Virus-infected cells** can secrete proteins that enter uninfected cells and disrupt signaling pathways.

Concluding Thoughts

This chapter has only scratched the surface of all that is known about microbial pathogenesis. It should be clear at this point that attachment, immune avoidance, and subversion of host signaling pathways are common goals of most successful pathogens, be they bacterial, viral, or parasitic. But even with all we know, there remains much to learn.

The remaining chapters deal with the basic principles used to diagnose disease and eradicate offending pathogens, but many pathogens remain hard to detect and difficult, if not impossible, to kill. So the more we know about the mechanisms microbes use to cause disease, the better we will be at developing effective countermeasures.

As you will learn in the coming chapters, new pathogens are constantly emerging. Over the last few decades, we have seen the development of HIV, SARS, avian flu, hantavirus, West Nile virus, *E. coli* O157:H7, and the re-emergence of flesh-eating streptococci, to name but a few. Can we ever stop pathogens from emerging? Probably not. For every countermeasure we develop, nature designs a counter-countermeasure. Our hope is that continuing research into the molecular basis of pathogenesis and antimicrobial pharmacology will keep us one step ahead.

CHAPTER REVIEW

Review Questions

1. Describe the differences between infection versus disease; pathogenicity versus virulence; LD_{50} versus ID_{50}.
2. What is meant by direct versus indirect routes of infection?
3. What are the characteristics of a good reservoir for an infectious agent?
4. Name the various portals of entry for infectious agents and name a disease associated with each.
5. Describe the basic features of a pathogenicity island.
6. Explain various ways bacteria can attach to host cell surfaces.
7. Describe the basic steps by which pili are assembled on the bacterial cell surface. How do type I and type IV pili differ?
8. Explain the five broad categories of toxin mode of action.
9. What is ADP-ribosylation and how does it contribute to pathogenesis?
10. Explain the differences between exotoxins and endotoxins.
11. Explain the mechanisms of secretion carried out by type II and type III protein secretion systems. What are the paralogous origins of these systems?
12. Describe the key features of *Salmonella* pathogenesis.
13. How can genomic approaches help identify pathogens in an infection?
14. What different mechanisms do intracellular pathogens use to survive within the infected host cell?
15. Describe different molecular strategies that microbes use to avoid the immune system.
16. How do bacteria determine whether or not they are in a host environment?
17. What is antigenic shift?
18. How is attachment of influenza virus different from HIV? Why does HIV produce an immune deficiency while influenza does not?
19. Explain the basics of how human papilloma virus can trigger cancer.

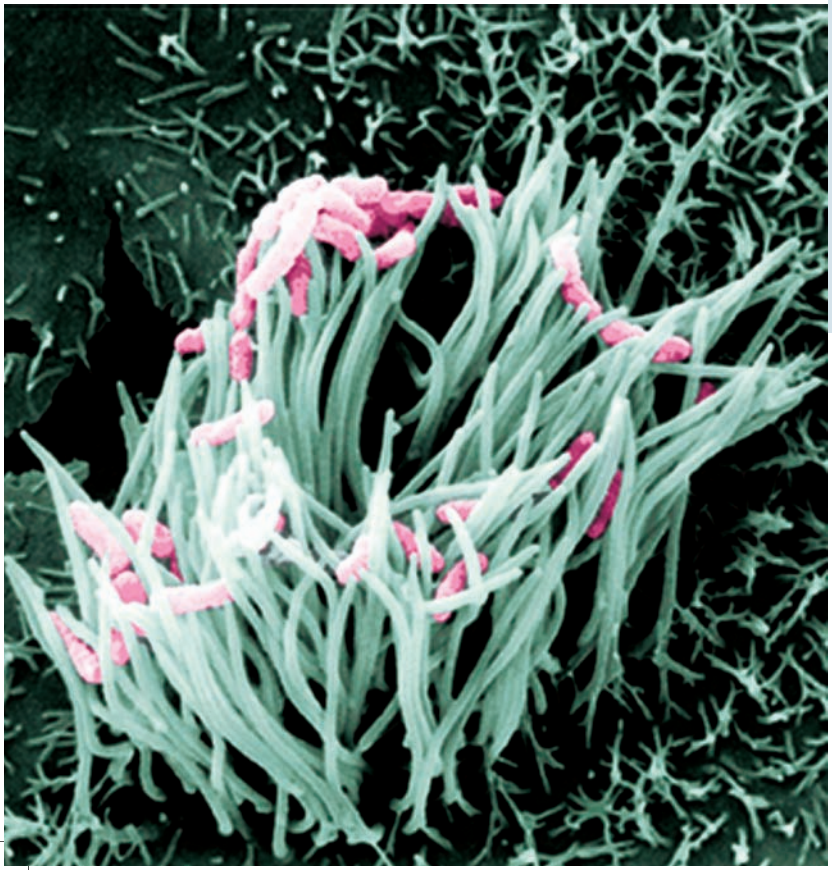
Chapter 26

Microbial Diseases

26.1 Characterizing and Diagnosing Microbial Diseases
26.2 Skin and Soft-Tissue Infections
26.3 Respiratory Tract Infections
26.4 Gastrointestinal Tract Infections
26.5 Genitourinary Tract Infections
26.6 Infections of the Central Nervous System
26.7 Infections of the Cardiovascular System
26.8 Systemic Infections
26.9 Immunization

In the American Civil War, twice as many people died from infections of their battle wounds as from the wounds themselves. Clearly, developments in medicine had not kept pace with innovations in rifle accuracy. Today, antibiotics can quell most wound infections. Yet millions of people still die as a result of dangerous microbes that spread by food, air, body fluids, and even insects. How do clinicians recognize these many different types of infections? What are the key symptoms or laboratory tests that help determine if a person suffers from a viral disease or bacterial disease?

Microbial diseases are with us daily and continue to be one of the main contributors to global mortality and morbidity. The emergence of new pathogens, the increasing development of drug resistance, and the threat of bioterrorism have combined to create an increased demand for investigations into disease mechanisms and the body's ability to combat the organisms responsible. Along with those basic studies, effective diagnostic algorithms are needed to quickly identify infectious diseases and prevent their spread. This chapter explores the general classes and causes of microbial diseases and introduces the art of diagnosis.



Scanning electron micrograph of primary cultured rabbit tracheal epithelial cells following 5 minutes of coincubation with virulent wild-type *Bordetella bronchiseptica*, a close relative of *B. pertussis*, the cause of human whooping cough. In this model for early host-pathogen interactions, wild-type *B. bronchiseptica* preferentially adheres to cilia and is rarely seen bound to aciliated cells or aciliated portions of ciliated cells. This adherence pattern impedes the ciliary elevator that normally removes bacteria from the lung. *B. bronchiseptica* is a common respiratory pathogen of cats and dogs but can cause whooping cough in immuno-compromised humans. Bacteria (approx. 1 μm in length) have been pseudocolored pink for easier visualization.

A visibly ill 16-year-old girl was taken to her pediatrician, where she complained of diarrhea, high fever (39.9°C; 102°F), and vomiting. She told the physician that she was healthy until two days prior. Upon physical exam, the doctor noticed that the girl had a much lower than normal blood pressure (76/48 mmHg), a rapid heart rate of 120 beats per minute, and an erythematous (red) rash on her trunk. Because of her deteriorating condition, the patient was admitted to the pediatric intensive care unit at the local hospital, and cultures were obtained. She was immediately given intravenous fluids and IV antibiotics, yet she died within a week. Patient history taken upon admission revealed that the girl had started her menstrual period four days before becoming ill, providing an important clue as to the cause of the disease.

This tragedy was part of a larger story that emerged in the late 1970s and early 1980s, when women started dying from this dangerous, new (emerging) disease. Now known as toxic shock syndrome, scientists and physicians learned that it was caused by certain strains of *Staphylococcus aureus* that produced a superantigen type of toxin (toxic shock syndrome toxin, or TSST; see Section 24.6). Why was the disease not seen in previous decades? The answer, surprisingly, turned out to be the use of one brand of superabsorbent tampons (since removed from the market). The tampons produced a rich growth environment for *S. aureus*. So if the patient were colonized by a TSST-producing strain, huge amounts of toxin would be released to circulate in the bloodstream. Today we recognize that toxic shock syndrome is a possible consequence of any *S. aureus* infection and can occur in both men and women. We now have tools to diagnose it quickly.

In Chapter 25, we discussed the arsenal of weapons that microbes use to cause disease (including TSST). But what of the diseases themselves? Microbial diseases are often presented from the microbe's point of view—for example, where in the body does *Staphylococcus aureus* cause disease? Another approach, which we take in this chapter, is to look at infections from the vantage point of the infected organ. We might ask, for example, what organisms cause vaginal infections versus lung infections, and how are they differentially diagnosed? Are the patient's complaints consistent with gastrointestinal tract disease or a lung infection? This approach is more attuned to the practices of health care workers and the foundation by which a physician interacts with a patient. An individual who goes to a clinician complaining of a fever, cough, and chest pain does not typically report having encountered a particular bacterium. The physician must determine from the patient that the disease is localized to the chest and then intuit that it may be a respiratory tract infection. Appropriate samples are then collected and sent to a clinical microbiology laboratory, where data are collected to confirm or dispute the presence of a specific etiologic agent such as *Streptococcus pneumoniae* or other lung pathogen.

In this chapter, microbial diseases are classified as respiratory, gastrointestinal, genitourinary, nervous system, skin and soft-tissue, bone and joint, cardiovascular, and generalized (disseminated) infections. We do not present an exhaustive compendium of microbial illnesses but a representative sampling of infections that illustrate key aspects of microbial disease. The material is arranged and presented so as to integrate your knowledge of microbiology and immunology within the framework of the practice of medicine and the study of infectious disease.

26.1 Characterizing and Diagnosing Microbial Diseases

Although this chapter will classify representative microbial diseases by organ system, there are other very instructive ways to group and study microbial infections. These include the organism and portal-of-entry approaches. Each has clear benefits and pitfalls. The organism approach is useful when examining the different ways a given species can cause disease. For instance, *E. coli* can cause urogenital tract infections, gastrointestinal infections, and meningitis. How do the various strains causing these diseases differ from one another? Are virulence factors present in the uropathogenic strain that are absent or different in the diarrhea-producing strain? (Virulence factors are discussed in Chapter 25; see Sections 25.2 and 25.3.)

Pathogens are also commonly classified by their route of infection (or portal of entry; see Chapter 23). In this approach, pathogens are classified as food-borne, airborne, blood-borne, or sexually transmitted. The port-of-entry approach has its merits, but it sometimes seems at odds with the disease itself. *Salmonella typhi*, for example, is categorized as a food-borne pathogen. Food-borne pathogens typically have a fecal-oral route of infection and cause pronounced gastrointestinal disease. Yet *S. typhi* does not actually cause gastrointestinal disease until very late in the disease process. After ingestion, it quickly enters the bloodstream from the intestine to produce a serious septicemia (blood infection) called enteric (typhoid) fever. At this stage, the organism cannot be found in feces. (Much later the organism can re-enter the intestine via the gall bladder and cause mild gastrointestinal symptoms.) The obvious value of knowing the route of infection is that society can design effective measures to avoid disease. Hand washing and proper food preparation, for instance, will effectively prevent the septicemia of typhoid fever. But clearly, all organisms entering via the gastrointestinal tract do not cause gastrointestinal disease.

The organ systems approach has its drawbacks as well, given that organisms that initially affect one organ system can disseminate to infect other organ systems. *Neisseria gonorrhoeae*, for example, initially infects the genitourinary tract, but can disseminate via the bloodstream, causing a blood infection. *Yersinia enterocolitica*, a cause of gastroenteritis, can disseminate from the intestine and cause abscesses elsewhere in the body. Yet we favor the organ systems approach because it is illuminating to know how microbial diseases present themselves to physicians treating patients. The physician's examination usually begins not by taxonomic evaluation of the agent or knowledge of the portal of entry, but with symptoms emanating from the organ system that has been affected. You will benefit, however, from studying infectious disease from various perspectives, and you should keep in mind factors such as the portal of entry and the taxonomy of the infectious organism.

Patient Histories Provide Important Diagnostic Clues

A problem often faced by clinicians is that many infectious diseases display similar symptoms, making diagnosis difficult. *Vibrio cholerae* and enterotoxigenic *E. coli*, for instance, both produce diarrheal diseases characterized by cramps, lethargy, and liters of watery stool each day. Cholera, however, is not commonly seen in the United States. Nevertheless, a clinician might suspect cholera if a patient recently traveled to or arrived from an endemic area (a specific geographical locale such as India or Bangladesh) where the disease is regularly observed. This travel information is not gained by examining the patient but comes from taking a "patient history."

Knowledge of the patient's hobbies can be equally important for diagnosing a disease. This is another critical part of taking a patient's history. For example, a person who is suffering from enlarged glands, fever, and headaches and who was recently rabbit hunting may have been exposed to the gram-negative rod *Francisella tularensis*, an intracellular pathogen that infects various wild animals and is the cause of tularemia, an illness also known as "rabbit fever" (**Fig. 26.1A**). A hunter with these symptoms could have accidentally infected a cut while cleaning the kill. Tularemia is an example of a **zoonotic disease**, an infection that normally affects animals but that can be transmitted to humans.

How can knowing a person's occupation be important? Consider the case of a man with acute pneumonia. The clinician discovers that the man is a sheep farmer. Knowing this, *Coxiella burnetii*, a pathogenic bacterial species that infects sheep and is shed in large quantities in placental materials, would be considered one of the possible sources of infection. The organism grows intracellularly only (it is an obligate intracellular pathogen). It infects sheep, cattle, and goats but does not usually cause clinical disease in these animals. *C. burnetii* is secreted in body fluids and shed in high numbers in the animal's amniotic fluids and placenta, heavily contaminating the soil. When the contaminated soil dries, the microbes become aerosolized whenever the dirt is disturbed. Humans (such as farmers) that inhale the dried particles can develop the lung infection called Q fever, another type of zoonotic disease (**Fig. 26.1B**).

One more example of an "occupational hazard" is illustrated by a woman with severe respiratory disease who works in a leather factory, handling animal hides. Knowing her occupation, a clinician would investigate whether she might have contracted anthrax (woolsorter's disease) from inhaling spores present on the animal hide.

Because patient histories are so helpful in diagnosing infectious diseases, we will present several case histories in the following sections and segue into discussions of various microbes that can infect each organ system. Key aspects of infectious diseases will be revealed as we proceed.

It should be stressed that further insight into pathogenesis and new innovations in diagnosis will come from the remarkable number of microbial genomes whose sequences have been completed as well as from those that are still under way. A sampling of the pathogens whose genomes have already been sequenced is presented in **Table 26.1.** Many of the ORFs identified have no known function and

Figure 26.1 Examples of bacteria that cause zoonotic diseases. A. *Francisella tularensis* (colorized SEM), the cause of tularemia. Tularemia is a highly infectious disease, usually spread via a tick vector but also through cuts. **B.** *Coxiella burnetii* (colorized TEM), the cause of Q fever. This irregularly-shaped organism undergoes developmental stages that range in size from 0.2 μm to 1 μm.

Table 26.1 Examples of pathogens whose genomes have been sequenced.[a]

Pathogen	Disease
Escherichia coli O157:H7	Diarrhea, hemolytic uremic syndrome (HUS)
Salmonella typhi	Typhoid fever
Yersinia pestis	Plague
Haemophilus influenzae	Meningitis, otitis media
Haemophilus ducreyi	Chancroid (sexually transmitted)
Vibrio cholerae	Cholera (severe diarrhea)
Vibrio vulnificus	Septicemia, wound infections
Pseudomonas aeruginosa	Wound infections, septicemia, respiratory infections
Coxiella burnetii	Q fever (respiratory)
Neisseria meningitidis	Meningitis, septicemia
Bordetella pertussis	Whooping cough (respiratory)
Helicobacter pylori	Stomach ulcers, gastric cancer
Campylobacter jejuni	Diarrhea
Rickettsia prowazekii	Epidemic typhus
Brucella suis	Flu-like disease, brucellosis
Bacillus anthracis	Anthrax (respiratory or wound)
Staphylococcus aureus	Boils, toxic shock syndrome, wound infections, osteomyelitis (bone)
Streptococcus pyogenes	Strep throat, wound infections
Listeria monocytogenes	Flu-like, diarrhea, stillbirths
Clostridium tetani	Tetanus
Clostridium perfringens	Wound infections
Mycoplasma pneumoniae	Respiratory
Mycobacterium tuberculosis	Tuberculosis (respiratory)
Mycobacterium leprae	Leprosy
Chlamydia trachomatis	Eye infection, urethritis (sexually transmitted)
Borrelia burgdorferi	Lyme disease
Treponema pallidum	Syphilis (sexually transmitted)
Leptospira interrogans	Septicemia

may eventually explain differences in host and tissue specificity and reveal new toxins or other pharmacologically active molecules produced by virulent microbes.

TO SUMMARIZE:

- **Pathogens can be classified** as food-borne, airborne, blood-borne, or sexually transmitted.
- **Patient histories** are vital in diagnosing microbial diseases.
- **Zoonotic diseases** are animal diseases accidentally transmitted to humans.

26.2 Skin and Soft-Tissue Infections

Skin infections range from simple boils to severe, complicated so-called "flesh-eating" diseases (**Table 26.2**). Recall that the integrity of the skin as well as the presence of normal skin flora prevent infection. However, even minor insults to the skin (such as a paper cut) can result in infections, most of which are caused by the gram-positive pathogen *Staphylococcus aureus*. Healthy individuals develop infections of the skin only rarely; however, people with underlying immunosuppressive diseases such as diabetes are at much higher risk.

Boils

Staphylococcus aureus is a common cause of the painful skin infections called boils, or carbuncles (**Fig. 26.2**). This gram-positive organism, often a normal inhabitant of the nares (nostrils), can infect a cut or gain access to the dermis via a hair follicle. It possesses a number of enzymes that contribute to disease, including **coagulase**, which helps coat the organism with fibrin, thereby walling off the infection from the immune system and antibiotics. As a result, boils generally require surgical drainage as well as antibiotic therapy. As noted earlier, some strains of *S.*

aureus also produce toxic shock syndrome toxin, a superantigen that can lead to serious systemic symptoms (see Chapters 24 and 25).

A particularily dangerous strain of *S. aureus* called methicillin-resistant *S. aureus* (MRSA) has recently emerged. *S. aureus* infections are commonly treated with penicillin-like drugs, such as methicillin. MRSA has developed resistance to methicillin and many other penicillin-like drugs through a mutation that alters one of the proteins (called a penicillin-binding protein; PBP) involved in cell wall synthesis. Because methicillin is normally used as a first line of defense against staphylococcal infections, treatment failure of MRSA can be life-threatening, and alternative drugs, such as vancomycin, need to be used. MRSA first appeared as agents of nosocomial infections—infections that occur after a patient enters a hospital. However, these antibiotic-resistant organisms are no longer contained only in the hospital. Individuals who have not been in a hospital are being infected with MRSA in what are called community-acquired infections. This is occuring at an epidemic rate in the United States (an incidence of approximately 20 per 100,000 population). Seventy percent of Staphylococcal skin infections are now caused by MRSA. Thus, a physician can no longer assume that a patient walking into the office with a staphylococcal infection will respond to methicillin. The doctor must assume that it may be MRSA. As a result, treatment regimens around the country are being forced to change. Today, vancomycin and linezolid are the antibiotics typically used to treat staph infections. Antibiotics are discussed in Chapter 27.

Other staphylococcal diseases are caused by toxin-producing strains in which the organism remains localized but the toxin disseminates. We have already mentioned TSST, but there are other toxins. For example, some strains of *Staphylococcus aureus* produce a toxin called **exfoliative toxin** that causes a blistering disease in children called staphylococcal scalded skin syndrome (**Fig. 26.2C**). Exfoliative toxin, like TSST, is a superantigen, but it also cleaves a skin cell adhesion molecule that when inactivated results in blisters.

Table 26.2 presents other common infections of the skin and soft tissues.

Case History: Necrotizing Fasciitis by “Flesh-Eating” Bacteria

One weekend in June, Cassi was camping with her three children. She suffered a minor cut on her finger, which she bandaged properly. She also injured the left side of her body while playing sports with her kids. Not thinking much of either of her minor injuries, she went to bed. Two days later, Cassi was extremely ill. Her symptoms included vomiting, diarrhea, and a fever. She was also in severe pain where she had injured her side, and the area had begun to bruise (the skin was not broken). By the next day, she could barely get out of bed, and by the end of the night, she was breathing with difficulty and could not see. Her side began to leak fluid and blood. Cassi was admitted to the hospital in shock, with no detectable blood pressure. An infectious disease specialist diagnosed the problem as necrotizing fasciitis, and she was rushed into surgery. In an effort to save her life, about 7% of her body surface was removed. Because the large wound infection in her side would need to resolve before a skin graft could be performed to repair it, the hole in Cassi's body was left wide open (**Fig. 26.3A**). *After nearly three months and several operations, Cassi recovered.*

What kind of organism can cause this type of devastating disease? The disease **necrotizing fasciitis**, also known as flesh-eating disease, is rare and is often caused by the gram-positive coccus *Streptococcus pyogenes*, a microbe normally associated with sore throat infections (pharyngitis). Although sometimes described as a recently emerging infectious disease, necrotizing fasciitis was first discovered in 1783, in France. Its incidence may have risen recently owing to the increased use of anti-inflammatory drugs, which increase a person's susceptibility to infection. In this case history, Cassi probably had this organism on her skin

Table 26.2 Common infectious diseases of the skin.

Disease	Symptoms	Etiological agent	Virulence factors
Bacterial			
Folliculitis	Boils	*Staphylococcus aureus* (G+ cocci); fibrin wall around abscess renders it poorly accessible to antibiotics	Coagulase, protein A, TSST, leucocidin, exfoliative toxin
Scalded skin syndrome	Peeling skin on infants, systemic toxin		
Impetigo	Skin lesions on the face, mostly children		
Scarlet fever	Sore throat, fever, rash	*Streptococcus pyogenes* (G+ cocci)	M-protein pili, C5a peptidase, hemolysin, pyrogenic toxins, others
Erysipelas	Skin lesions, usually facial, that spread to cause systemic infection		
Necrotizing fasciitis	Rapidly progressive cellulitis		
Viral			
Rubella[a]	Discolored, pimply rash; mild disease unless congenital	Rubella virus [ssRNA(+)]	
Measles[a]	Severe disease, fever, conjunctivitis, cough, rash	Rubeola virus [ssRNA(–)]	
Chickenpox[a]	Generalized discolored lesions	Varicella-zoster (dsDNA)	
Shingles	Pain and skin lesions, usually on trunk in adults		
Smallpox	Raised, crusted skin rash, highly contagious	Variola major (dsDNA)	
Warts	Rapid growth of skin cells	Papillomaviruses (dsDNA)	
Fungal			
Dermatomycosis	Dry, scaly lesions like athlete's foot	Dermatophytes	
Sporotrichosis	Granulomatous, pus-filled lesions; can disseminate to lungs or other organs	*Sporothrix schenckii*	
Blastomycosis	Granulomatous, pus-filled lesions; can disseminate to lungs or other organs	*Blastomyces dermatitidis*	BAD1 adherence
Candidiasis	Patchy inflammation of mouth (thrush) or vagina; can disseminate in immunocompromised patients	*Candida albicans*	Proteinase, phospholipase, Ssn6/Tup1 regulators, others
Aspergillosis	Infects wounds, burns, cornea, external ear	*Aspergillus* spp.	PacC/fos1 regulators, gliotoxin
Zygomycosis	Mainly affects diabetic patients; can rapidly disseminate	*Mucor* and *Rhizopus* spp.	

[a] Vaccine is available against this agent.

when the injury to her side occurred. The injured area probably suffered an invisible microabrasion, providing a good growth environment for the organism, leading to the secretion of potent toxins and death of surrounding tissues.

Rapid, aggressive antibiotic treatment is required in these extreme cases, even before the clinical microbiology lab has had time to identify the organism. Therapy can include several antibiotics, such as clindamycin and metronidazole, which act against anaerobes and gram-positive cocci, and gentamicin, a drug particularly effective against gram-negative microbes. (Chapter 27 further discusses these and other antibiotics.) Often, antibiotic treatment of patients with necrotizing fasciitis is ineffective because of insufficient blood supply to the affected tissues.

THOUGHT QUESTION 26.1 Why would treatment of an infection sometimes require multiple antibiotics?

WWW | Antibiotic treatment

Is There an Immunological Predilection to Necrotizing Faciitis?

S. pyogenes is best known for causing sore throats and for the immunological sequelae that can develop, such as rheumatic fever and glomerulonephritis. **Sequelae** are secondary diseases that develop after resolution of a primary infection. They are often the result of a cross-reactivity between bacterial and host antigens. The immune system, activated by the bacterial antigen, begins to attack the cross-reacting self antigens and damages tissues (see Section 24.8). Why some patients infected with *S. pyogenes* develop necrotizing faciitis while others do not may be due more to the immunological status of the patient than to the virulence arsenal of the microbe, but its arsenal is vast nonetheless.

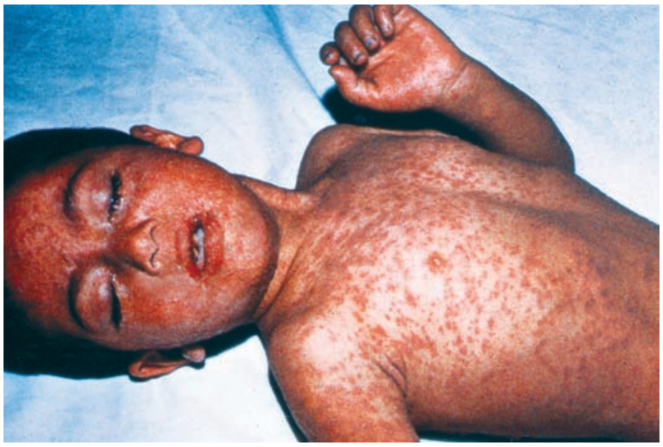
The source of many established putative virulence factor genes in *S. pyogenes* are the many prophages present in its genome. Prophages constitute approximately 10% of the organism's genome. One study found that a soluble factor produced by human pharyngeal cells can facilitate activation of at least some of these phages and cause horizontal transfer of the associated virulence factors between strains of this pathogen.

Viral Diseases Causing Skin Rashes

Several viruses can produce skin rashes, although their route of infection is usually through the respiratory tract. Measles, for example (see Section 6.1), is a highly contagious viral infection caused by a paramyxovirus, whose hallmark symptom is skin rash (Fig. 6.2). Also known as rubeola, the first signs are fever, cough, runny nose, and red eyes occurring 9–12 days after exposure. A few days later, spots in the mouth appear (Koplik's spots) along with a sore throat. Then a skin rash develops that typically starts on the face and spreads down the body. The virus replicates in the lymph nodes and spreads to the bloodstream (viremia), where it can infect endothelial cells of the blood vessels. The rash occurs when T cells begin to interact with these infected cells.

Although skin rash is the main symptom of measles, infection can also cause respiratory symptoms and complications, including pneumonia, bronchitis, croup, and even a fatal encephalitis in immunocompromised patients. In the United States, measles has been almost completely eliminated by the measles, mumps, and rubella (MMR) multivalent vaccine (one exception is the AIDS patient, where measles can be fatal). Worldwide, however, measles is still a serious problem in places where vaccinations are not routine.

Rubella virus, a togavirus, causes a maculopapular rash known as German measles, or three-day measles. The rash is similar but less red than that of measles (**Fig. 26.4**). German measles is an infection that primarily affects the skin and lymph nodes and is usually transmitted from



Peter Rowe, MD/DermAtlas

Figure 26.4 **German measles.** Skin rash caused by rubella virus.

person to person by aerosolization of respiratory secretions. It is not dangerous in adults or children; the virus can, however, cross the placenta in a pregnant woman and infect her fetus. If the virus crosses the placenta within the first trimester, the result is congenital rubella syndrome, which can cause death or serious congenital defects in the developing fetus.

Other viruses affecting the skin, such as chickenpox, the related disease shingles, and smallpox, are discussed in Chapters 6 and 11 and included in **Table 26.2**.

TO SUMMARIZE:

- ***S. aureus* and *S. pyogenes*** are common bacterial causes of skin infections. The organisms usually infect through broken skin.
- **Methicillin-resistant *S. aureus*** (MRSA) has become an important cause of community-acquired staphylococcal infections.
- **Necrotizing fasciitis** is usually caused by *S. pyogenes* but can be the result of other infections.
- **Infections of the skin** can disseminate via the bloodstream to other sites in the body.
- **Rubeola and Rubella viruses** infect through the respiratory tract, but their main manifestation is the production of similar maculopapular skin rashes.

26.3 Respiratory Tract Infections

Lung and upper respiratory tract infections are among the most common diseases of humans. Many different bacteria, viruses, and fungi are well adapted to grow in the lung. Successful lung pathogens come equipped with appropriate attachment mechanisms and countermeasures to avoid various lung defenses (such as alveolar macrophages). Although many microbes can cause lung infection, most respiratory diseases are of viral origin, and most viral infections (such as the common cold) do not spread beyond the lung. Fortunately, viral diseases by and large are self-limiting and typically resolve within two weeks; however, the damage caused by a primary viral infection can lead to secondary infections by bacteria.

Bacterial infections of the lung, whether of primary or secondary etiology, require intervention. Today this means antibiotic therapy. Before the advent of antibiotics, the only recourse was to insert a tube into the patient's back to drain fluid accumulating in the pleural cavity around the lung (a pathological process known as pleural effusion). Unless released, the pressure on the lung will collapse the alveoli and make breathing difficult.

Bacterial infections of the lung that arise secondarily to viral disease occur, in part, because the patient dehydrates. The resulting increase in mucus viscosity hampers the mucociliary elevator (described in Section 23.1), as will growth of the bacterium itself. Because a compromised mucociliary elevator makes it difficult to expel the microbe, the patient's susceptibility to secondary bacterial infection increases. Hence, cold sufferers are advised to drink plenty of fluids, which help decrease the viscosity of mucus and consequently improve mucociliary elevator function.

Case History: Bacterial Pneumonia

In March, an 80-year-old resident of a New Jersey nursing home had a fever accompanied by a productive cough with brown sputum (mucous secretions of the lung that can be coughed up). He reported to the attending physician that he had pain on the right side of his chest and suffered from night sweats. Blood tests revealed that his white blood cell (WBC) count was 14,000/μl with a makeup of 77% segmented forms (polymorphonuclear leukocytes, PMNs) and 20% bands (immature PMNs). The chest radiograph revealed a right upper lobe infiltrate with cavity formation (**Fig. 26.5A**). *From this information, the clinician made a diagnosis of pneumonia. Microscopic examination of the patient's sputum revealed gram-positive cocci in pairs and short chains surrounded by a capsule* (**Fig. 26.5B**). *Bacteriological culture of his sputum and blood yielded* Streptococcus pneumoniae.

Note that pneumonia is a disease, not a specific infection. Many different microbes can cause pneumonia (**Table 26.3**). The pneumococcus *S. pneumoniae* accounts for about 25% of community-acquired cases of pneumonia, but pneumococcal pneumonia occurs mostly among the elderly and immunocompromised, including smokers, diabetics, and alcoholics. A breakdown of pneumonia cases by causative organism is shown in **Figure 26.5C**.

The noses and throats of 30–70% of a given population can contain *S. pneumoniae*. The microbe can be spread from person to person by sneezing, coughing, or other close personal contact. Pneumococcal pneumonia may begin suddenly, with a severe shaking chill usually followed by high fever, cough, shortness of breath, rapid breathing, and chest pains.

After being aspirated into the lung, the microbe will grow in the nutrient-rich edema fluid of the alveolar spaces. Neutrophils and alveolar macrophages then arrive to try to stop the infection. They are called into the area from the circulation by chemoattractant chemokines released by damaged alveolar cells. The thick polysaccharide capsule of the pneumococcus, however, makes phagocytosis very difficult. In an otherwise healthy adult, pneumococcal pneumonia usually involves one lobe of the lungs; thus, it is sometimes called lobar pneumonia. The infiltration of PMNs and fluid lead to the typical radiological findings of diffuse cloudy areas. In contrast, infants, young children,

Bacteria range from 0.5 μm to 1.2 μm in diameter. **C.** Relative incidence of pneumonia caused by various microorganisms.

and elderly people more commonly develop an infection in other parts of the lungs, such as around the air vessels (bronchi), causing bronchopneumonia.

The white cell count in the case history is telling. The patient had an elevated WBC count (normal is 5,000 to 10,000/μl) and elevated band cells (normal is 0–8%). These increases are indicative of a bacterial, not viral, infection. Neutrophils (PMNs), the front line combatants against infection, rise in response to bacterial infections and are first released from bone marrow as immature band cells, whose presence is a sure sign of bacterial infection.

Several outbreaks of pneumococcal pneumonia have occurred over recent years in nursing homes, where numerous residents have been affected. This underscores the importance of elderly people receiving the pneumococcal polysaccharide vaccine (PPV) as a hedge against infection. While there are over 80 antigenic types of pneumococcal capsular polysaccharide, the injected vaccine contains only the 23 types that are most often associated with disease. A vaccine that is formulated to respond to multiple antigens is termed a **multivalent vaccine**. The immune response that results will protect vaccinated individuals against infection by those antigenic types. The vaccine is recommended for individuals over 65 as well as for those who are immunocompromised. The patient in this case history failed to receive the vaccine.

In addition to causing serious infections of the lungs (pneumonia), *S. pneumoniae* can invade the bloodstream (bacteremia) and the covering of the brain (meningitis). The death rates for these infections are about one out of every 20 who get pneumococcal pneumonia, about two out of 10 who get bacteremia, and three out of 10 who get meningitis. Individuals with special health problems, such as liver disease, AIDS (caused by HIV), or organ transplants, are even more likely to die from the disease because of their compromised immune systems.

An emerging infectious disease problem throughout the United States and the world is the increasing resistance of *S. pneumoniae* to antibiotics. At least 30% of the strains isolated are already resistant to penicillin, the former drug of choice for treating the disease. Chapter 27 discusses why antibiotic resistance is on the rise for this and other microbes.

Case History: Disseminated Disease from a Fungal Lung Infection

A 35-year-old male boxer named Tyrrell, recently admitted to a Maryland hospital, was in good health until six months ago, when he developed a chronic cough that produced blood-tinged white sputum. He also experienced flu-like symptoms, a decrease in appetite, and weight loss. One month prior to admission, he became so short of breath that he could no longer continue boxing. At that time, an X-ray taken in the emergency *room showed right upper lobe infiltrate, indicating pneumonia* (**Fig. 26.6A**). *A tuberculosis skin test was negative. He was given a prescription for the antibiotic azithromycin (a commonly used macrolide antibiotic to treat bacterial infections of the respiratory tract) and discharged. Despite antibiotic treatment, the cough never diminished and he developed several painless subcutaneous nodules. The largest nodule was on his left leg, contained pus, caused pain, and eventually hindered walking* (**Fig. 26.6B**). *This prompted his current admission to the hospital. The patient's history revealed that he installed home insulation for a living and had not traveled outside the area for the past year. He complained of fevers, chills, night sweats, and a 10-kg (22-lb) weight loss. His right tibia was tender to the touch, indicating bone involvement. He denied having prior pneumonia, sinus infection, arthritis, hematuria (blood in the urine), numbness, or muscle weakness. He had no history of intravenous drug use and had been in a monogamous relationship for four years. His white cell count was 10,500/mm*^{3} *with a normal differential of PMNs and band cells.*

In this case, the expression of frankly purulent material (pus) from the left leg nodule suggested that this was an infectious process. The infection in this patient probably started in the lung (clued by the cough), after which the organism disseminated throughout the body via the bloodstream. Fungus is a probable cause, given the chronic nature of the patient's symptoms. Tuberculosis, caused by the bacterium *Mycobacterium tuberculosis*, also causes a chronic lung infection and might have been suspected except for the negative TB skin test. The tuberculin skin test involves injecting a small amount of mycobacterial antigen called PPD (purified protein derivative) under the skin of the lower arm. A person who has been infected with *M. tuberculosis* will exhibit a localized delayed-type hypersensitivity reaction at the site of injection, although this does not equate to currently active disease.

The most likely fungal causes of infection in this case history are the endemic mycoses, such as histoplasmosis, blastomycosis, and coccidiomycosis. This patient had never traveled to the western United States, where coccidioidomycosis is endemic. This ruled out exposure to *Coccidioides*. Histoplasmosis most commonly presents as a flu-like pulmonary illness, with erythema nodosum (tender bumps on skin) and arthritis (swollen joints) or arthralgias (joint pain), none of which the patient had. Blastomycosis can disseminate to the lung, skin, bone, and genitourinary tract, which is consistent with the pattern of organ involvement seen in this patient. *Cryptococcus*, an encapsulated yeast, is not the likely cause, since it typically requires an immunocompromised host to cause disease, not the case in this instance. (*Cryptococcus*, which causes cryptococcosis, is an opportunistic pathogen that commonly infects AIDS patients.) The most prevalent clinical form of cryptococcosis is meningoencephalitis, although

disease can also involve the skin, lungs, prostate gland, urinary tract, eyes, myocardium, bones, and joints.

Amphotericin B, an antifungal agent, was finally given to this patient. His fever lowered almost immediately, and the skin nodules diminished. After two weeks, a fungus was found in the cultures of the nodule biopsy, bronchoalveolar lavage (washes), and urine (**Fig. 26.6C**). This fungus was identified by a DNA probe as *Blastomyces dermatitidis*, confirming the diagnosis of blastomycosis.

Blastomyces dermatitidis is a dimorphic fungus that resides in the soil of the Ohio and Mississippi River valleys and the southeastern United States. The portal of entry is the respiratory tract, and infection is usually associated with occupational and recreational activities in wooded areas along waterways, where there is moist soil with a high content of organic matter and spores. The incubation period ranges from 21 to 106 days. This patient most likely inhaled conidia (fungal spores) from the soil while crawling underneath houses installing insulation. The physician learned that he used only a T-shirt to cover his mouth and nose, not an effective method of keeping spores from entering the respiratory tract. He should have worn a respirator.

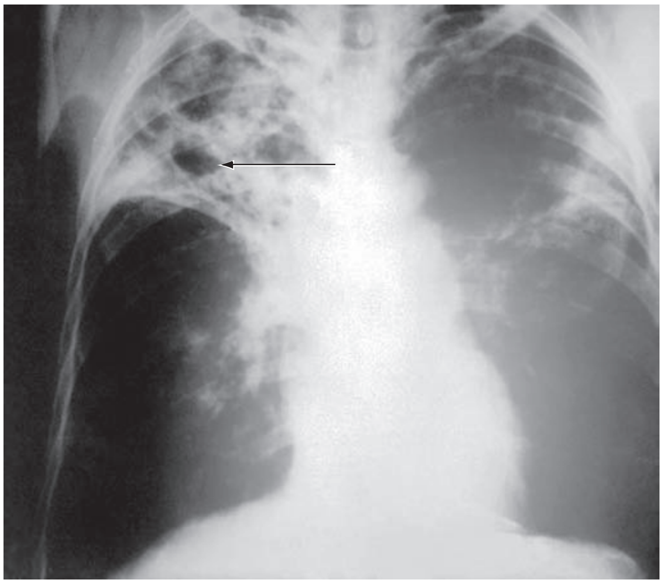
Several critical features of this case help differentiate it from the preceding case of pneumococcal pneumonia. First, the initial macrolide antibiotic, azithromycin, should have killed most bacterial sources of infection. Second, the X-ray finding of diffuse infiltrate is more indicative of fungal lung infection than bacterial infection, which in a patient of this age would likely be confined to one lobe. The patient was young and in good health prior to the infection, making it unlikely to be pneumococcal pneumonia. The blood count was also a clue. Fungal infections do not usually cause an increase in WBCs or an increase in band cells. Finally, the **metastatic lesions** (infectious lesions that develop at a secondary site away from the initial site of infection) on the leg were in no way consistent with *S. pneumoniae*. They arise when the organism moves through the bloodstream from the primary site of infection to another body site, where it can begin to grow. Many infectious diseases start out as a localized infection but end up disseminating throughout the body to cause metastatic lesions.

NOTE: The term "metastasis" means to spread disease from one organ to another noncontiguous organ. Only microbial infections and malignant cancer cells can metastasize.

Tuberculosis as a Reemerging Disease

Until recently, tuberculosis, caused by the acid-fast bacillus *Mycobacterium tuberculosis*, was considered of passing historical significance to physicians practicing in the developed world. In 1985, however, owing primarily to the newly recognized HIV epidemic and a growing indigent population, TB resurfaced, especially in inner-city hospitals. In 1991, highly virulent multidrug-resistant (MDR) strains of *M. tuberculosis* were reported. These strains not only produced fulminant (rapid onset) and fatal disease among patients infected with HIV (the time between TB exposure to death is 2–7 months), but also proved highly infectious. Tuberculin skin test conversion rates of up to 50% are reported in exposed health care workers. A positive tuberculin skin test is seen as a delayed-type hypersensitivity reaction to *M. tuberculosis* proteins [called partially purified derivative (PPD)] injected under the skin. More information on mycobacteria can be found in Section 18.4.

M. tuberculosis primarily causes a respiratory infection, but can disseminate through the bloodstream to produce abscesses in many different organ systems. Disseminated disease is called miliary TB because the size of the infected nodules, called tubercles, approximates the size of millet seeds. The organisms are spread from person to person (no animal reservoir) through aerosolization of respiratory secretions. Once in the lung, the bacteria are phagocytized by macrophages and survive ensconced within modified phagolysosomes. A delayed-type hypersensitivity response results, and small hard tubercles form. Over time, the tubercles develop into caseous lesions that have a cheese-like consistency and can calcify into the hardened Ghon complexes seen on typical X-ray findings (**Fig. 26.7**).



CDC

Figure 26.7 Calcified Ghon complex of tuberculosis. The arrow points to a complex in a patient's right upper lobe. Note the difference in appearance compared to Figure 26.6A.

Table 26.3 Microbes causing respiratory tract diseases.

Disease	Symptoms	Etiologic agent
Bacterial		
Inhalation anthrax	Fever, muscle aches, hypotension, respiratory failure	*Bacillus anthracis* (G+ rod)
Diphtheria	Tracheal pseudomembrane	*Corynebacterium diphtheriae* (G+ rod)
Whooping cough	Fever, runny nose, sneezing, violent cough followed by inhalation "whoop"	*Bordetella pertussis* (G– coccobacilli)
Tuberculosis	Fever, chills, cough, bloody sputum, fatigue, weight loss	*Mycobacterium tuberculosis* (acid-fast bacillus)
Pneumonia	Infects cystic fibrosis patients; fever, chills, cough, chest pain	*Pseudomonas aeruginosa* (G– rod)
Pneumonia	Fever, chills, cough, chest pain	*Streptococcus pneumoniae* (G+ diplococcus)
Psittacosis	Fever, sore throat, chest pain, runny nose	*Chlamydophila psittaci*
Pneumonia	Fever, sore throat, chest pain, runny nose (also associated with cardiovascular disease)	*Chlamydophila pneumoniae*
"Walking pneumonia"	Fever, sore throat, nonproductive cough, chills	*Mycoplasma pneumoniae* (wall-less microbe)
Legionnaires' disease (legionellosis)	Fever, chest pain, chills, cough, muscle pain, vomiting, diarrhea	*Legionella pneumophila* (G– rod)
Viral		
CMV disease	Fever, chills, cough, chest pain	Cytomegalovirus (CMV); dsDNA
RSV disease	Fever, chills, cough, chest pain	Respiratory syncytial virus; ssRNA (–)
Influenza	Fever, chills, cough, chest pain, sore throat, muscle pain	Influenza and parainfluenza viruses; ssRNA (–), segmented
	Sore throat, fever, runny nose	Adenovirus; dsDNA
Severe acute respiratory syndrome	Fever, chills, cough, chest pain	SARS virus; ssRNA (+)
Fungal		
Aspergillosis	Lung, sinuses, fever, chills, breathing difficulty	*Aspergillus* spp.
Histoplasmosis	Flu-like; pulmonary infiltrate	*Histoplasma capsulatum*
Coccidioidomycosis	Flu-like; pulmonary infiltrate	*Coccidioides immitis*
Blastomycosis	Chest pain, cough, skin lesion, pulmonary infiltrate	*Blastomyces dermatitidis*
Pneumocystosis	Infects AIDS patients; cough, fever, weight loss	*Pneumocystis jiroveci* (formerly *carinii*)

[a] Bacillus Calmette-Guérin (a weakened strain of the bovine tuberculosis strain).

Virulence properties	Source	Treatment	Vaccine
Peptide capsule, PA, LF, and EF toxins	Airborne	Ciprofloxacin	+, Military
Diphtheria toxin	Airborne; localizes to nasopharynx	Penicillin	+
Tracheal cytotoxin, adenylate cyclase toxin, filamentous hemagglutinin (adhesin)	Respiratory droplets	Erythromycin	+
Cord factor, wax D Intracellular growth	Human	Combination therapy (rifampin, isoniazid, ethambutol, pyrazinamide)	+ BCG[a]
Exotoxin A, phospholipase C, exopolysaccharide, others	Water, soil	Quinolones, aminoglycosides	
Capsule, pneumolysin	Inhalation	Macrolides, quinolones, ceftriaxone	Multivalent from capsule antigens
Obligate intracellular growth; prevents phagolysosome fusion	Bird droppings, dust; inhalation	Tetracycline, erythromycin	
Intracellular, obligate; prevents phagolysosome fusion	Person-to-person	Quinolone	
Adhesin tip	Inhalation, person-to-person	Erythromycin and other macrolides	
Intracellular growth, hemolysin, cytotoxin, protease	Inhalation	Erythromycin	
	Saliva, tears, breast milk	Gangcyclovir	Experimental
	Respiratory droplets	Treat symptoms; ribovarin	
	Respiratory droplets	Relenza	+
	Respiratory droplets	Treat symptoms	+, Military
	Respiratory droplets		
	Inhalation	Amphotericin B, voriconazole	
	Inhalation; bird, chicken, bat droppings	Amphotericin B, itraconazole	
	Inhalation	Amphotericin B, fluconazole	
	Inhalation	Amphotericin B, itraconazole	
	Inhalation	Trimethoprim sulfamethoxazole	

After a period of 4–12 weeks, patients with disease exhibit a productive cough generating sputum and experience fever, night sweats, and weight loss. They also become tuberculin test positive owing to delayed-type hypersensitivity. However, it is important to note that a positive tuberculin skin test does not signify *active* disease, only that the person was infected at one time. The bacterium may have been killed by the immune system without having caused disease. Treatment of active disease is aggressive and involves a four-drug regimen including isoniazid, rifampin, pyrazinamide, and ethambutol given over a course of several months. MDR strains are treated with a nine-drug regimen.

Viral Diseases of the Lung

Numerous viruses can cause lung infections (see **Table 26.3**). Influenza, rhinovirus, and SARS are discussed in Chapters 6, 11, and 25. An important viral lung infection not discussed elsewhere is respiratory syncytial disease, caused by **respiratory syncytial virus (RSV)**. A negative-sense, single-strand RNA, enveloped virus, RSV is the most common cause of bronchiolitis and pneumonia among infants and children under 1 year of age. Illness begins most frequently with fever, runny nose, cough, and sometimes wheezing. RSV is spread from respiratory secretions through close contact with infected persons or by contact with contaminated surfaces or objects. Infection can occur when the virus contacts mucous membranes of the eyes, mouth, or nose and possibly through the inhalation of droplets generated by a sneeze or cough. Unlike rubella or rubeola, which infect the respiratory tract and disseminate though the body, RSV remains localized in the lung.

The majority of children hospitalized for RSV infection are under 6 months of age. RSV can cause repeated infections throughout life, usually associated with moderate-to-severe cold-like symptoms. Severe lower respiratory tract disease may occur at any age, especially among the elderly or people with compromised cardiac, pulmonary, or immune systems. As yet, a vaccine to control this disease is not available.

Table 26.3 presents many other bacterial, fungal, and viral microbes that can cause respiratory tract infection. Be aware that very different diseases can produce similar symptoms. For instance, people constantly confuse influenza (the flu) with the common cold. Symptomatically, they may start out similarly, but there are telling differences. **Influenza** is characterized by fever, myalgia (muscle aches), pharyngitis (sore throat), and headache. A runny nose is *not* one of the symptoms. The common cold, however, manifests as a runny nose, nasal congestion, sneezing, and throat irritation. No myalgia. The observant clinician will note the difference.

TO SUMMARIZE:

- **The mucociliary elevator** is a primary defense mechanism used by the lung to avoid infection.
- **Pneumonia** is a disease that can be caused by many microorganisms.
- **An elevated white cell count** in blood is an indicator of bacterial infection.
- **Pneumococcal vaccine** should be administered to the elderly because they are often immunocompromised.
- **Fungal agents** commonly cause long-term, chronic infections.
- **Tuberculosis** is an ancient yet reemerging bacterial disease with an increasing mortality rate caused by the development of multidrug-resistant strains, the susceptibility of HIV patients, and an increasing indigent population.
- **Localized infections in the lung can disseminate** via the bloodstream to form metastatic lesions at other body sites.
- **Respiratory syncytial virus** is one of several viruses that can cause lung disease but rarely disseminates.

26.4 Gastrointestinal Tract Infections

Nearly everyone has experienced diarrhea—a condition characterized by frequent loose bowel movements accompanied by abdominal cramps. Hundreds of millions of cases occur each year in the United States. The loose stools usually result from inflammation (called gastroenteritis) due to viral growth, bacterial growth, or toxin production, causing large amounts of water and electrolytes to leave the intestinal cells and enter the intestinal lumen. As a result, the patient not only suffers diarrhea, but can become dangerously dehydrated. As with respiratory tract infections, most diarrheal disease is viral in origin, with rotavirus being the primary culprit. Among the bacteria, the gram-negative curved bacillus *Campylobacter* is the most frequent cause of self-limiting diarrheal disease.

The main symptoms of gastroenteritis, whether bacterial or viral, are watery diarrhea and vomiting. A more severe form of gastroenteritis is called **dysentery**, whose symptoms include abdominal pain, a persistent desire to empty the bowels, and diarrhea with passage of blood or mucus. Bacterial causes of dysentery include several *Shigella* species and some strains of *E. coli.* An ameba, *Entamoeba histolytica*, can also cause a form of the disease called amebic dysentery. Features of bacterial dysentery are discussed in more detail later in this section.

Remarkably, *Staphylococcus aureus* causes gastrointestinal disease without ever producing infection. Everyone has heard of the local church picnic where scores of people became violently ill within hours of eating unrefrigerated potato salad. *S. aureus* is the usual cause of these disasters. Not all strains of *S. aureus* cause food poisoning, but certain strains can secrete enterotoxins into tainted foods such as pies, turkey dressing, or potato salad. After ingestion, the toxin travels to the intestine, where it enters the bloodstream and stimulates nerves leading to the vomit center in the brain. Because the toxin is preformed, symptoms occur quickly after ingestion. Within 2–6 hours, the poisoned patient will begin vomiting and may also experience diarrhea. The disease, though violent, is not life-threatening and usually resolves spontaneously within 24–48 hours. In contrast, diarrhea caused by infectious agents, such as *Salmonella enterica*, that must first grow in the victim do not occur until 12–24 hours after ingestion, sometimes longer. A clinician noting quick onset of symptoms in a patient will immediately suspect staphylococcal food poisoning. Obviously, antibiotic treatment is not needed for staph food poisoning but may be indicated for other gastrointestinal infections.

Antibiotics Are Often Inappropriate When Treating Gastroenteritis

Although antibiotic treatment of infectious gastroenteritis seems intuitive, it is rarely used. Most gastrointestinal infections are viral, and so antibiotics are ineffective. Likewise, gastroenteritis caused by bacteria usually resolves spontaneously without antibiotic treatment. Of course, severe systemic disease stemming from gastroenteritis can develop, often in the young or elderly. Diseases such as typhoid fever (*Salmonella typhi*) or bacillary dysentery (*Shigella dysenteriae*) will respond well to antibiotics.

In some cases, antibiotic treatment can actually *trigger* gastrointestinal disease. For example, the antibiotic clindamycin can kill most normal intestinal flora except the naturally resistant gram-positive anaerobe *Clostridium difficile*, the causative agent of pseudomembranous enterocolitis. Unrestrained by microbial competition, *C. difficile* will grow in the intestine and produce specific toxins that can damage intestinal cells. The organism's growth leads to inflammation and the formation of pseudomembrane structures along the intestinal wall (refer to **Fig. 23.8**). Because they block the intestinal mucosa, pseudomembranes cause malabsorption of nutrients and water, which results in diarrhea. As the pseudomembrane enlarges, it begins to slough off and pass into the stool. Diagnosis of this disease involves PCR identification of the organism or immunological identification of the toxin in fecal samples.

Case History: Diarrhea and Dysentery

In April, a 6-year-old girl from Montgomery County, Pennsylvania, arrived at the ER with bloody diarrhea, a temperature of 39°C, abdominal cramping, and vomiting. Hospital admission was five days after a kindergarten field trip to the local dairy farm. The child's health history was otherwise unremarkable. At the time of hospital admission, the parents were questioned as to the child's activities during the trip. They confirmed that the child purchased a snack while at the farm. Upon laboratory analysis, a fecal smear was positive for leukocytes, and isolation of organisms confirmed the presence of gram-negative rods that produced Shiga toxins 1 and 2. Subsequent testing of the isolate by pulsed-field gel electrophoresis was indistinguishable from E. coli *O157:H7. By this time, the child developed further problems. Symptoms included puffy face and hands as well as neurological abnormalities. Initial examination suggested renal failure, and laboratory analyses supported this diagnosis with thrombocytopenia (reduced blood platelet count) and hemolytic uremic syndrome (HUS; renal failure). The child was treated by fluid and electrolyte replacement (intravenous). Antibiotics were not administered.*

In this case history, the presence of leukocytes in a fecal smear is a sign that the intestinal pathogen has invaded the epithelial mucosa of the intestine. Breaching this barrier sends out a chemical call to neutrophils, which then enter the area. *Shigella dysenteriae*, *Salmonella enterica*, and enteroinvasive *E. coli* (EIEC) are invasive; because they actually enter enterocytes, they are considered intracellular pathogens. Enterohemorrhagic *E. coli* (EHEC), which also produces leukocytes and blood in stools, is not an intracellular parasite (it is not invasive), but causes damaging attachment and effacing lesions, described in Section 25.2, that causes destruction of the mucosal epithelium. The resulting inflammation, in conjunction with damage caused by Shiga toxin, leads to blood and white cells in the stool. *E. coli* O157:H7, the etiological agent in the case history, is a common serotype of EHEC.

There are at least six different classes of pathogenic *E. coli* that differ based on their repertoire of pathogenicity islands, plasmids, and virulence factors. They include EIEC and EHEC, already mentioned, enterotoxigenic *E. coli* (ETEC) and uropathogenic *E. coli*, (UPEC), both described in Chapter 25, as well as enteropathogenic *E. coli* (EPEC) and enteroaggregative *E. coli* (EAEC). All but UPEC cause gastrointestinal disease. To tell them apart, each group has telltale O and H antigens that can be identified using serology.

NOTE: "O antigen" is part of the bacterium's LPS, while "H antigen" is flagellar protein. Thus, O157:H7 denotes the specific version of LPS (O157) and flagellar protein (H7) found on *E. coli* O157:H7. Other pathogenic strains of *E. coli* have different O and H antigens.

Shiga toxin. *Shigella* and EHEC, the agent in the preceding case history, both produce toxins called Shiga toxin 1 and 2 that are encoded by genes of bacteriophage genomes embedded in the bacterial chromosome. These toxins inhibit host protein synthesis and, in the process, damage endothelial cells in the kidney and brain. Endothelial damage triggers the formation of platelet-fibrin microthrombi (clots) that occlude blood vessels in the various organs, leading to two major syndromes—hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TPP). HUS occurs when the microthrombi are limited to the kidney. The microclots clog the tiny blood vessels in this organ and cause decreased urine output, ultimately leading to kidney failure and death. In TPP, the clots occur throughout the circulation. This will cause reddish skin hemorrhages called petichiae and purpura. Neurological symptoms (for example, confusion, severe headaches, possibly coma) then arise from microhemorrhages in the brain. The hemorrhaging occurs because platelets needed for normal clotting have been removed from the circulation as they form the microthrombi. The decreased number of platelets is called thrombocytopenia.

The toxins, which are absorbed through the intestine and disseminated via the bloodstream, have five B subunits used to bind to target cell membranes and one A subunit imbued with toxic activity (see Section 25.4). The A subunit, upon entry, destroys protein synthesis by cleaving an adenine from 28S rRNA in eukaryotic ribosomes.

Enterohemorrhagic *E. coli* (EHEC). *E. coli* O157:H7 is a recently emerged pathogen that can colonize cattle intestines without causing disease and as a result can contaminate meat products following slaughter. The organism is sometimes referred to as the “Jack-in-the Box” microbe, a reference to the first documented large-scale U.S. outbreak in 1993, linked to fast-food hamburgers purchased at a Washington state Jack-in-the-Box restaurant. As many as 600 people were sickened in that outbreak, and 3 children died. Though 1993 marked the first large-scale outbreak in the United States, the first report of the disease in this country occurred 11 years earlier, in 1982.

E. coli O157:H7 rarely affects the health of the reservoir animal. But when an infected steer is slaughtered, fecal contamination of the carcass can happen, despite manufacturers’ considerable efforts to prevent it. Grinding the tainted meat into hamburger will distribute the microbe throughout. As a result, cooking burgers to 160°C is essential to kill any existing EHEC. Also be aware that cross-contamination between foods is possible. Using the same cutting board to prepare meat and salad is a great way to contaminate the salad, which will not be cooked.

Despite its common association with hamburger, vegetarians are not safe from this organism. During heavy rains, waste from a cattle farm can easily wash into nearby vegetable fields unless precautions are taken. If the cattle waste contains *E. coli* O157:H7, the crops are contaminated. One such outbreak occurred in 2006, when spinach from certain areas of California became contaminated with this pathogen, prompting a nationwide recall of bagged spinach and a month without spinach salad.

Early on, the remarkably low infectious dose of *E. coli* O157:H7 mystified researchers. However, we have since learned that *E. coli* has an impressive level of acid resistance that rivals that of the gastric pathogen *Helicobacter pylori*. Acid resistance mechanisms permit survival of *E. coli* in the acidic stomach and enable a mere 10–100 individual organisms to cause disease.

As already noted, EHEC strains produce two toxins that are identical to the Shiga toxins produced by *Shigella* species. The toxins cleave host ribosomal RNA, thereby halting translation. As discussed earlier, one consequence of Shiga toxin is HUS. The development of HUS, as in the case history described, is a common consequence of *E.* coli O157:H7 infection. Unfortunately, HUS can only be treated with supportive care, such as blood transfusions and dialysis throughout the critical period until kidney function resumes. Antibiotic treatment can increase the release of Shiga toxins from the organisms and actually trigger HUS. Thus, antimicrobial therapy is not recommended.

In contrast to the case just described, many gastrointestinal infections do not produce fecal leukocytes or blood in the stool. Diarrheal diseases caused by *V. cholerae* (cholera) or enterotoxigenic *E. coli* (ETEC), which produces a cholera-like disease, do not involve invasion of the intestinal lining by the microbe and yield copious amounts of watery diarrhea. In these two toxin-driven diseases, the bacteria attach to cells lining the intestine and secrete toxins that are imported into the target cells (see Section 25.4).

Epidemiology of EHEC. **Epidemiology** is the study of factors and mechanisms involved in the spread of disease. The father of epidemiology was the British physician John Snow, who, even before there was a clear connection between bacteria and disease, managed to trace the source of a cholera epidemic in London in 1854 to a single well in the city. He found that the addresses of all the cholera patients clustered around just one of the city’s numerous water pumps that had, as it turns out, been contaminated with human feces. Sealing the well ended the epidemic.

The U.S. Centers for Disease Control (CDC) used the same basic strategy to identify the risk factors associated with the case study presented earlier. Fifty-one infected patients and 92 controls (children who visited the farm but did not become ill) were interviewed. Infected patients were more likely than controls to have had contact with cattle, an important reservoir for *E. coli* O157:H7. All 216 cattle on the farm were sampled by rectal swab, and 13% yielded *E. coli* O157:H7 with a DNA restriction pattern indistinguishable from that isolated from the patients. This finding indicated that the cattle were the source of infection. Activities that promoted hand-mouth contact, such as nail-biting and purchasing food from an outdoor concession were more common among the children that contracted disease (fecal-oral route of infection). Furthermore, separate areas were not established for eating and interactions with farm animals. Visitors could touch cattle, calves, sheep, goats, llamas, chickens, and a pig while eating and drinking. Hand-washing facilities were unsupervised and lacked soap, and disposable hand towels were out of the children's reach. All of these situations provided opportunity for infection.

Type III secretion and diarrhea. Type III secretion was first described in Section 25.5, where we discussed the pathogenesis of *Salmonella enterica*, but these secretion systems are present in numerous gram-negative pathogens, such as EHEC in our case history. Recall that type III protein secretion systems directly inject proteins from the cytoplasm of a bacterial pathogen into the cytoplasm of a target eukaryotic host cell. The system delivers proteins across three membranes—two for the gram-negative bacterial pathogen and one for the target cell.

In addition to stimulating bacterial entry into host cells, bacterial proteins injected by type III transport systems cause host cells to secrete pro-inflammatory cytokines. The cytokines then "call in" inflammatory cells and alter ion transport through the epithelial membrane. Excessive export of ions such as chloride causes water to leave the cell in an attempt to equilibrate the internal and external ionic concentrations. The water entering the intestine results in diarrhea. We are just beginning to understand how the type III–translocated effector proteins induce these host cellular responses and how this leads to intestinal inflammation during an infection.

Although most gastrointestinal disease is intestinal in locale, specialized microbes can also target the stomach, with its harsh acidic environment.

Case History: Ulcers—It's Not What You Eat

Gary is a 34-year-old accountant who immigrated to Nebraska from Poland seven years ago. Since his teenage years, he has been bothered periodically by episodes of epigastric pain (pain around the stomach), nausea, and heartburn. Antacids usually alleviated the symptoms. Over the years, he received several courses of treatment with Tagamet or Pepcid to reduce acid secretion and provide relief. Recently, an upper-GI endoscopy was performed, in which a long, thin tube tipped with a camera and light source was inserted into Gary's mouth and into his stomach. The view through the endoscope showed some reddened areas in the antrum (bottom part) of the stomach. The endoscope was also equipped with a small clawlike structure that obtained a small tissue sample from the lining of Gary's stomach. A urease test performed on the antral biopsy turned positive in 20 minutes. Histological examination of the biopsy confirmed moderate chronic active gastritis (inflammation of the stomach lining) and revealed the presence of numerous spiral-shaped organisms. Cultures of the antral biopsy were positive for H. pylori.

Painful and sometimes life-threatening gastric ulcers were for many years blamed on spicy foods and stress. These factors were believed to cause increased acid production that ate away at the stomach lining, even though the gastric mucosa is normally well protected from stomach acid, which can fall as low as pH 1.5. This argued against the model but was ignored. In the 1980s, based on their discovery of odd, helical-shaped bacteria present in the biopsies of gastric ulcers, Australians Robin Warren and Barry Marshall (a medical intern at the Royal Perth Hospital at the time; **Fig. 26.8A**) proposed that bacteria, not pepperoni, caused ulcers (**Fig. 26.8B**). Their hypothesis was viewed with skepticism and declared as heresy by the established medical community. Faced with disbelief bordering on ridicule, the young intern drank a vial of the helical organisms and waited. A week later he began vomiting and suffered other painful symptoms of gastritis. Barry Marshall could not have been happier. He had proved his point. We now know that this curly-shaped microbe causes the vast majority of stomach ulcers.

The discovery of *Helicobacter pylori* and its association with gastric ulcer disease led to an upheaval

CNRI/Photo Researchers, Inc.

Figure 26.8 A bacterial cause of gastric ulcers. A. Australian physician Barry Marshall was so sure he was right about the cause of stomach ulcers, he swallowed bacteria to prove his point. **B.** View of *H. pylori* in stomach crypts (colorized SEM). Bacteria are approximately 2 μm in length.

in gastroenterology. Prior to this discovery, treatment focused on suppressing acid production, which did not provide long-term relief. Within one year after acid-suppressive therapy, up to 80% of patients suffer a relapse of their ulcer. Therapy now includes antimicrobial treatment to kill the bacteria and acid suppression therapy to prevent further inflammation while the ulcer heals. Warren and Marshall, who recovered from his gastritis, received the 2005 Nobel Prize in Physiology or Medicine for their groundbreaking work.

The exact mechanism by which the organism causes gastric ulcers is not known, although a variety of virulence factors have been described (see Section 25.6). The urease enzyme of *H. pylori* is a characteristic virulence feature. Urease converts urea, produced by the gastric lining, to ammonia and carbon dioxide. The ammonia neutralizes acid in and around the organism and allows the microbe to survive in the stomach. In an animal model, the urease enzyme of *H. pylori* was found to be important for bacterial colonization in the stomach. Treatment with urease inhibitors such as acetohydroxamic acid, however, does not lead to eradication of *H. pylori*. This failure is likely due to protection afforded the organism once it reaches the mucous layer that blankets the gastric epithelium (see **Fig. 26.8B**). The pH of this environment is closer to neutral, so urease may no longer be needed. Tools useful for diagnosing *H. pylori* include histology, rapid urease testing, and serology (for example, enzyme-linked immunosorbent assay (ELISA) to detect antibody to the CagA antigen).

Enzyme-linked immunosorbent assay (ELISA). ELISA is a common immunological tool to detect the presence, in serum, of antibodies to a specific organism—an indication of infection. The assay is performed by coating wells in a plastic dish with an antigen (for example, *Helicobacter* CagA). Serum from the patient is then added to the well. If antibodies to CagA are present, they will bind to the CagA antigen. Unbound antibody is removed by washing, and a secondary antibody that binds human IgG is added to the well. These anti-antibodies have an enzyme linked to them. A sandwich is formed as follows: [plastic dish]–[CagA protein]–[anti-CagA antibody]–[anti-IgG antibody]–[enzyme]. When the appropriate enzyme substrate is added to the well, the enzyme acts on it to produce light or a chromogenic product that can be detected. The more anti-CagA antibody present in the serum, the more light or product is produced by the linked enzyme. Applications of ELISA and further discussion of the methodology involved are described in Section 28.2.

***H. pylori* infection, cancer, and bad breath.** Problems caused by *H. pylori* are not limited to gastric ulcers. The microbe has also been associated with gastric cancer. The evidence is not yet conclusive, but many individuals with gastric cancer are also colonized by *H. pylori*. The most compelling experimental proof is that gerbils infected with this organism develop gastric cancer. In addition, when the CagA protein of *H. pylori* is injected into gastric epithelial cells, it is phosphorylated on a tyrosine residue and activates a regulatory cascade that causes the gastric cell to proliferate (**Fig. 25.33**). The connection between *H. pylori* and gastric cancer is sobering when you consider that *H. pylori* can be detected in about two-thirds of the world's population, especially in impoverished countries.

There is also the unusual case of a patient with a 60-year history of halitosis (extreme bad breath) that was resistant to all standard therapies but was cured by a triple-drug therapy regimen used for *H. pylori*. This case is an illustration of how microorganisms can cooperate to cause disease. *H. pylori* did not cause the smell. It appears that the patient did not produce much stomach acid. As a result, the urease produced by *H. pylori* easily neutralized the remaining stomach acid, allowing anaerobes ingested with food to start putrefying the stomach contents, leading to the foul-smelling breath. Other examples of disease caused by microbial cooperation will be described later.

Rotavirus Is the Single Greatest Cause of Gastroenteritis

Many people wrongly think that most cases of diarrhea are caused by a bacterial agent. Actually, a virus, **rotavirus**, causes more intestinal disease than any bacterial species. It is highly infectious; it is endemic around the globe; and it affects all age-groups, although children between 6 and 24 months are most severely affected. Spread by the fecal-oral route, it is estimated that by age 3, all children have had a rotavirus infection.

The incubation period is approximately two days, after which the victim suffers frequent watery, dark green, explosive diarrhea. All of this may be accompanied by nausea, vomiting, and abdominal cramping. Severe dehydration and electrolyte loss due to the diarrhea will cause death unless supportive measures, such as fluid replacement, are undertaken. There is no cure, but most patients recover if rehydrated properly. Few deaths from rotavirus occur in the United States, but each year more than 600,000 children worldwide die from this viral diarrhea, which is why efforts to develop a safe, effective vaccine are so important. Success in this endeavor seems close at hand.

Protists (Protozoa) Are Another Major Cause of Diarrheal Diseases

Most students of biology are familiar with protozoa (more properly called protists) such as paramecia and amebas, but many are surprised to learn that some species of protists cause serious human diseases. For instance,

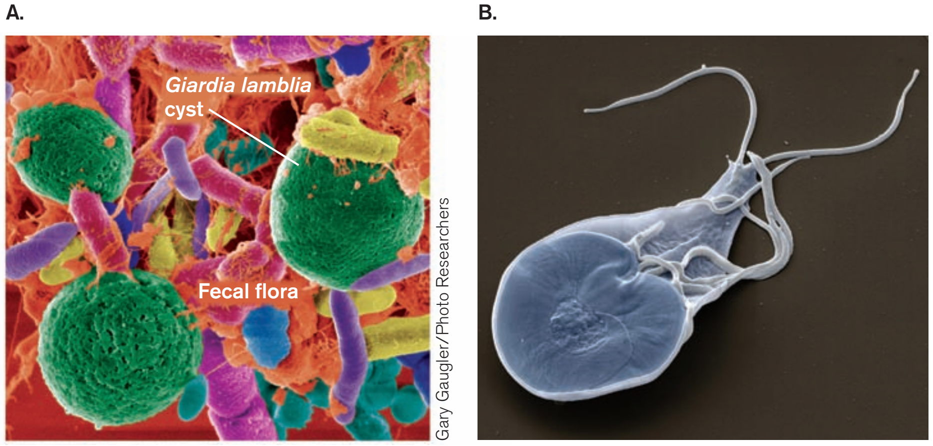

Figure 26.9 ***Giardia lamblia.*** This protist is a major cause of diarrhea in the world. **A.** Cysts (7 to 14 μm) present in fecal matter (colorized SEM). **B.** Trophozoite form (colorized SEM, 5 to 15 μm in length).

Gary Gaugler/Photo Researchers

Oliver Meckes/Nicole Ottawa/Photo Researchers

Entamoeba histolytica and *Cryptosporidium parvum* cause the diarrheal diseases amebic dysentery and cryptosporidiosis, respectively. In 2005, the CDC tallied 2,640 cases of cryptosporidiosis, a reportable disease in the United States. Two other amebas, *Nagleria* and *Acanthamoeba*, cause amebic menigoencephalitis. Because some species of *Acanthamoeba* can infect the eye, soft contact wearers should take precautions to prevent contamination of their lenses.

The flagellated protozoan *Giardia lamblia* is a major cause of diarrhea throughout the world. In the United States alone, *G. lamblia* was responsible for over 11,000 reported cases of giardiasis diarrhea in 2005 and likely caused thousands more that were not reported. *Giardia lamblia* enters a human or other host as a cyst present in drinking water contaminated by feces (**Fig. 26.9A**). Aside from humans, *G. lamblia* can be found in various rodents, deer, cattle, and even household pets. It is very infectious. Ingestion of as few as 25 cysts can lead to disease. Following ingestion, the hard, outer coating of the cyst is dissolved by the action of digestive juices to produce a trophozoite, which attaches itself to the wall of the small intestines and reproduces (**Fig. 26.9B**). Offspring quickly encyst and are excreted out of the host's body.

Asymptomatic carriers of *G. lamblia* are common—it has been estimated that anywhere from 1 to 30% of children in U.S. day-care centers are carriers. Disease usually manifests as greasy stools alternating between a watery diarrhea, loose stools, and constipation. However, some patients will experience explosive diarrhea. Diagnosis is usually done by observing the cysts or trophozoite forms of the protozoan in feces. Metronidazole is a drug often used to cure the disease. As for prevention, proper treatment of community water supplies is essential.

We have examined only a handful of the microbes that cause gastrointestinal infection. Others are presented in **Table 26.4**.

TO SUMMARIZE:

- **Diarrhea** leads to dehydration, for which fluid replacement is a critical treatment. Antibiotic treatment is usually not recommended.
- **Staphylococcal food poisoning** is not an infection. It is a toxigenic disease.
- **Antibiotic treatments** can sometimes cause gastrointestinal disease (for example, pseudomembranous enterocolitis by *Clostridium difficile*).
- **Bacteria that invade intestinal epithelial mucosal cells** lead to the presence of blood and white blood cells in fecal contents. This occurs with intracellular pathogens such as *Shigella*, *Salmonella*, and EIEC.
- **Bacteria that do not invade intestinal cells** usually produce watery diarrhea. EHEC is an exception because the attachment and effacing lesions it produces result in bloody stools.
- **Bacterial toxins** produced by bacterial enteric pathogens can cause systemic symptoms.
- **John Snow** founded the science of epidemiology while studying a cholera outbreak in London.
- **The bacterium *H. pylori***, a common cause of gastric ulcers, lives in the stomach and is highly acid resistant.
- **Rotavirus** is the single greatest cause of diarrhea worldwide.
- ***Giardia lamblia*** is a major protozoan cause of diarrhea worldwide.

26.5 Genitourinary Tract Infections

Although the genital and urinary tracts are different organ systems, their close association in the body has led them to be grouped together when discussing infections.

Table 26.4 Microbes causing diseases of the gastrointestinal tract.

Disease	Symptoms	Etiologic agent	Virulence factors	Source	Treatment
Bacterial					
Staphylococcal food poisoning	Symptoms within 4 h of ingestion; nausea, vomiting, diarrhea	*Staphylococcus. aureus* (G+)	Enterotoxin	Preformed toxin in foods	Supportive
Botulism	Symptoms begin quickly; flaccid paralysis	*Clostridium botulinum* (G+, anaerobe)	Neurotoxin	Preformed toxin in food	Antiserum
Salmonellosis	Symptoms after 18 h; abdominal pain, diarrhea; invade intestinal M cells	*Salmonella enterica* [gram negative (G–)]	Type III secretion, intracellular growth	Chickens, other animals; fecal-oral	Oral rehydration; antibiotics if severe
Typhoid fever	Headache, fever, chills, abdominal pain, rash (rose spots), hypotension, diarrhea in late stages	*Salmonella typhi* (G–)	Type III secretion, intracellular growth, PhoPQ regulators, Vi antigen capsule	Human carriers (gall bladder reservoir), food, water	Quinolones
Traveler's diarrhea	Watery diarrhea	Enterotoxigenic *Escherichia coli*	Labile and stable toxins	Humans; food, water	Oral rehydration
Gastroenteritis	Bloody diarrhea, HUS	Enterohemorrhagic *E. coli*	Intimin, Tir, type III secretion, Shiga toxin	Contaminated foods (hamburger) and crops	Oral rehydration; antibiotics if severe
Shigellosis	Bloody diarrhea, HUS	*Shigella* spp. (G–)	Shiga toxin, type III secretion, intracellular growth, actin-based motility, escape phagosome	Human fecal-oral route	Oral rehydration; antibiotics if severe
Cholera	Watery diarrhea	*Vibrio cholerae* (G–)	Cholera toxin, TCP pili, ToxR regulator	Human waste-contaminated water	Oral rehydration, antibiotics
Gastroenteritis	Diarrhea, blood in stool	*V. parahaemolyticus* (G–)	Enterotoxin	Raw seafood	Self-limiting
Gastroenteritis	Watery diarrhea, nausea	*Clostridium perfringens* (G+)	Alpha toxin	Soil, food	Self-limiting
Pseudomembranous enterocolitis	Fever, abdominal pain, diarrhea, pseudomembrane in colon	*C. difficile* (G+)	Cytotoxin, antibiotic resistance	Animals, normal flora	Vancomycin
Gastroenteritis	Fever, muscle pain, watery diarrhea, blood in stool, headache	*Campylobacter jejuni* (G–)	Cytotoxin, enterotoxin, adhesin	Poultry, unpasteurized milk	Erythromycin
Gastric ulcers	Abdominal pain, bleeding, heartburn	*Helicobacter pylori* (G–)	Adhesin, urease CagA, vacuolating toxin	??	Triple drug (omeprazole, clarithromycin, metronidazole)
Viral					
Stomach "flu"	Nausea, vomiting, diarrhea	Noroviruses (Norwalk virus)	??	Fecal-oral route	Oral rehydration
	(Most common cause)	Rotavirus	??	Fecal-oral	Oral rehydration

Urinary Tract Infections

The urinary tract includes the kidneys, ureters, urinary bladder, and urethra. Infections anywhere along this route are called urinary tract infections (UTIs). Urinary tract infections are the second most common type of bacterial infection in humans, ranking in frequency just behind respiratory infections such as bronchitis or pneumonia. Along with numerous office visits, bladder infections and other urinary tract infections result in 100,000 hospital admissions and $1.6 billion in medical expenses each year. Most sufferers are women. One in five women will get a urinary tract infection at some point in her life, and 20–40% of those infected will develop recurrent infections.

Urine, as produced in the kidneys and stored in the bladder, is normally sterile. Microorganisms must be introduced into the bladder to cause infection. Active infection of the urinary tract occurs in one of three basic ways:

- **Descending infection from the kidney.** Descending infection occurs when an infected kidney sheds bacteria that descend via the ureters into the bladder. Kidney infections arise when microorganisms are deposited in the kidneys from the bloodstream.
- **Ascending infection to the kidney.** This is when an established infection in the bladder ascends along the ureter to infect the kidney.
- **Infection from the urethra to the bladder.** Bacteria residing along the superficial urogenital membranes of the urethra can ascend to the bladder. This is more common in women than men. Microorganisms can also be introduced into the bladder by means of mechanical devices such as catheters or cystoscopes that are passed through the urethra into the bladder.

THOUGHT QUESTION 26.2 Why do you think most urinary tract infections occur in women?

Urine is bacteriostatic to most of the commensal organisms inhabiting the perineum and vagina, such as *Lactobacillus*, *Corynebacterium*, diphtheroids, and *Staphylococcus epidermidis*. In contrast, many gram-negative organisms thrive in urine. As a result, most urinary tract infections are caused by facultative gram-negative rods from the GI tract. The most common etiological agents of UTI are:

- Certain serotypes of *E. coli* that comprise the uropathogenic *E. coli* (75% of all UTI)
- *Klebsiella*, *Proteus*, *Pseudomonas*, *Enterobacter* (20%)
- *S. aureus*, *Enterococcus*, *Chlamydia*, fungi, *Staphylococcus saprophiticus*, other (5%)

Case History: Classic Urinary Tract Infection

Lashandra is 24 years old and has been experiencing back pain, increased frequency of urination, and dysuria (painful urination) over the past three days. She consulted her general practitioner, who requested that a mid-stream specimen of urine be examined. This was the first time Lashandra had ever suffered from persisting dysuria. Upon microscopic examination, the urine was found to contain more than 50 leukocytes per µl and 35 red blood cells per µl. No epithelial squamous cells were seen. The urine culture plated on agar medium yielded more than 10^5 colonies per milliliter (meaning more than 10^5 organisms per milliliter in the urine) of a facultative anaerobic gram-negative bacillus capable of fermenting lactose.

The first question to ask in this case is whether the patient had a significant UTI. The purpose of the mid-stream urine collection is to provide laboratory data to make this determination. Even though urine in the bladder is normally sterile, urine becomes contaminated with normal flora that have adhered to the urethral wall. In a mid-stream collection, the patient urinates briefly, stops to position a collection jar, and resumes urinating to collect a midstream sample. This minimizes the number of organisms in the sample by washing away organisms clinging to the urethra before actually collecting the sample. Nevertheless, the collected sample will still contain low numbers of organisms representing normal flora of the urethra. A diagnosis of UTI is made when the number of bacteria in the sample becomes greater than 10^5/ml. (However, that number can be as low as 1,000/ml in symptomatic women.) The patient in the case history is symptomatic and has sufficient numbers of bacteria in her urine to indicate a UTI.

The laboratory found the organism to be a gram-negative bacillus that ferments lactose, suggesting *E. coli* as the likely culprit. Given that the normal habitat of *E. coli* is the gastrointestinal tract and this is the first UTI suffered by the patient, the infection is likely the result of an inadvertent introduction of the microbe into the urethra. The organism makes its way up the urethra and into the bladder. If the patient had a recurring UTI, it could result from organisms entering the bladder from a descending route along the ureter from an infected kidney (also see **Special Topic 26.1**).

Gram-negative rods not only thrive in urine, but may be adapted to cause urinary tract infections through specialized pili. These pili have terminal receptors for glycolipids and glycoproteins present on urinary tract epithelial cells (**Fig. 26.10A**). Uropathogenic strains of *E. coli*, for example, typically have P-type pili, with a terminal receptor for the P antigen (a rather appropriate name for a bladder-specific virulence factor). The P antigen is a blood group marker found on the surface of cells lining the perineum and urinary tract; it is expressed by approximately 75% of the population. These individuals are particularly susceptible to UTIs. The P antigen can also be shed and found in vaginal and prostate secretions. When this happens, the secreted P antigens can be protective by acting as a decoy.

Special Topic 26.1 Intracellular Biofilm Pods Are Reservoirs of Infection

Doctors used to think that women suffering from recurrent bladder infections were repeatedly infected as a result of sexual activity or poor hygiene, a presumption many women with chronic infections found frustrating and offensive. New evidence indicates that bacteria may actually hide inside bladder cells, forming a reservoir for reinfection.

Specialized colonies of *E. coli* have been found living in the surface layer of cells lining the bladders of infected mice (**Fig. 1A**). Though the mouse served as a model system, the bacteria used were originally isolated from humans. These strains of *E. coli* cause about 80% of all urinary tract infections. The bacteria use pili to latch onto proteins coating the bladder cells. Those proteins form a protective substance, known as uroplakin, that strengthens the epithelial cells and shields them from toxins that may build up in the urine (**Fig. 1B**). The bacteria can slip under the protective barrier and penetrate superficial cells lining the bladder. Once inside the cell, the microbes begin to multiply, and the epithelial cell fills with bacteria also coated with uroplakin, taking on the appearance of a pod (**Fig. 1C**).

The pod-like *E. coli* biofilms we describe here are notoriously resistant to antibiotic treatment and attacks by the immune system. Living inside host cells and surrounded by uroplakin, the *E. coli* in the bladder pods have devised a clever mechanism for surviving. Bacteria living on the edges of the biofilm may break free, leading to subsequent rounds of infection. Understanding the cycle of infection and pod formation may help researchers design drugs to prevent new urinary tract infections or stop established ones.

Although pods have so far been found only in mice, researchers are tracking women with persistent infections to see whether pods are also present in humans. Biofilms hiding inside cells elsewhere in the body also may act as reservoirs for other hard-to-treat chronic or recurring infections, such as ear infections.

Figure 1 **Bladder pods of uropathogenic *E. coli*.** Scott Hultgren's laboratory (Washington University, St. Louis) has discovered that intracellular bacterial communities extend like pods into the bladder lumen. **A.** Increasing magnifications of large intracellular communities of uropathogenic *E. coli* (UTI89) inside pods on the surface of a mouse bladder infected for 24 hours (SEM). **B.** Confocal photos of a whole-mounted bladder infected with UTI89 expressing green fluorescent protein from the plasmid pcomGFP. Uroplakin on the surface of the two pods is revealed by treatment with antibody to uroplakin (primary antibody) and tetramethyl rhodamine isothiocyanate–labeled secondary antibody (red). The series starts on the left with the lumenal surface and progresses toward the right in sections that move downward through the epithelium. Optical section thickness, 1 μm. **C.** Hematoxylin- and eosion-stained sections of UTI89-infected mouse bladders show a bacterial factory 6 hours after inoculation (top panel) and a pod 24 hours after inoculation (bottom panel). Bacteria in the pod were densely packed and shorter and completely filled the host cell. **D.** Scott Hultgren.

Figure 26.10 Uropathogenic *E. coli*. **A.** Bladder cell with adherent uropathogenic *E. coli* (SEM). Bacteria are approx. 1 µm in length. **B.** Distribution of pathogenicity islands (PAI) in uropathogenic *E. coli*. The location of each insert is given in map units within the circle representing the genome. The 0–100 map units are called centisomes. Each centisome is approximately 44 kb of DNA. O is arbitrarily placed at the *thr* (threonine) gene. The origin of replication on this map is near 82 centisomes. A chromosomal gene flanking the insert is also provided. The size of each island is provided above the insert. A key virulence gene for each island is listed.

They bind to the bacterial receptor, preventing binding of the organism to the surface epithelium. Individuals most susceptible to UTIs are those who express P antigen on their cells but lack P antigen in their secretions.

Urinary tract infections are among those most frequently acquired during a hospital stay (so-called nosocomial infections). In these cases, the causal organism is less likely to be *E. coli* and more likely to be another gram-negative bacterium or *Staphylococcus*. Many UTIs resolve spontaneously, but others can progress to destroy the kidney or, via gram-negative septicemia, the host. As a result, antibiotic therapy is recommended. In older patients, UTIs frequently show atypical symptoms, including delirium, which disappears when the UTI is treated.

THOUGHT QUESTION 26.3 Urine samples collected from six hospital patients were placed on a table at the nurses' station awaiting pickup from the microbiology lab. Several hours later, a courier retrieved the samples and transported them to the lab. The next day, the lab reported that four of the six patients had UTI. Would you consider these results reliable? Would you start treatment based on these results?

What makes uropathogenic *E. coli* different from other *E. coli*? This is a question still under investigation, but genomic analysis has exposed five pathogenicity islands unique to these strains (**Fig. 26.10B**). The functions of these pathogenicity islands are still under investigation.

Sexually Transmitted Diseases

Sexually transmitted diseases (STDs) are defined as infections transmitted primarily through sexual contact, which may include genital, oral-genital, or anal-genital contact. The organisms or viruses involved are generally very susceptible to drying and require direct physical contact with mucous membranes for transmission. Because sex can take many forms in addition to intercourse, these microbes can initiate disease in the urogenital tract, rectum, or oral cavities. Examples of common sexually transmitted diseases are given in **Table 26.5**.

Case History: Secondary Syphilis

A pregnant 18-year-old woman came to the county urgent-care clinic with a low-grade fever, malaise, and headache. She was sent home with a diagnosis of influenza. She again sought treatment seven days later after she discovered a macular rash (flat, red) developing on her trunk, arms, palms of her hands, and soles of her feet. Further questioning of the patient when serology results were known revealed that one year ago, she had a painless ulcer on her vagina that healed spontaneously.

The vaginal ulcer, the long latent period, and secondary development of rash on the hands and feet described in the case history are classic symptoms of syphilis. Syphilis was recognized as a disease as early as the sixteenth century, but the organism responsible, the spirochete *Treponema pallidum*, was not discovered until 1905 (**Fig. 26.11A**). The illness has several stages. The disease

Table 26.5 Microbes causing sexually transmitted diseases.

Disease	Symptoms	Etiologic agent	Virulence factors	Treatment
Gonorrhea	Purulent discharge, burning urination; can lead to sterility	*Neisseria gonorrhoeae* (G–)	Type IV pili, phase variation	Ceftriaxone
Syphilis	1°Chancre, 2°Joint pain, rash 3°Gummata, aneurism, CNS damage	*Treponema pallidum* (spirochete)	Motility	Penicillin
Nongonococcal urethritis	Watery or mucoid urethral discharge, burning urination	*Chlamydia trachomatis*	Intracellular growth; prevents phagolysosome fusion	Azithromycin
Trichomoniasis	Vaginal itching, painful urination, strawberry cervix	*Trichomonas vaginalis* (protozoan)	Cytotoxin	Metronidazole
Chancroid	Painful genital lesion	*Haemophilus ducreyi* (G–)	?	Erythromycin
Acquired immunodeficiency syndrome (AIDS)	Fever, diarrhea, cough, night sweats, fatigue, opportunistic infections	HIV	gp120, rev and nef proteins, tat protein	Azidothymidine, AZT, protease inhibitors, Zidovudine
Genital herpes	Painful ulcer on external genitals, painful urination	Herpes simplex 2	Cell fusion protein, complement-binding protein, latency	Acyclovir, iododeoxyuridine
Genital warts	Warts on external genitals	Human papillomavirus	E6, E7 proteins	Vaccine now available

has often been called the great imitator because its symptoms in the second stage, as exhibited in the case history, can mimic many other diseases. The incubation stage can last from two to six weeks after transmission, during which time the organism multiplies and spreads throughout the body. **Primary syphilis** is an inflammatory reaction at the site of infection called a **chancre**. About a centimeter in diameter, the chancre is painless and hard, and it contains spirochetes. Patients are usually too embarrassed to seek medical attention, and because it is painless, hope that it will "go away." It does go away after several weeks, and without scarring. The disease has now entered the primary latent stage. Over the next five years, symptoms may be absent, but at any time, as described in the case history, the infected person can develop the rash typical of **secondary syphilis** (**Fig. 26.11B**). The rash can be similar to rashes produced by many different diseases, which contributes to the "great imitator" label. The patient remains contagious in this stage. Some patients eventually progress over years to **tertiary syphilis**, in which a great number of symptoms can develop, mostly cardiovascular and nervous systems. The patient can develop dementia and eventually dies from the disease.

Figure 26.11 **Syphilis.** **A.** *Treponema pallidum* (darkfield microscopy). Organisms are 10–25 μm long. **B.** Rash of secondary syphilis.

The presence of the organism in tissues can be detected with fluorescent antibody, but the initial screen is usually serological (that is, patient serum is tested for antibodies). Antibiotics are useful for eradicating the organism, but there is no vaccine, and cure does not confer immunity.

The disease is particularly dangerous in pregnant women. The treponeme can cross the placental barrier and infect the fetus to cause **congenital syphilis**. At birth, infected newborns will have notched teeth (visible on X-rays), perforated palates, and other congenital defects. Women should be screened for syphilis as part of their prenatal testing to prevent these congenital infections.

Columbus and the New World theory of syphilis. An outbreak of syphilis that spread throughout Europe soon after Columbus and his crew returned from the Americas (1493) led to the theory that Columbus brought the treponeme to Europe from the New World. However, the theory that Columbus brought syphilis to Europe is most likely wrong. Native Americans buried *before* Columbus arrived in America showed no signs of syphilis. Furthermore, in recent years, pre-Columbian skeletons—such as those unearthed at the Hull friary in England—have been found with distinctive signs of syphilis. While some historians disagree, the progenitor organism was probably brought to Europe by African slaves long before the discovery of America, and it was in Europe that it developed into venereal syphilis. Thus, the crew of the Columbus voyages may actually have brought the disease to America along with smallpox and measles.

The Tuskegee experiment. Unfortunately, much of what we know of syphilis is the result of the infamous Tuskegee experiment conducted in the 1930s in Alabama. The study was entitled "Untreated Syphilis in the Negro Male." Through dubious means and deception, a group of African-American males were enlisted in a study that promised treatment but whose real purpose was to observe how the disease progressed without treatment. Today, such experiments are barred thanks to strict institutional review board (IRB) oversights in which human subjects must sign informed consent forms. An interesting treatise on the Tuskegee experiment can be found on the Web at the National Center for Case Study Teaching in America (Search for Bad Blood).

Chlamydial Infections Are Often Silent

Chlamydia is the most frequently reported sexually transmitted infectious disease in the United States, according to the Centers for Disease Control and Prevention, but many people are completely unaware that they are infected. Three-fourths of infected women, for instance, have no symptoms.

The chlamydiae are unusual gram-negative organisms with a unique developmental cycle. They are obligate intracellular pathogens that start as a small, nonreplicating infectious elementary body that enters target eukaryotic cells. Once inside vacuoles, they begin to enlarge into replicating reticulate bodies (**Fig. 26.12**). As the vacuole fills, the reticulate bodies divide to become new nonreplicating elementary bodies. *Chlamydia trachomatis* and *Chlamydophila pneumoniae* can both cause STDs, as well as other diseases, such as trachoma of the eye or pneumonia.

People most at risk of developing genitourinary tract infections with chlamydia are young, sexually active men and women; anybody who has recently changed sexual partners; and anybody who has recently had another sexually transmitted disease. The astute clinician knows that when one STD is discovered, others may also be present. A recent report indicates that *Chlamydia* can bind to sperm in a process called hitchhiking. It is thought that this interaction helps the organism spread to females.

Left untreated, chlamydia can cause serious health problems. In women, the organism can produce pelvic

inflammatory disease. Pelvic inflammatory disease is a damaging infection of the uterus and fallopian tubes that can be caused by several different microbial species. The damage produced can lead to infertility, tubal pregnancies, and chronic pelvic pain. Men left untreated can suffer urethral and testicular infections and a serious form of arthritis.

Case History: Gonorrhea

A 22-year-old mechanic saw his family doctor for treatment of painful urination and urethral discharge. His medical history was unremarkable. The patient was sexually active, with three regular and several "one time–good time" partners. Physical examination was unremarkable except for prevalent urethral discharge. The discharge was Gram stained and sent for culture. The Gram stain revealed many pus cells, some of which contained numerous phagocytosed gram-negative diplococci (**Fig. 26.13A**). *Blood was drawn for syphilis serology, which proved negative. The patient was given an intramuscular injection of ceftriaxone (250 mg), and oral tetracycline (500 mg, four times a day) was prescribed for seven days. The bacteriology lab was able to recover the bacteria seen in the Gram-stained smear of the urethral discharge. The organism produced characteristic colonies on chocolate agar (agar plates containing heat-lysed red blood cells that turn the medium chocolate brown;* **Fig. 26.13B***). The case was subsequently reported to the state public health department. Upon his return visit, the patient's symptoms had resolved, and a repeat culture was negative. The patient confirmed that all three of his regular sexual contacts were seen at the STD clinic.*

The disease here is classic gonorrhea caused by *Neisseria gonorrhoeae*. A characteristic distinguishing *Neisseria* infections from *Chlamydia* infections is that bacterial cells are seen in gonorrheal discharges but not in chlamydial discharges. Gonorrhea has been a problem for centuries and remains epidemic in this country today. Symptoms generally occur 2–7 days after infection but can take as long as 30 days to develop. Most infected men exhibit symptoms; only about 10–15% of men do not. Symptoms include painful urination, yellowish white discharge from the penis, and in some cases swelling of the testicles and penis. The Greek physician Galen (AD 129–ca199) originally mistook the discharge for semen. This led to the name gonorrhea, which means "flow of seed."

In contrast to men, most infected women (80%) do not exhibit symptoms and constitute the major reservoir of the organism. If they are asymptomatic, they have no reason to seek treatment and thus can spread the disease. When symptoms are present, they are usually mild. A symptomatic woman will experience a painful burning sensation when urinating and will notice vaginal discharge that is yellow or occasionally bloody. She may also complain of cramps or pain in her lower abdomen, sometimes with fever or nausea. As the infection spreads throughout the reproductive organs (uterus and fallopian tubes), pelvic inflammatory disease occurs (see earlier discussion of chlamydia). It is important to note that there is no serological test or vaccine for gonorrhea because the organism frequently changes the structure of its surface antigens.

Although *N. gonorrhoeae* is generally serum sensitive owing to its sensitivity to complement, certain serum-resistant strains can make their way to the bloodstream and carry infection throughout the body. As a result, both sexes can develop purulent arthritis (joint fluid containing pus), endocarditis, or meningitis. An infected mother can also infect her newborn during parturition (birth), leading to a serious eye infection called ophthalmia neonatorum. Because of this risk and because most infected

Figure 26.13 ***Neisseria gonorrhoeae.*** **A.** Within pus-filled exudates, the gram-negative diplococci are found intracellularly inside PMNs. The intracellular bacteria (approx. 0.6 to 1 μm in diameter) in this case are no longer viable, having been killed by the antimicrobial mechanisms of the white cell. **B.** Colonies of *N. gonorrhoeae* growing on chocolate agar (agar plates containing heat-lysed red blood cells that turn the medium chocolate brown). **C.** *N. gonorrhoeae* binding to CD4+ T cells (colorized SEM), inhibiting T-cell activation and proliferation, which may explain the ease of reinfection.

women are asymptomatic, all newborns receive antimicrobial eyedrops at birth.

Because adults engage in a variety of sexual practices, *N. gonorrhoeae* can also infect the anus or the pharynx, where it can develop into a mild sore throat. These infections generally remain unrecognized until a sex partner presents with a more typical form of genitourinary gonorrhea. Because no lasting immunity is built up, reinfection with *N. gonorrhoeae* is possible. This is due in part to the phase variation in various surface antigens that takes place and because the organism can apparently bind to CD4+ T cells, inhibiting their activation and proliferation to become memory T cells (**Fig. 26.13C**).

THOUGHT QUESTION 26.4 Considering that *N. gonorrhoeae* is exquisitely sensitive to ceftriaxone, why do you suppose the patient was also treated with tetracycline? And why can one person be infected repeatedly with *N. gonorrhoeae*?

Human Immunodeficency Virus (HIV) Causes Sexually Transmitted and Blood-Borne Disease

Discovered in 1981, HIV caused the greatest pandemic of the late twentieth century and remains a serious problem today, especially in Africa, where it is estimated that 10–30% of the population are infected with HIV (prevalence in the United States is less than 1%). HIV has claimed the lives of more than 22 million people worldwide, over half a million in the United States alone. The molecular biology and virulence of HIV are discussed in Chapters 11 and 25. This section focuses on the disease that HIV causes—acquired immunodeficiency syndrome (AIDS).

HIV, a lentivirus in the retroviral family, is a prominent example of viruses that can be transmitted either sexually (vaginally, orally, anally, homosexually, or heterosexually) or through direct contact with body fluids, such as occurs with blood transfusion or the sharing of hypodermic needles by intravenous drug users. HIV is *not* transmitted by kissing, tears, or mosquito bite. It can, however, be transferred from mother to fetus through the placenta (transplacental transfer). **Figure 26.14A** illustrates the incidence of AIDS cases by year. The drop-off beginning in 1990 corresponds to the development of more effective treatment regimens. Starting in 1999, however, the trend began climbing upward once again. The proportion of AIDS cases by sex and ethnicity is described in Chapter 25 (see **Fig. 25.37**).

Having entered the bloodstream, HIV infects CD4+ T cells and replicates very rapidly, producing a billion particles per day. The subsequent decrease in CD4+ T cells leads to the disease symptoms collectively called AIDS. Though the symptoms of AIDS may take years to develop (the average time between infection and AIDS is 11 years), nearly all HIV-infected individuals eventually become ill and die from the disease.

The first stage of the disease, previously known as AIDS-related complex (ARC), can include fever, headache, a macular rash, weight loss, and the appearance of antibodies to HIV in serum. These early, relatively mild symptoms can manifest within a few months of infection, resolve within a few weeks, and then may recur. The debilitated immune system leads to secondary infections by the yeast *Candida albicans* (candidiasis) and related species (**Fig. 26.14B**).

After several years, the disease can progress to the second stage, AIDS, marked by a significant depletion of the CD4+ T cell population. In 1993, the CDC revised its

Figure 26.14 Acquired immunodeficiency syndrome. **A.** Number of AIDS cases in the United States by major transmission category and year. In 1993, government agencies developed a specific definition of HIV infection that is used for public health surveillance only (vertical dotted line). It is estimated that 250,000–300,000 HIV-infected individuals are unaware of their HIV infection. **B.** Oral candidiasis. The white patches are caused by secondary infection by the yeast *Candida albicans*. **C.** *Pneumocystis jiroveci* infection of the lung. Note the cuplike appearance of the fungus, almost like crushed Ping-Pong balls. Organisms range from 2 to 6 μm in diameter.

definition of AIDS to include all persons with a CD4+ cell count of less than 200/μl. Once the CD4+ T cell population falls below 400 cells/μl, opportunistic infections begin to arise and disease processes begin. Opportunistic infections include pneumonia by *Mycobacterium avium–intracellulare* or *Pneumocystis jiroveci* (**Fig. 26.14C**), cryptococcal meningitis, *Histoplasma capsulatum* infection, and tuberculosis.

The third stage of AIDS includes changes in mental cognition, muscular action, and reflexes. Cardiovascular disease and brain tumors are also common. The neurological changes appear coincident to inflammation and demyelination of neurons.

The fourth stage of disease is marked by the appearance of various cancers triggered when the depressed immune system cannot detect and destroy cancers initiated by secondary agents. For instance, Kaposi's sarcoma (**Fig. 25.37C**) is a common cancer seen in AIDS patients caused by human herpes virus type 8 (HHV8).

Diagnosis of AIDS involves detecting anti-HIV antibodies and determining CD4+ cell count in a patient. Assay for HIV to determine viral load is done via quantitative PCR to detect HIV-specific genes such as *gag*, *nef*, or *pol*. Remember, a person who is HIV-positive does not necessarily have AIDS; it may take years to develop. A vaccine is not yet available to prevent AIDS, in part because the envelope proteins of the virus (see **Fig. 11.29**) typically change their antigenic shape. However, progression of the disease can be controlled by antimicrobials that inhibit two HIV enzymes critical to the replication of the virus—reverse transcriptase and protease; this is discussed further in Chapter 27.

The Protozoan *Trichomonas vaginalis* Causes a Common Vaginal Infection

Trichomonas vaginalis is a flagellated protozoan (**Fig. 26.15**) that causes an unpleasant sexually transmitted vaginal disease called trichomoniasis. Approximately 2–3 million infections occur each year in the United States. It can occur in men or women; however, men are usually asymptomatic. Even among infected women, 25–50% are considered asymptomatic carriers.

There is no cyst in the life cycle of *T. vaginalis*, so transmission is via the trophozoite stage only (discussed in Chapter 20). The female patient with trichomoniasis may complain of vaginal itching and/or burning and a musty vaginal odor. An abnormal vaginal discharge also may be present. Males will complain of painful urination (dysuria), urethral or testicular pain, and lower abdominal pain.

Owing to colonization by lactobacilli (which produce large amouts of acidic lactic acid), the normal, healthy vagina has a pH of less than 4.5. However, since *Trichomonas vaginalis* feeds on bacteria, the pH of the vagina rises as the numbers of lactobacilli decrease. Definitive diagnosis requires demonstrating the flagellated protozoan in secretions by microscopy. PMNs, which are the primary host defense against the organism, are also usually present. As with giardiasis, this disease is treated with metronidazole.

THOUGHT QUESTION 26.5 Human immunodeficiency virus was discussed in this section and in Chapter 25. Like the plague, it is a blood-borne disease. Why, then, do fleas and mosquitoes fail to transmit HIV?

TO SUMMARIZE:

- **Urinary tract diseases** can result from ascending (to the kidney) or descending (from the kidney) routes of infection. The most common route leading to bladder infection, however, is through the urethra.
- ***E. coli*** is the most common cause of UTI.
- **Syphilis, gonorrhea, and chlamydia** are the most common sexually transmitted diseases.
- **A patient with one sexually transmitted disease** often has another sexually transmitted disease.
- **Complement sensitivity** prevents dissemination by *N. gonorrhoeae*. In contrast, *N. meningitidis*, a cause of meningitis, frequently disseminates in the bloodstream because it is complement resistant.
- **HIV depletion of CD4+ T cells** results in lethal secondary infections and cancers.
- ***Trichomonas vaginalis*** is a flagellated protozoan that causes a sexually transmitted vaginal disease. The reservoir for this organism is the male urethra and female vagina.

26.6 Infections of the Central Nervous System

Microbes cannot gain easy access to the brain in large measure because of the **blood-brain barrier**, a filter mechanism that allows only selected substances into the brain. The blood-brain barrier works to our advantage when harmful substances, such as bacteria, are prohibited from entering. However, it works to our disadvantage when substances we want to enter the brain, such as antibiotics, are kept out. The barrier is not a single structure but is a function of the way blood vessels, especially capillaries, are organized in the brain. Furthermore, the endothelial cells in those vessels have tight junctions that do not allow most compounds or microbes to cross. And yet, brain infections do occur.

Case History: Meningitis

*In April 2001, a 4-month-old infant from Saudi Arabia was hospitalized with fever, tender neck, and purplish spots (purpuric spots) on her trunk (***Fig. 26.16A***). Suspecting meningitis, the clinician took a cerebral spinal fluid (CSF) sample and examined it by Gram stain. The smear revealed gram-negative diplococci inside PMNs. The CSF was turbid with 900 leukocytes per µl, and* Neisseria meningitidis *was confirmed by culture. The child was treated with cefotaxime and made a full recovery. Her father, the person who brought her in, was clinically well. However, meningococcus was isolated from his oropharynx, as well as from the throat of the patient's 2-year-old brother. Isolates from the patient, her father, and her brother were positive by agglutination with meningococcus A, C, Y, W135 polyvalent reagent. The father's vaccination certificate confirmed that he had received a quadrivalent meningococcal vaccine. All three isolates were sent to the WHO (World Health Organization) Collaborating Center, which confirmed meningococcus serogroup W135. The three isolates were examined by pulsed-field gel electrophoresis and were found to be indistinguishable (that is, they had identical DNA restriction patterns).*

Meningitis is an inflammation of the meninges—the membrane that surrounds the brain and spinal cord. Meningitis can be either bacterial or viral in origin. Sinus and ear infections can extend directly to the meninges, while septicemic spread requires passage through the blood-brain barrier. Viral meningitis is serious but rarely fatal in people with a normal immune system. The symptoms generally persist for seven to ten days and then completely resolve. Bacterial meningitis is usually caused by *Streptococcus pneumoniae*, *Neisseria meningitidis*, or *Haemophilus influenzae*. Symptoms of bacterial meningitis can include sudden onset of fever, headache, neck pain or stiffness, painful sensitivity to strong light (photophobia), vomiting (often without abdominal complaints), and irritability. Prompt medical attention is extremely important because the disease can quickly progress to convulsions and death.

The meningococcus *Neisseria meningitidis* (**Fig. 26.16B**) can colonize the human oropharynx, where it causes mild, if any, disease. At any given time, 10–20% of the healthy population can be colonized and asymptomatic. The organism spreads directly by person-to-person contact or indirectly via droplet nuclei from sneezing or fomites. The problem arises when this organism enters the bloodstream. Unlike the gonococcus, *N. meningitidis* is very resistant to complement owing to its production of a polysaccharide capsule. The capsule allows the microbe to produce a transient blood infection (bacteremia) and reach the blood-brain barrier.

N. meningitidis uses type IV pili to adhere to these endothelial cells and becomes intracellular. Then, utilizing the process of **transcytosis**, in which a cell moves from one side of a host cell to another, the microbe moves to the brain side of the capillary, where it exits. Once in the cerebral spinal fluid, microbes can multiply almost at will. **Figures 26.16C** and **D** shows the remarkable damage

Figure 26.16 Bacterial meningitis. Meningococcal disease is dreaded by parents and medical practitioners alike for its rapid onset and the difficulty of obtaining a timely and accurate diagnosis. **A.** Purpuric spots produced by local intravascular coagulation due to *Neisseria meningitidis* endotoxin. The rash in meningitis typically has petechial (small) and purpuric (large) components. **B.** *N. meningitidis* (SEM, approx. 1 µm diameter). **C.** Normal brain. **D.** Autopsy specimen of meningitis due to *Streptococcus pneumoniae.* Note the greening of the brain, compared with the pink normal brain.

that *N. meningitidis* and other microbes, such as *S. pneumoniae*, cause in the brain.

Several antigenic types of capsules, called type-specific capsules, are produced by different strains of pathogenic *N. meningitidis*: types A, B, C, W135, and Y. Types A, C, Y, and W135 are usually associated with epidemic infections seen among people kept in close proximity, such as college students or military personnel. Type B meningococcus is typically involved in sporadic infections. Antibodies to these capsular antigens are used to classify the capsular types of the organisms causing an outbreak. Knowing the capsular type of organism involved in each case helps determine whether the disease cases are related and where the infection may have started.

Meningococcal meningitis is highly communicable. As a result, close contacts, such as the parents or siblings of any patient with meningococcal disease, should receive antimicrobial prophylaxis within 24 hours of diagnosis; a single dose of ciprofloxacin (a quinolone antibiotic, discussed in Section 27.4) can be given to adults, and two days of rifampicin given to children.

Highly susceptible populations can be immunized with a vaccine containing the four capsular structures. Generally, large numbers of people housed together are susceptible to this disease. For instance, it is a significant problem in college dormitories, prompting several colleges to request that incoming students be vaccinated.

THOUGHT QUESTION 26.6 Normal cerebral spinal fluid is usually low in protein and high in glucose. The protein and glucose content does not change much during a viral meningitis, but bacterial infection leads to greatly elevated protein and lowered glucose levels. What could account for this?

Case History: Botulism—It Is What You Eat

In June, a 47-year-old resident of Oklahoma was admitted to the hospital with rapid onset of progressive dizziness, blurred vision, slurred speech, difficulty swallowing, and nausea. Findings on examination included drooping eyelids, facial paralysis, and impaired gag reflex. He developed breathing difficulties and required mechanical ventilation. The patient reported that during the 24 hours before onset of symptoms, he had eaten home-canned green beans and a stew containing roast beef and potatoes. Analysis of the patient's stool detected botulinum type A toxin, but no Clostridium botulinum *organisms were found. The patient was hospitalized for 49 days, including 42 days on mechanical ventilation, before being discharged.*

Bacterial Neurotoxins That Cause Paralysis

Imagine a disease that causes complete loss of muscle function. Using secreted exotoxins, two microbes cause lethal paralytic diseases. In one instance, the victim suffers a flaccid paralysis in which the muscles go limp, as in the case history just given, causing paralysis and respiratory difficulty. Voluntary muscles fail to respond to the mind's will because botulinum toxin interferes with neural transmission. The disease (called botulism) is typically food-borne and is caused by an anaerobic, gram-positive, spore-forming bacillus named *Clostridium botulinum*.

In striking contrast to botulism is tetanus, a very painful disease in which muscles continuously and involuntarily contract (called tetany or spastic paralysis). Tetanus is caused by **tetanospasmin**, a potent exotoxin made by another anaerobic, gram-positive spore-forming bacillus called *Clostridium tetani* (**Fig. 26.17A**). Tetanospasmin interferes with neural transmission, but in contrast to botulism toxin, it causes *excessive* nerve signaling to muscles, forcing the victim's back to arch grotesquely while the arms flex and legs extend. The patient remains locked this way until death. Spasms can be strong enough to fracture the patient's vertebrae. **Figure 26.17B** shows the result of injecting a mouse's hind leg with just a tiny amount of tetanus toxin. In both botulism and tetanus, death can result from asphyxiation.

Botulism is typically caused by ingesting preformed toxin, although infected wounds or germination of ingested spores can also occasionally produce disease. The microbe germinates in the food and produces toxin. Because the organism is an anaerobe, an anaerobic environment must be present. Home-canning processes are designed to remove oxygen in the canned food as well as sterilize the food, but if the sterilization process is not complete, surviving spores germinate and produce toxin. The toxin is susceptible to heat, but will remain active in improperly cooked food. After ingestion, the toxin is absorbed from the intestine. As in the case history given here, it is not unusual for the organism to be absent from stool samples. This is why serological identification of the toxin is important.

Note that a rare form of botulism, called infant botulism or "floppy head syndrome," can occur when infants are fed honey. Honey can harbor *C. botulinum* spores that can germinate in the gastrointestinal tract after which the growing vegetative cells will secrete toxin.

THOUGHT QUESTION 26.7 Knowing the symptoms of tetanus, what kind of therapy would you use to treat the disease?

Toxin structure. Botulism and tetanus toxins share 30–40% identity and have similar structures and nearly identical modes of action. Botulinum and tetanus toxins are each composed of two peptides—a large, or heavy, fragment analogous to a B subunit of AB toxins and a small, or light, fragment analogous to an A subunit. Both

(PDB code: 3BTA)

toxins are initially made as single peptides (about 150 kDa) that are cleaved after secretion to form two fragments (heavy and light chains) that remain tethered by a disulfide bond (**Fig. 26.17C**). Each heavy chain includes the binding domain, which binds to receptor molecules (gangliosides) on the nerve cell membrane, and a translocation domain that makes a pore in the nerve cell through which the toxin passes. The light chains (catalytic domains) are proteases that disrupt the movement of exocytic vesicles containing neurotransmitters needed for contraction or relaxation. **Figure 26.17D** shows a three-dimensional rendition of tetanus toxin with the three domains marked.

Mechanism of action. Both toxins bind to target membranes and are brought into the cell by endocytosis. The low pH that forms in the endosome reduces the disulfide bonds holding the two halves of the toxin together and causes the heavy chain to assemble as a channel through the membrane. That channel allows release of the proteolytic light chain into the cytoplasm. The toxic subunit then cleaves key host proteins such as synaptobrevin (VAMP), involved in the exocytosis of vesicles containing neurotransmitters (**Fig. 26.18**).

With such a high degree of mechanistic similarity, why do tetanus and botulism toxins have such drastically different effects? The answer is based on where each toxin acts in the nervous system. Both toxins enter at peripheral nerve ends where nerve meets muscle. The disease botulism results from the ingestion of preformed toxin in poorly prepared, contaminated foods. Whether the organism is also ingested is immaterial. Once botulism toxin

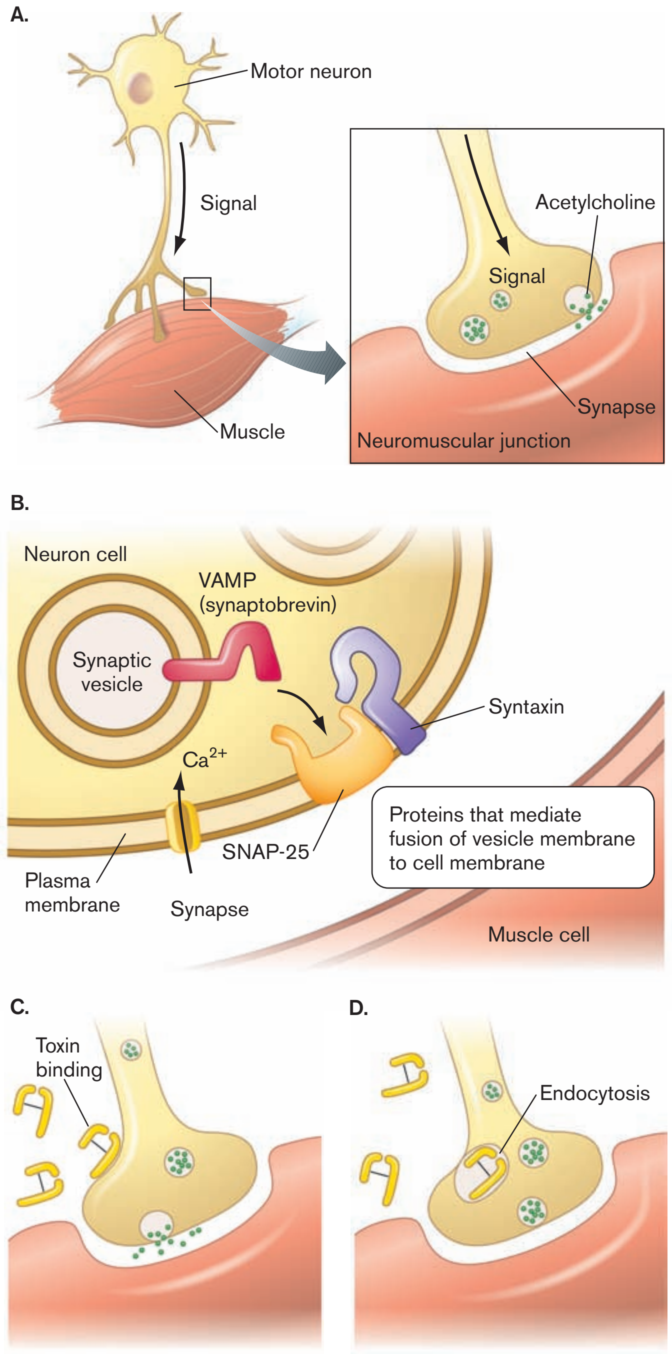

Figure 26.18 Mechanism of action of botulism toxin. **A.** The neuromuscular junction. Inset shows vesicles filled with neurotransmitters. **B.** A series of proteins within the nerve are needed to allow synaptic vesicles to bind to the nerve endings. Fusion of the membranes releases acetylcholine into the neuromuscular junction. Botulinum toxin types A and E cut SNAP-25. Botulinum toxins B, D, F, and G cut VAMP. Botulinum toxin C1 cuts syntaxin and SNAP-25. **C, D.** Toxin binds via the heavy chain and is endocytosed into the nerve terminal. Once the toxin cleaves its target, the nerve terminal is no longer able to release acetylcholine.

enters a peripheral nerve, it will immediately cleave peptides, such as VAMP, associated with the exocytic release of the neurotransmitter acetylcholine (**Fig. 26.18**). Without acetylcholine to activate nerve transmission, muscles will not contract and the patient is paralyzed.

Although botulism disease is now rare, the toxin has gained renewed interest in recent years. It is considered a select biological toxic agent of potential use to bioterrorists, but that is not where most interest lies. Because it can safely relax muscles in a localized area if injected in small doses, botulism toxin, or Botox, is used cosmetically by plastic surgeons to reduce facial wrinkles in their patients.

Tetanus, in contrast to botulism, is not a food-borne disease. *C. tetani* spores are introduced into the body by trauma (such as by stepping on a dirty, rusty nail). Necrotic tissue then provides the anaerobic environment required for germination. Growing, vegetative cells release tetanospasmin, which enters the peripheral nerve cells at the site of injury. But rather than cleaving targets here, the toxin travels up axons in the direction opposite to nerve signal transmission until it reaches the spinal column, where it becomes fixed at the presynaptic inhibitory motor neuron. There the toxin also cleaves proteins like VAMP, but the function of vesicles in these nerves is to release *inhibitory* neurotransmitters that dampen nerve impulses. Tetanus toxin blocks release of the inhibitory neurotansmitters GABA and glycine into the synaptic cleft, leaving nerve impulses unchecked. As a result, impulses come too frequently and produce the generalized muscle spasms characteristic of tetanus. **Figure 26.19** illustrates the mechanism of action of tetanus toxin.

THOUGHT QUESTION 26.8 How do the actions of tetanus toxin and botulinum toxin actually help the bacteria colonize or obtain nutrients?

THOUGHT QUESTION 26.9 If *C. botulinum* is an anaerobe, how might botulism toxin get into foods?

Case History: Eastern Equine Encephalitis

In August, Mr. C brought his 21-year-old son, Rich, to a New Jersey emergency room. Rich appeared dazed and had trouble responding to simple commands. When questioned about his son's activities over the past few months, Mr. C told the physician that Rich planned to enter veterinary school in the fall and had spent the month of July relaxing and sunning himself on New Jersey beaches. Aside from the shore, his favorite locale was a pond in a wooded area near a horse farm. On the afternoon prior to admission, Rich became lethargic and tired. He returned home and went to bed. That evening, his father woke him for supper but Rich was confused and had no appetite. By 11 p.m., Rich had a fever of 40.7°C and could not respond to questions. A few hours later, when his father had

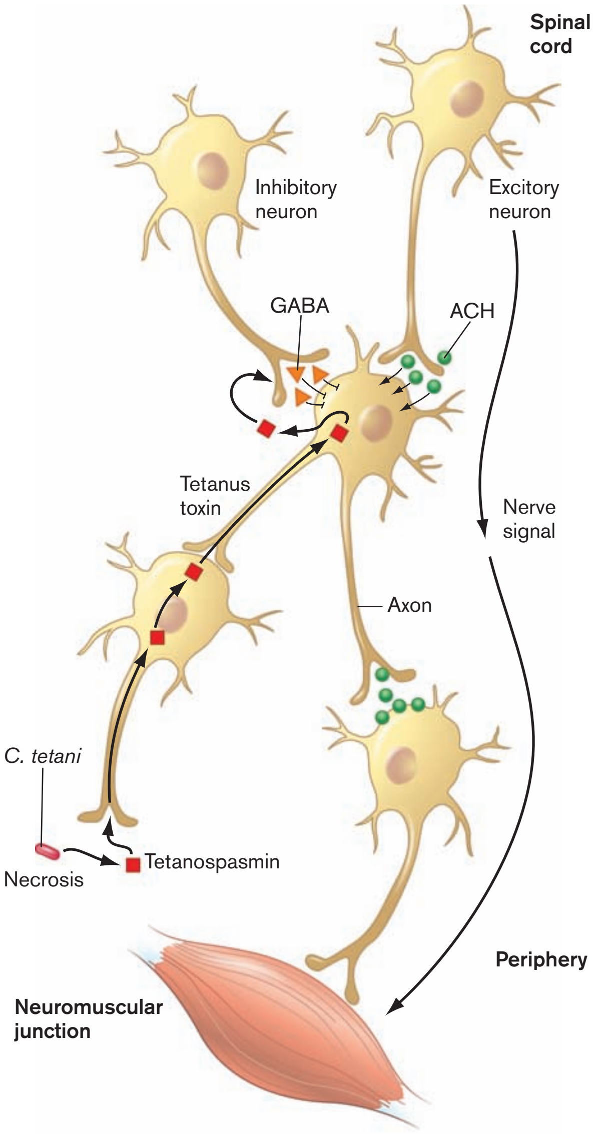

Figure 26.19 Retrograde movement of tetanus toxin to an inhibitory neuron. Tetanus toxin enters the nervous system at the neuromuscular junction and travels retrogradely up the axons until reaching an inhibitory neuron located in the central nervous system. There it cleaves VAMP protein (Fig. 26.18B) associated with exocytosis of vesicles containing inhibitory neurotransmitters. GABA = gamma-aminobutyric acid; ACH = acetylcholine.

trouble rousing him, he brought Rich to the ER. Over the next week, Rich's condition worsened to the point where his limbs were paralyzed. Two weeks later, he died.

Serum samples taken upon entering the hospital and a few days before he died showed a sixfold rise in antibody titer to eastern equine encephalitis (EEE) virus. Brain autopsy showed many small foci of necrosis in both the gray and white matter.

The EEE virus, a member of the family Togaviridae, is transmitted from bird to bird by mosquitoes. Horses contract the disease in the same way. Rich contracted it inadvertently while visiting the pond. The disease, an encephalitis, is often fatal (35% mortality) but fortunately rare. One reason human disease is rare is that the species of mosquito that usually transmits the virus between marsh birds does not prey on humans. But sometimes a human-specific mosquito bites an infected bird and then transmits EEE virus to humans. Another reason human disease is rare is that the virus generally does not fare well in the body. Many persons infected with EEE virus have no apparent illness because the immune system thwarts viral replication. However, as already noted, mortality is high in those individuals that do develop disease.

An interesting point in the case history is that diagnosis relied on detecting an increase in antibody titer to the virus. Typically, at the point that disease symptoms first appear, the body has not had time to generate large amounts of specific antibodies. After a week or so, often when the patient is nearing recovery (convalescence), antibody titers have risen manyfold. The rule of thumb is that a greater than fourfold rise in antibody titer between acute disease and convalescence (or in this case death) indicates that the patient has had the disease. While this knowledge could not help the patient in this case, it was valuable in terms of public health and prevention strategies.

Several bacterial, fungal, and viral causes of encephalitis and meningitis are given in **Table 26.6**.

Prion Diseases Are Caused by Proteins

An unusual infectious agent called the prion has been implicated as the cause of a series of relatively rare but invariably fatal brain diseases (**Table 26.7**). Prions are infectious agents that do not have a nucleic acid genome. It seems that a protein alone can mediate an infection. The **prion** has been defined as a small proteinaceous infectious particle that resists inactivation by procedures that modify nucleic acids. The discovery that proteins alone can transmit an infectious disease has come as a surprise to the scientific community. Diseases caused by prions are especially worrying, since prions resist destruction by many chemical agents and remain active after heating at extremely high temperatures. There have even been documented cases in which sterilized surgical instruments, originally used on a prion-infected person, still held infectious agent and transmitted the disease to a subsequent surgery patient.

How can a nonliving entity without nucleic acid be an infectious agent? Prions associated with human brain disease are thought to be aberrantly folded forms of a normal brain protein. The theory is that when a prion is introduced into the body and manages to enter to the brain, it will cause normally folded forms of the protein to refold incorrectly. The improperly folded proteins fit together like Lego blocks to produce damaging aggregated structures within brain cells.

Table 26.6 Microbes causing meningitis/encephalitis.

Type of meningitis	Etiologic agent	Virulence factors	Typical initial infection or source	Treatment	Vaccine
Bacterial (septic)	*Streptococcus pneumoniae* (G+)	Capsule, pneumolysin	Lung	Ampicillin	Multivalent, capsule
	Neisseria meningitidis (G–)	Capsule IgA protease, endotoxin	Throat	Cephalosporin (3rd generation), ceftriaxone	Multivalent, capsule
	Haemophilus influenzae type B (G–)	Polyribitol capsule IgA protease Endotoxin	Ear infection	Cephalosporin (3rd generation), ceftriaxone	Type b polysaccharide
	Other G– bacilli		Septicemia		
	Group B streptococci (G+)	Sialic acid capsule, streptolysin, inhibition of alternate complement path	Neonate infected during parturition	Ampicillin	Capsular
	Listeria monocytogenes (G+)	Intracellular growth, PrfA regulator, actin-based motility	Mild GI disease of mother	Ampicillin plus gentamicin	
	Mycobacterium tuberculosis	Cord factor, wax D, intracellular growth	Lung	Combination therapy (rifampin, isoniazid, ethambutol, pyrazinamide)	BCG
	Staphylococcus aureus (G+)	Coagulase, protein A, TSST, leucocidin	Septicemia	Methicillin, vancomycin	
	Staphylococcus epidermidis (G+)	Biofilm, slime	Complication of surgical procedure	Vancomycin, methicillin	
Aseptic[a]	Fungi (e.g., *Coccidioides*, *Cryptococcus*)		Sinusitis, direct spread to meninges	Ketoconezole, fluconazole	
	Amebas (e.g., *Naegleria*)		Swimming in contaminated waters	Amphotericin B	
	T. pallidum		Syphilis		
	Mycoplasmas	Adhesin tip	Respiratory	Erythromycin	
	Leptospira	Burrowing motility	Septicemia, water contaminated with animal urine	Erythromycin	
Viral	Viruses (90% caused by enteroviruses)			Self-limiting	
Eastern equine encephalitis	EEE virus	?	Mosquito bite	None; often fatal	
West Nile disease	West Nile virus	?	Mosquito bite	Supportive therapy[b]	

[a] Aseptic meningitis refers to an inability to isolate bacterial sources by ordinary means.

[b] Supportive therapy means hospitalization, intravenous fluids, airway management, respiratory support, prevention of secondary infections.

Table 26.7 Prion diseases.

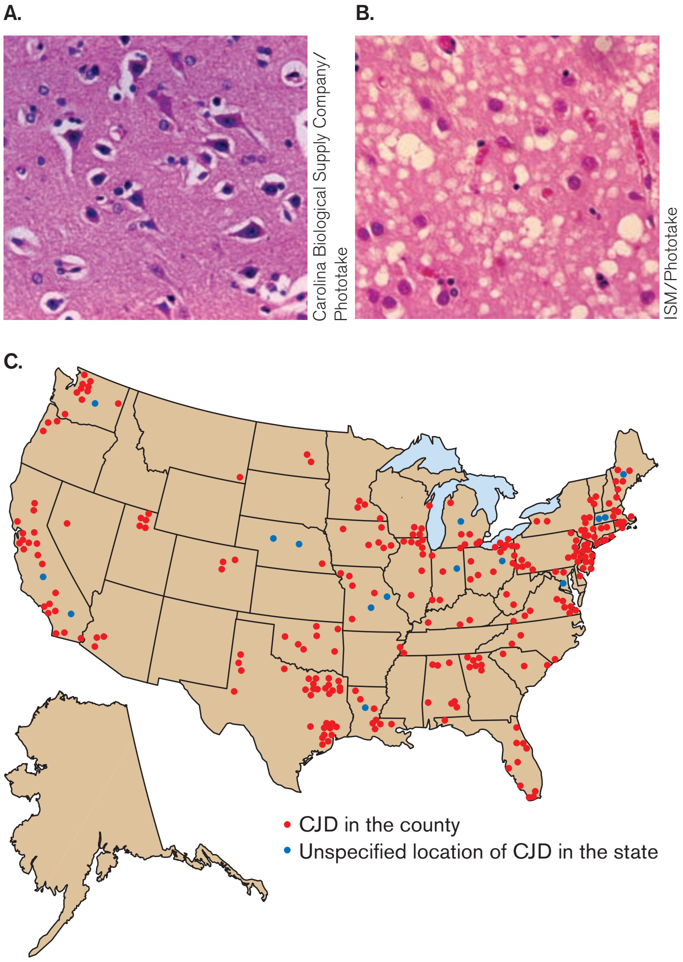
Disease	Susceptible animal	Incubation period	Disease characteristics
Creutzfeldt-Jakob [sporadic, familial, new variant (vCJD)]	Human	Months (vCJD) to years	Spongiform encephalopathy (degenerative brain disease)
Kuru	Human	Months to years	Spongiform encephalopathy
Gerstmann-Straussler-Scheinker syndrome	Human	Months to years	Genetic neurodegenerative disease
Fatal familial insomnia	Human	Months to years	Genetic neurodegenerative disease with untreatable insomnia
Mad cow disease	Cattle	5 years	Spongiform encephalopathy
Wasting disease	Deer	Months to years	Spongiform encephalopathy

Some investigators suggest that living, infectious agents, such as *Spiroplasma* (a spiral-shaped genus whose members lack cell walls), can somehow precipitate a conformational change in the normal brain protein, converting it to an infectious prion protein. This proposal is not, however, universally accepted and has yet to be proved.

Prion diseases are often called **spongiform encephalopathies** because the postmortem appearance of the brain includes large, spongy vacuoles in the cortex and cerebellum. These are visible in a brain sample from a victim of one of these diseases, called Creutzfeldt-Jakob disease (CJD) (**Figs. 26.20A** and **B**). Most mammalian species appear to develop these diseases.

Since 1996, mounting evidence points to a causal relationship between outbreaks in Europe of a disease in cattle called bovine spongiform encephalopathy (BSE, or "mad cow disease") and a disease in humans called variant Creutzfeldt-Jakob disease (vCJD). Both disorders are invariably fatal brain disorders. They have unusually long incubation periods (measured in years) and are caused by an unconventional transmissible agent.

As of this writing, only four cases of BSE have been detected in the United States. Due to aggressive surveillance efforts in the United States and Canada (where only nine cases have been found), it is unlikely, but not impossible, that BSE will be a food-borne hazard to humans in this country. The CDC monitors the trends and current incidence of typical and variant CJD in the United States (**Fig. 26.20C**).



Carolina Biological Supply Company/Phototake

ISM/Phototake

Figure 26.20 **Spongiform encephalopathies.** **A.** Normal brain section. **B.** Section of brain taken from a CJD victim. Note the "Swiss-cheese" appearance, indicating brain damage. **C.** Locations of CJD (not vCJD) cases in the USA.

TO SUMMARIZE:

- ***N. meningitidis*** is resistant to serum complement because it produces a type-specific capsule. This allows the organism to reach and then cross the blood-brain barrier.
- **A vaccine for *N. meningitidis*** is available, but none exists for *N. gonorrhoeae*.
- **Tetanospasmin** causes spastic paralysis.
- **Botulinum toxin** causes flaccid paralysis.
- **Serological diagnosis of an infectious disease** can be done if a fourfold rise in specific pathogen antibody titer occurs between the acute and convalescent stages.
- **Spongiform encephalopathies** are believed to be caused by nonliving proteins called prions.

26.7 Infections of the Cardiovascular System

Infections of the cardiovascular system include septicemia, endocarditis (inflammation of the heart's inner lining), pericarditis (inflammation of the heart's outer lining) and, possibly, atherosclerosis (the deposition of fatty substances along the inner lining of arteries). These are all life-threatening diseases.

Septicemia is, by strict definition, the presence of bacteria or viruses in the blood. The presence of viruses is a condition called **viremia**, while bacteria in the circulation is more specifically called **bacteremia**. In practice, however, the terms *septicemia* and *bacteremia* are often used interchangeably. Septicemia can develop from a local infection situated anywhere in the body, although blood factors such as complement can nonspecifically kill many types of bacteria that enter the blood. Nevertheless, gram-positives, gram-negatives, aerobes, and anaerobes can all produce septicemia under the right conditions.

Endocarditis can be either viral or bacterial in origin. It can be a consequence of many bacterial diseases, such as brucellosis, gonorrhea, psittacosis, staphylococcal and streptococcal infections, candidiasis, and Q fever. Among the many viral causes are Coxsackie virus, ECHO virus, Epstein-Barr, and HIV. Bacterial infections of the heart are always serious. Viral infections, although common, are rarely life-threatening in healthy individuals and are usually asymptomatic.

Case History: Bacterial Endocarditis

Elizabeth is 38 years old and has a history of mitral valve prolapse (a common congenital condition in which a heart valve does not close properly). She was recently admitted to the hospital complaining of fatigue, intermittent fevers for five weeks and headaches for three weeks, symptoms the physician recognized as possible indications of endocarditis. Elizabeth reported having a dental procedure a few weeks prior to the onset of symptoms. A sample of her blood placed in a liquid bacteriological media grew gram-positive cocci, which turned out to be Streptococcus mutans, *a member of the viridans streptococci. As a result, the diagnosis of bacterial endocarditis was confirmed. The patient began a one-month course of intravenous penicillin G and gentamicin therapy and eventually recovered to normal health.*

Endocarditis (inflammation of the heart) is traditionally classified as acute or subacute, based on the pathogenic organism involved and the speed of clinical presentation. Subacute bacterial endocarditis (SBE) has a slow onset with vague symptoms. It is usually caused by a bacterial infection of a heart valve (**Fig. 26.21**). Subacute bacterial endocarditis infections are usually (but not always) caused by a viridans streptococcus from the oral flora (for example, *Streptococcus mutans*, a common cause of dental caries). Viridans streptococci is a general term used for normal flora streptococci whose colonies produce green alpha hemolysis on blood agar (viridans from the Greek viridis, to be green). Most patients who develop infective endocarditis have mitral valve prolapse (90%), although this is frequently not the case when patients are intravenous drug abusers or have hospital-acquired (nosocomial) infections.

© Department of Pathology, The University of New South Wales, Sydney Australia

Figure 26.21 Views of bacterial endocarditis. **A.** Whole-heart view, showing vegetations on the mitral valve. **B.** Close-up of mitral valve endocarditis, showing vegetation (arrow).

As in the case history presented here, bacterial endocarditis often begins at the dentist's office. Following a dental procedure (such as tooth restoration), oral flora can transiently enter the bloodstream and circulate.

S. mutans, which is not normally a serious health problem, can become lodged onto damaged heart valves, grow as a biofilm, and secrete a thick glycocalyx coating that encases the microbes and forms a vegetation on the valve, damaging it further. If untreated, the condition can be fatal within six weeks to a year.

When more virulent organisms, such as *Staphylococcus aureus*, gain access to cardiac tissue, a rapidly progressive (acute) and highly destructive infection ensues. Symptoms of acute endocarditis include fever, pronounced valvular regurgitation (back flow of blood through the valve), and abscess formation.

Most patients with subacute bacterial endocarditis present with a fever that lasts several weeks. They also complain of nonspecific symptoms, such as cough, shortness of breath, joint pain, diarrhea, and abdominal or flank pain. Endocarditis is suspected in any patient who has a heart murmur and an unexplained fever for at least one week. It should also be considered in an intravenous drug abuser with a fever, even in the absence of a murmur. In either case, a definitive diagnosis requires blood cultures that grow bacteria. Blood cultures involve taking samples of a patient's blood from two different locations (such as two different arms). Growth of the same organism in cultures taken from two body sites rules out inadvertent contamination with skin flora, which would likely yield growth only in one culture. The blood is then added to liquid culture medium and incubated at 37°C. Incubation should be done aerobically and anaerobically.

Curing endocarditis is difficult because the microbes are usually ensconced in a nearly impenetrable glycocalyx. Consequently, eradicating microorganisms from the vegetations almost always requires hospitalization, where high doses of intravenous antibiotic therapy can be administered and monitored. Antibiotic therapy usually continues for at least a month, and in extreme cases, surgery may be necessary to repair or replace the damaged heart valve.

Although at increased risk, patients with heart valve prolapse should not shy away from the dentist. Prophylactic treatment with penicillin or erythromycin taken an hour before a procedure will kill any oral flora that enter the bloodstream and prevent the development of endocarditis.

Viruses such as adenovirus and some enteroviruses can also cause endocarditis as well as a condition known as myocarditis, an inflammation of the heart muscle.

THOUGHT QUESTION 26.10 A patient presenting with high fever and in an extremely weakened state is suspected of having a septicemia. Two sets of blood cultures are taken from different arms. One bottle from each set grows *Staphylococcus aureus*, yet the laboratory report states that the results are inconclusive. New blood cultures are ordered. Why might this be?

Atherosclerosis and Coronary Artery Disease

Atherosclerosis can occur in most blood vessels. Coronary artery disease is the result of atherosclerotic deposits in the arteries of the heart, which can produce a heart attack if blood flow is occluded. The causes of atherosclerosis have been studied and debated for many years. It now appears that microbes may have an important role in the development of this disease. *Chlamydophila pneumoniae*, for example, is suspected of involvement. Serological studies indicate that a large number of patients with coronary heart disease have antibodies to this organism. Although it is still not clear if *Chlamydophila* truly causes atherosclerosis, one possible model is presented in **Figure 26.22.** Infection of alveolar macrophages leads to circulating "activated" macrophages that generate inflammatory cytokines and factors that result, among other things, in lowered high-density cholesterol (the "good" cholesterol) and increased clotting—all of which can damage endothelial cells and form plaques. In support of an infection model, some studies indicate that antibiotic treatment will reduce the number of recurrent heart attacks in patients with acute coronary artery disease.

Malarial Parasites Feed on Blood

Malaria is the most devastating infectious disease known. Each year 300–500 million people develop malaria worldwide, and 1–3 million of these people, mostly children, die. Fortunately, the disease is relatively rare in the United States; only around 1,000 cases occur annually and almost all are acquired as a result of international travel to endemic areas (**Fig. 26.23A**). Once again, this illustrates the diagnostic importance of knowing a patient's history.

The disease is caused by four species of *Plasmodium*; *P. falciparum* (the most deadly), *P. malariae*, *P. vivax*, and *P. ovale*. The life cycle of *Plasmodium*, discussed in detail in Chapter 20, is complex and involves two cycles—an asexual erythrocytic cycle in the human and a sexual cycle in the mosquito (discussed in Chapter 20; **Fig. 20.37**).

In the erythrocytic cycle, the organisms enter the bloodstream through the bite of an infected female *Anopheles* mosquito (the mosquito injects a small amount of saliva containing *Plasmodium*). The haploid sporozoites travel immediately to the liver, where they undergo asexual fission to produce merozoites. Released from the liver, the merozoites attach to and penetrate red blood cells, where *Plasmodium* consumes hemoglobin and enlarges into a trophozoite. The protist nucleus divides, so that the cell, now called a schizont, contains up to 20 or so nuclei. The schizont then divides to make the smaller, haploid merozoites (**Fig. 26.23B**). The glutted red blood cell eventually lyses, releasing merozoites that can infect new red blood cells (**Fig. 20.36**).

🟥 Areas where malaria is prevalent

Dennis Kunkel/Visuals Unlimited

Figure 26.23 Malaria is a major disease worldwide. A. Endemic areas of the world where malaria is prevalent. **B.** *Plasmodium falciparum* (TEM). Schizont after completion of division. A residual body of the organism (yellow-green) is left over after division. The erythrocyte has lysed and only a ghost cell remains; no cytoplasm is seen surrounding the merozoites just being released. Free merozoites are seen outside the membrane.

Sudden, synchronized release of the merozoites and red cell debris triggers the telltale symptoms of malaria—violent, shaking chills followed by high fever and sweating. The erythrocytic cycle, and thus the symptoms, repeats every 48–72 hours. After several cycles, the patient goes into remission lasting several weeks to months, after which there is a relapse.

Much of today's research focuses on why malarial relapse happens. Why does the immune system fail to eliminate the parasite after the first episode? When *Plasmodium* invades the red blood cells, it lines the blood cells with a protein, PfEMP1, that causes them to stick to the sides of blood vessels. This removes the parasite from circulation, but the protein cannot protect the parasite from patrolling macrophages, which eventually detect the invader and recruit other immune cells to fight it. So, during a malarial infection, a small percentage of each generation of parasites switches to a different version of PfEMP1 that the body has never seen before. In its new disguise, *P. falciparum* can invade more red blood cells and cause another wave of fever, headaches, nausea, and chills.

These sticky surface proteins are the antigens that the body's immune system recognizes and attacks. Once the immune system fights off one version of falciparum malaria, the parasite alters which gene is expressed. The resulting antigenic variation blinds the immune system, allowing a new wave of illness. The body now has to repeat the recognition and attack responses all over again. The parasite has 60 cloaking genes, called *var*, that can be turned on and off individually, changing the organisms' antigenic structure, like a criminal repeatedly changing his disguise to elude police.

In April 2005, Australian scientists Alan Cowman, Brendan Crabb, and colleagues (Walter and Eliza Hall of Institute of Medical Research) showed that *var* genes are regulated by chromosome packaging, which unwraps one gene to be expressed at a time and literally packs away the inactive genes. DNA can be encased so securely by some proteins that other proteins cannot access the nucleic acid for transcription, a process known as epigenetic silencing. Becoming immune to all the types of malaria can take upwards of five years and requires constant exposure; otherwise the immunity is lost. Many children do not live long enough to gain immunity to malaria in all its forms.

Diagnosis involves microscopic demonstration of the protist within erythrocytes (Wright stain) or through serology to identify antimalarial antibodies. Treatment regimens include chloroquine or mefloquine, which kill the organisms in their erythrocytic asexual stages, and primaquine, effective in the exoerythrocytic stages. The chloroquine family of drugs acts by interfering with the detoxification of heme generated from hemoglobin digestion. Malaria parasites accumulate the hemoglobin released from red blood cells in plasmodial lysosomes, where digestion occurs. The parasites use the amino acids from hemoglobin to grow but find free heme toxic. To prevent eating themselves to death from accumulating too much heme, the organism detoxifies heme via polymerization, which produces a black pigment. Many antimalarial drugs, such as chloroquine, prevent polymerization by binding to the heme. As a result, the increased iron (from heme) level kills the parasite.

Chloroquine is given prophylactically to persons traveling to endemic areas. Unfortunately, *Plasmodium* has been developing resistance to these drugs, forcing development of new ones. The antigenic shape-shifting carried out by this parasite has so far stymied development of an effective vaccine.

TO SUMMARIZE:

- **Blood cultures** are useful in diagnosing septicemia and endocarditis.
- **Endocarditis** can have acute or subacute onsets.
- **Subacute bacterial endocarditis** is usually an endogenous infection caused by *S. mutans.*
- ***Chlamydophila pneumoniae* infection** may contribute to atherosclerosis.
- **Malaria, caused by *Plasmodium* species**, manifests as repeated episodes of chills, fever, and sweating owing to the organism's ability to alter the antigenic appearance of its surface proteins and evade the immune response.

26.8 Systemic Infections

Many pathogenic bacteria can produce a septicemia as a way to disseminate throughout the body and infect other organs. These organisms cause what are considered systemic infections.

Case History: The Plague

A 25-year-old New Mexico rancher was admitted to an El Paso hospital because of a two-day history of headache, chills, and fever (40°C). The day before admission, he began vomiting. The day of admission, an orange-sized, painful swelling in the right groin area was noted (**Fig. 26.24A**). *A lymph node aspirate and a smear of peripheral blood were reported to contain gram-negative rods that exhibited bipolar staining* (**Fig. 26.24B**). *The patient's white blood cell count was 24,700/μl (normal is 4,300–10,800/μl), and platelet count was 72,000/μl (normal is 130,000–400,000/μl). In the two weeks prior to becoming ill, the patient had trapped, killed, and skinned two prairie dogs, four coyotes, and one bobcat. The patient had cut his left hand shortly before skinning a prairie dog. PCR and typical biochemical testing of a gram-negative rod isolated from blood cultures identified the organism as* Yersinia pestis, *the organism that causes plague. The patient received an antibiotic cocktail of gentamicin and tetracycline. He eventually recovered after six weeks in intensive care.*

Plague is caused by the bacterium *Yersinia pestis*, which can infect both humans and animals. During the Middle Ages, the disease, known as the Black Death, decimated over a third of the population of Europe. Such was the horror it evoked that invading armies would actually catapult dead plague victims into embattled fortresses. This was probably the first use of biowarfare.

Contrary to popular belief, *Y. pestis* is present in the United States. The organism is endemic in 17 western states. It is normally transmitted from animal to animal, typically rodents like rats and even prairie dogs (**Fig. 26.24C**) by the bite of infected fleas. **Figure 26.25** illustrates the various infective cycles of the plague bacillus. Humans are not typically part of the natural infectious cycle. However, in the absence of an animal host, the flea can take a blood meal from humans and thereby transmit the disease to them. During the Middle Ages, urban rats venturing back and forth to the countryside became infected by the fleas of wild rodents that served as a reservoir. Upon returning to the city, the rat flea passed the organism on to other rats, which then died in droves. The rat fleas, deprived of their normal meal, were forced to feed on city dwellers, passing the disease on to them.

Individuals bitten by an infected flea or accidentally infected through a cut while skinning an infected animal first exhibit the symptoms of **bubonic plague**. Bubonic plague emerges as the organism moves from the site of infection to the lymph nodes, producing characteristically enlarged nodes called buboes (see **Fig. 26.24A**). From the lymph nodes, the pathogen can enter the bloodstream, causing **septicemic plague**. In this phase, the patient can go into shock from the massive amount of endotoxin in the bloodstream. Neither bubonic nor septicemic plague is passed from person to person. As the organism courses through the bloodstream, however, it will invade the lungs and produce **pneumonic plague**, which can be easily transmitted from person to person through aerosol droplets generated by coughing (**Fig. 26.24D**). Pneumonic plague is the most dangerous form of the disease because it can kill quickly and spread rapidly through a population. Pneumonic plague is so virulent that an untreated patient can die within 24–48 hours. Identification of the organism is usually achieved postmortem.

The organism has numerous virulence factors, including so-called V and W cell surface lipoprotein antigens that inhibit phagocytosis. Another factor, the F1 protein surface antigen, is partly responsible for *Y. pestis* survival in the gut of the flea. It blocks flea digestion, making the flea feel "starved" even after a blood meal. Therefore, the flea jumps from host to host in a futile effort to feel full. This curious effect on the insect vector is another unique aspect of how plague spreads so quickly.

Y. pestis also uses type III secretion systems to inject virulence proteins (YopB and YopD) into host cell membranes. Unlike *Salmonella*, which uses type III–secreted proteins to gain entrance into host cells, *Y. pestis* is not primarily an intracellular pathogen. Injection of the Yop proteins disrupts the actin cytoskeleton and so helps the organism evade phagocytosis. By evading phagocytosis, the organism avoids triggering an inflammatory response and produces massive tissue colonization.

Plague has disappeared from Europe; the last major outbreak occurred in 1772. The reason for its disappearance is not known but is thought to be the result of human interventions. Although it wasn't until the nineteenth century that doctors understood how germs could cause disease, Europeans recognized by the sixteenth century that plague was contagious and could be carried from one area to another. Beginning in the late seventeenth century, governments created a medical boundary, or *cordon sanitaire*, between Europe and the areas to the east from which epidemics came. Ships traveling west from the Ottoman Empire were forced to wait in quarantine before passengers and cargo could be unloaded. Those who attempted to evade medical quarantine were shot.

Case History: Lyme Disease

Brad, a 9-year-old from Connecticut, developed a fever and a large (8-cm) reddish rash with a clear center (Erythema migrans) on his trunk (**Fig. 26.26A**)*. He also had some left facial nerve palsy. Brad had returned a week previously from a Boy Scout camping trip to the local woods, where he did a lot of hiking. When asked by his physician, Brad admitted finding a tick on his stomach while in the woods, but thought little of it. The doctor ordered serological tests for* Borrelia burgdorferi *(the organism responsible for Lyme disease),* Rickettsia rickettsii *(which produces Rocky Mountain spotted fever), and* Ehrlichia equi *(which causes ehrlichiosis). The ELISA test for* B. burgdorferi *came back positive, confirming a diagnosis of Lyme disease. The boy was given a three-week regimen of doxycycline (a tetracycline derivative), which led to resolution of the rash and palsy.*

Lyme arthritis was first reported in Lyme, Connecticut, in the 1970s, but the causative organism, *B. burgdorferi*, was not identified until 1982. Since then, Lyme disease (aka borreliosis) has become the most common vector-borne illness in the United States and is considered an emerging infectious disease. The main endemic areas are the northeastern coastal area from Massachusetts to Maryland, Wisconsin and Minnesota, and northern California and Oregon. Lyme disease is also common to parts of Europe, such as Sweden, Germany, Austria, Switzerland, and Russia.

Figure 26.25 The cycles of plague. The sylvatic cycle occurs in the wild, where fleas transmit the organism between rodents. An accidental interaction with urban rats can trigger a similar urban cycle. Humans can be infected through contact with infected fleas coming from either cycle. This starts bubonic plague symptoms that can progress to pneumonic plague. Pneumonic plague is highly infectious, which can cause epidemic spread of the disease.

Figure 26.26 Lyme disease. A. Erythema migrans rash. **B.** *Borrelia burgdorferi* (dark-field microscopy), the agent of Lyme disease (cell length 5 to 30 μm). **C.** *Ixodes* vector (SEM). **D.** Host associations of *Ixodes scapularis*. Tick stages are drawn actual size. Ticks engorged with blood will be larger.

B. burgdorferi is a spirochete (**Fig. 26.26B**) transmitted to humans by ixodid ticks (hard ticks; **Figs. 26.26 C** and **D**). In the northeast and central United States, where most cases occur, the deer tick *Ixodes scapularis* transmits the spirochete, usually during the summer months. In the western United States, *I. pacificus* is the tick vector.

During its nymphal stage (the stage after taking its first blood meal), *I. scapularis* is the size of a poppy seed. Its bite is painless, so it is easily overlooked. Infection takes place when the tick feeds because the spirochete is regurgitated into the host. However, the organism grows in the tick's digestive tract and takes about two days to make its way to the tick's salivary gland, so if the tick is removed before that time, the patient will not be infected. Once it is transferred to the human, the microbe can travel rapidly via the bloodstream to any area in the body, but prefers to grow in skin, nerve tissue, synovium (joint lining), and the conduction system of the heart.

Lyme disease has three stages. Three general stages of Lyme disease are recognized. Stage 1 infections occur 3–30 days after the initial exposure. Approximately 75% of patients experience an erythema migrans rash, usually at the site of the tick bite, that varies in appearance but is classically erythematous with central clearing ("bulls-eye" rash). This stage is often associated with constitutional symptoms such as fever, myalgias, arthralgias, and headache.

Stage 2 occurs weeks to months after the initial infection. In this stage, the patient can be quite ill with malaise, myalgias (muscle pain), arthralgias (joint pain), or neurological or cardiac involvement. Common neurological manifestations include Bell's palsy (facial paralysis), inflammation of spinal nerve roots, and chronic meningitis. The most common cardiac manifestation is an irregular heart rhythm.

Stage 3 borreliosis occurs months to years later and can involve the synovium, nervous system, and skin, though skin involvement is more common in Europe than in North America. Arthritis occurs in the majority of previously untreated patients; it is usually intermittent, involves the large joints, particularly the knee, and lasts from weeks to months in any given joint. Joint fluid analysis typically shows a WBC count of 10,000 to 30,000/μl. Late neurological involvement may include peripheral neuropathy and encephalopathy, manifested by memory, mood, and sleep disturbances.

Treatment with antibiotics is recommended for all stages of Lyme disease, but is most effective in the early stages. Treatment for early Lyme disease (stage 1) is a course of doxycycline for 14–28 days. Lyme arthritis is typically slow to respond to antibiotic therapy. Despite antimicrobial drug treatment, patients with persistent active arthritis and persistently positive PCR tests may have incomplete microbial eradication and may be the most likely to benefit from repeated treatment with injected antibiotics.

Curiously, 25% of people infected with *B. burgdorferi* never experience erythema migrans, and many infected individuals are also unsure of tick bites. Hence, patients with Lyme disease may present with arthritis as their first complaint. Although this makes diagnosis extremely difficult, knowing that the patient lives or recently traveled to an endemic area can provide a critical clue.

Many other bacteria can cause septicemia and systemic illness (**Table 26.8**). Gram-negative organisms like *E. coli*, *S. typhi*, and *Francisella* and gram-positive microbes like *S. aureus*, *Enterococcus*, and *Bacillus anthracis* can grow in the bloodstream if they can gain entrance. Even anaerobes that are normal inhabitants of the intestine (for example, *Bacteroides fragilis*) can be lethal if they escape the intestine and enter the blood, as might happen following surgery. This is one reason surgical patients are given massive doses of antibiotics immediately before and after surgery.

Hepatitis Viruses Target the Liver

Hepatitis is a general term meaning inflammation of the liver. Hepatitis is caused by several viruses, including hepatitis A, B, and C viruses. Although these viruses are members of very different families, they all target the liver. We include them under the section on systemic infections because their infectious routes take them to the bloodstream before arriving at the liver.

Hepatitis A virus (HAV) is a single-stranded RNA picornavirus (**Fig. 26.27A**) that causes an acute infection spread person-to-person by the fecal-oral route, but can also result from eating undercooked shellfish collected from contaminated waters. The organism replicates in the intestinal endothelium and is disseminated via the bloodstream to the liver. After replicating in hepatocytes, the progeny enter the bile and are released into the small intestine, explaining why stools are so infectious. Though the virus has an early viremic stage after leaving the intestine, it is rarely transmitted by transfusion because the viremic stage is transient, ending after development of liver symptoms. In contrast, hepatitis B and C viruses produce persistent viremia and are readily transmitted by transfusion.

Many people who are infected with HAV are asymptomatic or exhibit very mild symptoms that include nausea, vomiting, diarrhea, low-grade fever, and fatigue. As the virus attacks the liver, the patient may become jaundiced (from accumulation of bilirubin in the skin), and their urine will turn dark brown. There is no specific treatment, but the disease usually lasts for only a few months and then resolves without establishing a carrier state. Disease can, however, be prevented if immunoglobulin is given to someone who has had contact with an infected individual. There is an inactivated hepatitis A vaccine available called HepA vaccine, which is administered after 1 year of age. For those not vaccinated, frequent hand washing is important for preventing the spread of the disease because it interrupts the fecal-oral cycle.

Dennis Kunkel/Visuals Unlimited

Figure 26.27 Structures of hepatitis A and hepatitis B viruses. Both viruses are icosahedral in shape. **A.** Hepatitis A (TEM), spread by fecal-oral route, is a single-stranded RNA virus in the Picornaviridae family (30 nm in diameter). **B.** Hepatitis B (TEM) is an enveloped, double-stranded DNA virus in the Hepadnaviridae family (40 nm in diameter).

Table 26.8 Microbes causing systemic disease.

Disease	Symptoms	Etiologic agent	Virulence properties	Source	Treatment	Vaccine
Lyme disease	Stage 1: rash Stage 2: chills, headache, malaise, systemic involvement Stage 3: neurological changes	*Borrelia burgdorferi* (spirochete)	Antigenic variation, OspE (binds complement)	Deer tick	Penicillin, tetracycline	+
Brucellosis	Fever, weakness, sweats, splenomegaly, osteomyelitis, endocarditis, others	*Brucella abortis* (G– rod)	Intracellular, growth in monocytes	Animal products, unpasteurized milk	Doxycycline	
Leptospirosis	Fever, photophobia, headache, abdominal pain, skin rash, liver involvement, jaundice,	*Leptospira interrogans* (spirochete)	Burrowing motility	Urine of infected animals	Erythromycin, penicillin	
Epidemic typhus	Chills, fever, headache, muscle pain, splenomegaly, coma	*Rickettsia prowazekii* (G– rod)	Obligate intracellular growth, escapes phagosome	Human louse, flying squirrel flea	Tetracycline, chloramphenicol	
Tularemia	Fever, chills, headache, muscle pain, rash, bacteremia	*Francisella tularensis* (G– rod)	Intracellular	Rabbits, rodents, insect vectors	Gentamicin, streptomycin	
Typhoid fever	Septicemia, chills, fever, hypotension, rash (rose spots)	*Salmonella typhi* (G– rod)	Type III secretion, intracellular growth, PhoPQ regulators, Vi antigen capsule	Gallbladder of human carrier	C. profloxacin, ceftriaxone	Vi antigen
Typhoid fever	Septicemia, chills, fever, hypotension	*Salmonella cholerasuis* (G–) rod)	Intracellular growth, invasin	Animals, poultry	Ceftriaxone	
Vibriosis	Serious with immunocompromised patients; fever, chills, multi-organ damage, death	*Vibrio vulnificus* (G– curved rod)	Cytolysin, capsule	Seawater, raw oysters	Tetracycline plus aminoglycoside	
Bubonic plague	Buboes (swollen lymph glands), high fever, chills, headache, cough, pneumonia, septicemia	*Yersinia pestis* (G– rod)	Intracellular growth, type III secretion of YOPs (*Yersinia* outer proteins), phospholipase D, toxin	Rodents, rodent fleas, human respiratory aerosol, potential bioterrorism agent	Streptomycin or tetracycline	

In contrast to HAV, hepatitis B virus is a partially double-stranded circular DNA virus (family Hepadnaviridae) that causes diseases of varying severity. These include acute and chronic hepatitis; cirrhosis; and hepatocarcinoma. The virus also wears a membrane envelope donned when progeny viruses are released from infected cells. The virion coat protein, a surface antigen, is called HBsAg. The virus makes an excess amount of HBsAg, so it is sometimes extended as a tubular tail on one side of the virus particle and is often found in the blood of infected individuals in the form of noninfectious filamentous and spherical particles (**Fig. 26.27B**). The presence of HBsAg in blood in an indicator of HBV infection.

HBV is primarily transferred via blood transfusions, contaminated needles shared by IV drug users, and any human body fluid (saliva, semen, sweat, breast milk, tears, urine, feces). It can be transferred transplacentally to a fetus and can be sexually transmitted. Infection by HBV has two stages: a short-term acute phase and a long-term chronic phase that, if it extends beyond six months, may never resolve. Symptoms resemble the flu but with jaundice and brown urine. Liver damage caused by HBV infection is in large part due to an efficient cell-mediated immune response. Cytotoxic T cells and natural killer cells cause immune lysis of infected liver cells. Over the long term, chronic hepatitis will lead to a scarred and hardened liver (cirrhosis), the only recourse being a liver transplant. Fortunately, about 90% of those infected are able to fight off infection and never proceed to the chronic stage. A HepB vaccine (made from recombinant HBsAg) is available. Its administration is recommended after birth followed by booster shots administered by 2 months and 18 months of age.

Hepatitis C virus (HCV) causes another form of hepatitis. HCV is a single-stranded linear DNA virus with a lipid coat; it is a member of the Flaviviridae family. It is transmitted by blood transfusions and is, in fact, responsible for 90% of transfusion-related cases of hepatitis. It can also be transmitted by needle sticks and, less frequently, by sex. Over 100 million people worldwide are infected with HCV. Most (80%) HCV-infected individuals do not exhibit symptoms, and in those that do, symptoms may not appear for 10–20 years. At least 75% of patients that exhibit symptoms ultimately progress to chronic hepatitis requiring a liver transplant. Fortunately, infection can be detected using an ELISA assay. Liver biopsies of HCV patients are used to determine the extent of liver damage, which in turn helps establish the stage of disease.

Prevention of HBC or HCV infection for health care personnel includes avoiding inadvertent needle sticks and, if one should occur, the administration of immunoglobulin within seven days. Chronic hepatitis can be treated with interferon but only with modest success. Though vaccines have been developed for HAV and HBV, no vaccine is yet available for HCV. It is important to note that since hepatitis viruses can be spread via contaminated blood products, all blood donations collected by the Red Cross and other agencies are tested for the presence of these viruses, as well as for HIV. Thus, the blood supply is safe.

TO SUMMARIZE:

- **Septicemia** is caused by many gram-positive and gram-negative bacterial pathogens. It can start with the bite of an infected insect, introduction via a wound, escape from an abscess, or by the pathogen penetrating mucosal epithelium (as through the intestine or vagina); it can lead to disseminated, systemic disease.
- **Plague** has sylvatic and urban infection cycles involving transmission between fleas and rats.
- ***Y. pestis*-infected flea** bites lead to bubonic plague. Bubonic plague can progress to septicemic and pneumonic stages.
- **Aerosolized respiratory secretions** will directly spread *Y. pestis* pneumonic plague from person to person (no insect vector).
- **Lyme disease** is caused by the spirochete *Borrelia burgdorferi*, which is transmitted from animal reservoirs to humans by the bite of *Ixodes* ticks.
- **Three stages of Lyme disease**: stage 1, a bull's-eye rash (erythema migrans); stage 2, joint, muscle, and nerve pain; stage 3, arthritis with WBCS in the joint fluid.
- **Hepatitis** is caused by several unrelated viruses; among them, HAV, HBV, and HCV account for most disease.
- **HAV** is transmitted by the fecal-oral route, does not establish chronic infection, and can be prevented by a vaccine.
- **HBV and HCV** can be transmitted by blood products (such as transfusions) and shared hypodermic needles and can lead to chronic hepatitis.
- **Vaccine for HBV**, but not HCV, is available.

26.9 Immunization

In our discussion of various infections caused by bacteria and viruses, we often noted the availability of vaccines that prevent disease. In Chapter 24, we also listed many of the available vaccines and their basic makeup (see Table 24.2). As noted in that table, some vaccines utilized killed organisms (examples are the hepatitis A vaccine or the Salk inactivated polio vaccine), while others contained attenuated microbes (BCG for tuberculosis or the Sabin live polio vaccine) or consist of purified components of an infectious agent (*Streptococcus pneumoniae* and *Haemophilus influenzae b* capsular antigens). Some vaccines are injected in combination as polyvalent vaccines to control multiple diseases (measles, mumps, and rubella), while others are given individually but may change from year to year (influenza viral capsid proteins).

Table 26.9 **Recommended childhood and adolescent immunization schedule, by vaccine and age—United States, 2007.**

Vaccine	Age ⟶ Birth	1 month	2 months	4 months	6 months	12 months
Hepatitis B[a]	HepB (dose1)	HepB (dose 2)			HepB	
Rotavirus			Rota (dose1)	Rota (dose 2)	Rota (dose 3)	
Diphtheria, tetanus, pertussis[b]			DTaP (dose1)	DTaP (dose 2)	DTaP (dose 3)	
Haemophilus influenzae type b[c]			Hib (dose1)	Hib (dose 2)	Hib[c] (dose 3)	Hib (dose 4)
Inactivated poliovirus			IPV (dose1)	IPV (dose 2)	IPV (dose 3)	
Measles, mumps, rubella[d]						MMR (dose 1)
Varicella[e]						Varicella (dose 1)
Meningococcal[f]						
Pneumococcal[g]			PCV (dose 1)	PCV (dose 2)	PCV (dose 3)	PCV
Influenza[h]					Influenza (yearly)	
Hepatitis A[i]						HepA series

This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines, as of December 1, 2005.

🟦 Indicates age groups that warrant special effort to administer those vaccines not previously administered.

🟧 Range of recommended ages 🟦 Catch-up immunization 🟪 Assessment at age 11–12 years

[a] Hepatitis B vaccine (HepB). *At birth:* All newborns should receive monovalent HepB soon after birth and before hospital discharge.

[b] Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).

[c] *Haemophilus influenzae* type b conjugate vaccine (Hib).

[d] Measles, mumps, and rubella vaccine (MMR).

[e] Varicella vaccine.

[f] Meningococcal vaccine (MCV4). Meningococcal conjugate vaccine (MCV4) should be administered to all children at age 11–12 years as well as to unvaccinated adolescents at high school entry (age 15 years). Vaccine contains four types of capsule.

[g] Pneumococcal vaccine. The heptavalent pneumococcal conjugate vaccine (PCV) is recommended for all children 2–23 months and for certain children aged 24–59 months. The final dose in the series should be administered at age ≥12 months. Pneumococcal polysaccharide vaccine (PPV) is recommended in addition to PCV for certain high-risk groups. PPV contains 23-capsule antigens.

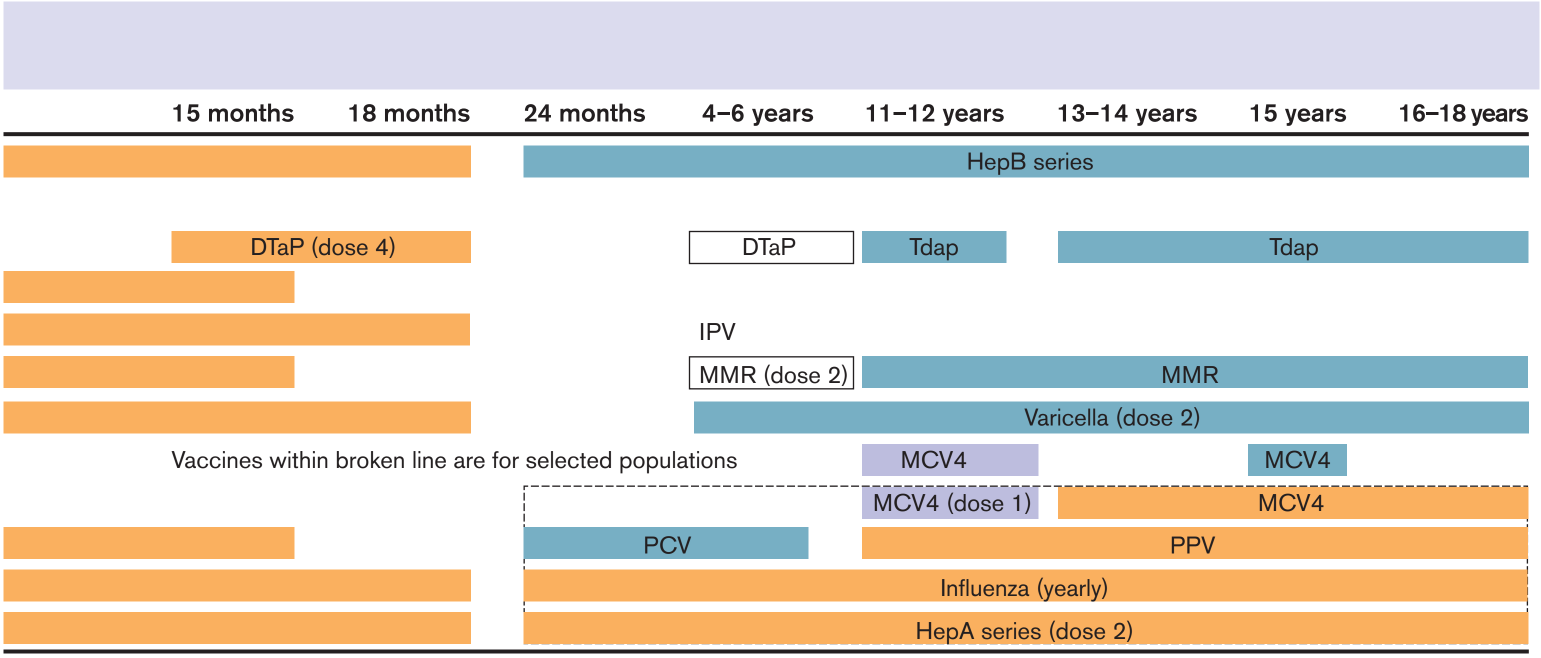
[h] Influenza vaccine. Influenza vaccine is recommended annually for children aged ≥6 months with certain risk factors (including, but not limited to, asthma, cardiac disease, sickle-cell disease, human immunodeficiency virus infection, diabetes, and conditions that can compromise respiratory function or handling of respiratory secretions or that can increase the risk of aspiration), health-care workers, and other persons (including household members) in close contact with persons in groups at high risk (see *MMWR* 2005; 54[No. RR-8]).

[i] Hepatitis A vaccine (HepA). HepA is recommended for all children at age 1 year (i.e., 12–23 months).

Source: http://www.immunize.org/cdc/child-schedule.pdf

Contrary to what you may think, multiple vaccines can be given simultaneously and safely. Most vaccines are administered during childhood, when the diseases can be most devastating. **Table 26.9** provides the current immunization schedule recommended for children and adolescents by the Centers for Disease Control and Prevention. As you will notice, all of these vaccines are given in multiple doses, called booster doses. The exception to this rule is the influenza vaccine, which is given in a single dose but changes every year. The reason for multiple doses, as noted in Chapter 24, is that secondary exposure to an antigen provides a more robust and long-lasting immunity. However, most vaccines are not administered until 2 months of age because maternal antibody crossing through the placenta to the fetus (or to a newborn through breast milk) will persist for a short time in the newborn, temporarily protecting the baby from disease and possibly dampening the response to an antigen administered during that time.

You might wonder whether all members of a community must be vaccinated against a given microbe in order to lower the risk of disease for every individual in that community. It depends on the disease. For infections spread by person-to-person contact, the risk of disease to an unvaccinated person can actually be lowered dramatically if only around two-thirds of the community are vaccinated. This concept, called community (or herd) immunity, works because it interrupts the transmission



of the disease. If one individual contracts the disease, the chance that he or she will come into contact with another unvaccinated person and transmit the disease is much reduced. Thus, the risk of disease to any one unvaccinated person is lessened as a result of community immunity.

Herd immunity works well for diseases such as diphtheria, whooping cough (pertussis), measles, and mumps. However, herd immunity will not lower the risk of an unvaccinated person contracting tetanus, which is not spread by person-to-person contact. *Clostridium tetani*, the agent whose toxin causes tetanus, is a ubiquitous soil organism transmitted through punctured skin. The risk of tetanus for an unvaccinated person doesn't change even if every other person in the community is vaccinated against tetanus.

It is important to note that the vast majority of people who receive vaccines suffer no, or only mild, reactions, such as fever or soreness at the injection site. Very rarely do more serious side effects, such as allergic reactions, occur. Vaccines are *extremely* safe. You may find some unsettling, erroneous information on the Internet purporting a link between vaccinations and other diseases, such as diabetes or autism, but no well-controlled scientific study supports these claims. Clearly, the risks, including death, associated with these preventable infectious diseases are far greater than the minimal risk associated with being vaccinated against them. As proof of this point, the undervaccination of children in the United States in the 1980s and 1990s has led to an increase in cases of whooping cough (25,616 in 2005), caused by *Bordetella pertussis*. Nevertheless, the successful vaccination programs carried out in the United States have come close to eradicating many diseases once feared, such as polio, rubella, and diphtheria, and have dramatically reduced the morbidity and mortality of many others.

The one caveat to this is that the current risk of infection for some diseases (because they are so rare) is lower than the risk of an adverse reaction to immunization. However, failing to vaccinate, as just mentioned, will result in a population susceptible to the microbe and a resurgence of serious disease.

TO SUMMARIZE:

- **Vaccines** can be made from live attenuated organisms, killed organisms, or purified microbe components.
- **Herd immunity** can help protect unimmunized persons from diseases transmitted from person to person.
- **Serious side effects** very rarely result from immunizations.

Concluding Thoughts

This chapter described key concepts of infectious disease using just a small sample of disease-causing pathogens. Many more pathogens can be explored in further studies. The principal goal with this and the previous chapter was to illustrate how microbial metabolism can undermine the physiology of a human host. The next chapter will describe how humans fight back using pharmacology to sabotage the physiology of the infecting microbes.

CHAPTER REVIEW

Review Questions

1. How are pathogens classified as to their portal of entry?
2. Discuss some common skin infections.
3. What causes boils?
4. What are the symptoms of necrotizing fasciitis?
5. What is the difference between primary and secondary infections?
6. How do pneumococci avoid engulfment by phagocytes?
7. What causes the clouding seen in X-rays of infected lungs?
8. What are the key features of the pneumococcal vaccine?
9. Name the common fungal causes of lung disease.
10. What is a metastatic lesion?
11. Why is diarrhea watery?
12. What is the most common microbial cause of diarrhea?
13. List common bacterial agents that cause diarrhea.
14. Would you suspect *Salmonella* infection in a cluster of nauseated patients rushed to the hospital directly from a church picnic? Why or why not?
15. What is the significance of finding leukocytes in stool?
16. What is one reservoir of *E. coli* O157:H7?
17. How is a diagnosis of a UTI made?
18. What is an important virulence determinant of uropathogenic *E. coli*?
19. What is the most common sexually transmitted disease?
20. How is gonorrhea different in men and women?
21. Why will *N. gonorrhoeae* not usually disseminate in the bloodstream, while *N. meningitidis* will?
22. Name the major causes of bacterial meningitis. What are the two routes of infection?
23. If tetanus and botulism toxins have the same mode of action, why do they cause opposite effects on muscles?
24. What are some virulence factors of *Y. pestis*?

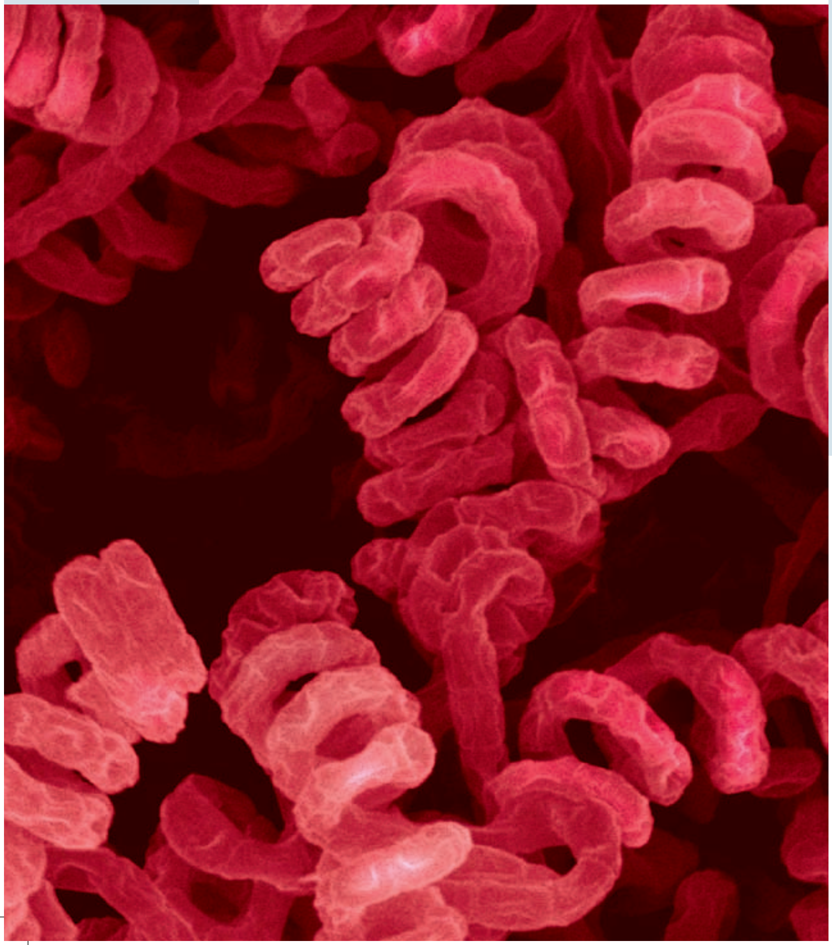
Antimicrobial Chemotherapy

27.1 The Golden Age of Antibiotic Discovery
27.2 Basic Concepts of Antimicrobial Therapy
27.3 Measuring Drug Susceptibility
27.4 Mechanisms of Action
27.5 Antibiotic Biosynthesis
27.6 The Challenges of Antibiotic Resistance
27.7 The Future of Drug Discovery
27.8 Antiviral Agents
27.9 Antifungal Agents

The discovery of antibiotics less than 80 years ago has played a major role in increasing life expectancy throughout the world. Prior to 1918, the average life expectancy in the United States was 45–50 years. That number is now between 70 and 75 years, thanks in part to antibiotics. Yet we face the possibility that antibiotics will become useless. Over several decades, antibiotics have been used indiscriminately to treat patients and are often included in animal feed—not to treat animals but to grow larger ones. These abuses, combined with the ability of bacteria to become antibiotic resistant, have led experts to predict an impending crisis where the human race is vulnerable to infectious diseases we once thought had been conquered.

Important questions about chemotherapeutic agents will be addressed in this chapter, including: Why do antimicrobials inhibit the growth of bacteria, but not humans or animals? What is antibiotic resistance? How do clinicians know which antibiotic to use to treat an infection? We will also discuss what makes a good antibiotic target, and how new antibiotics are discovered.



The genome of *Streptomyces avermitilis*, shown here as an SEM, may yield new antibiotics through unrecognized pathways of secondary metabolism. *S. avermitilis* produces avermectins, a group of antiparasitic agents used in human and veterinary medicine. The genome was found to contain 9,025,608 bases that encode at least 7,574 potential open reading frames (ORFs). Thirty gene clusters related to secondary metabolite biosynthesis were identified, corresponding to 6.6% of the genome. It is thought that some of these pathways may yield other useful antibiotics.
Source: Cover of *Nature Biotechnology.* May 2003. 21(5).

Antibiotics undeniably have been a benefit to modern society. We live longer and contribute more to society than in the past, in large measure because of antibiotics. Infections we consider minor today often killed their victims just 50 or 60 years ago. But there has been a downside. Consider the case of a 56-year-old man with diabetes who entered the hospital for a heart transplant. The operation went well, but one week after the surgery, he developed a severe chest wound infection notable for exuded pus. Treatment with methicillin, a penicillin derivative commonly used to treat infections, failed and the patient became comatose. The diagnostic microbiology laboratory ultimately identified the agent as a methicillin-resistant *Staphylococcus aureus* (MRSA), prompting the surgeon to immediately place the patient on intravenous vancomycin for six weeks. Vancomycin is an antibiotic, structurally different from methicillin, that can usually kill methicillin-resistant bacteria. Fortunately, this patient recovered; too often, they do not.

Where did the infection come from? Surprising as it may seem, this drug-resistant pathogen was a resident of the hospital itself. To find the source, nasal swabs were taken of all hospital personnel and screened for the presence of *S. aureus.* The results revealed that several members of the surgery team actually harbored this organism as part of their normal flora. But which individual was the actual source of the patient's infection? In what could be described as an example of forensic microbiology, each strain was subjected to pulsed-field gel electrophoresis, and the resulting genomic restriction patterns were compared with that of the isolate from the infected patient. A match pointed to the source. The unwitting culprit turned out to be the perfusionist who manipulated the tubing used for cardiopulmonary bypass.

Hospital-acquired, or **nosocomial**, infections are not unusual. As many as 5–10% of all patients admitted to acute-care hospitals acquire nosocomial infections. This leads to over 80,000 deaths each year. The deaths are due, in part, to the poor health of the patient and in part to the antibiotic-resistant nature of bacteria lurking in hospitals. In fact, as much as 60–70% of staph infections that develop in a hospital setting are the result of methicillin-resistant *S. aureus.*

We begin this chapter with a discussion of the golden age of antibiotic discovery (1940–1960) and move on to describe the basic concepts of antibiotics and their use and misuse. We will also delve into the ways genomic and proteomic approaches broaden our ability to search for new antibiotics and identify new antibiotic targets—all part of our attempt to stay one step ahead of evolving, antibiotic-resistant pathogens.

Alexander Fleming's photo of the dish with bacteria and penicillin mold. **B.** The chemical structure of penicillin G. **C.** Alexander Fleming at work in his laboratory. **D.** Howard Florey. **E.** Pictures taken in 1942, shortly after the introduction of penicillin, show the improvement in a child suffering from an infection four days (panel 3) and nine days (panel 5) after treatment. Panels 5 and 6 show her fully recovered.

27.1 The Golden Age of Antibiotic Discovery

Antibiotics (from the Greek, meaning "against life") are compounds produced by one species of microbe that can kill or inhibit the growth of other microbes. While we think of antibiotics as being a recent biotechnological development, their use has historical precedent. Ancient remedies called for cloths soaked with organic material to be placed on wounds to allow them to heal faster. This organic material likely contained "natural antibiotics" that killed bacteria and prevented further infection. The medicinal properties of molds were also recognized for centuries. Historical accounts refer to the ancient Chinese successfully treating boils with warm soil and molds scraped from cheeses, and in England, a paste of moldy bread was a home remedy for wound infections up until the beginning of the twentieth century.

The modern antibiotic revolution began with the discovery of penicillin in 1928 by Sir Alexander Fleming (1881–1955). His discovery was actually a rediscovery, and was arguably one of the greatest examples of serendipity in science. Although Fleming generally receives the credit for discovering penicillin, a French medical student, Ernest Duchesne (1875–1912), originally discovered the antibiotic properties of *Penicillium* in 1896.

Duchesne observed that Arab stable boys at the nearby army hospital kept their saddles in a dark and damp room to encourage mold to grow on them. When asked why, they told him the mold helped heal saddle sores on the horses. Intrigued, Duchesne prepared a solution from the mold and injected it into diseased guinea pigs. All recovered. Although he submitted his work as a dissertation to the Pasteur Institute, it was ignored because of his young age and because he was unknown.

Penicillium was forgotten in the scientific community until Fleming rediscovered it one day in the late 1920s. Petri dishes were glass in those days and could be rewashed and sterilized. Fleming was preparing to wash a pile of old Petri dishes he'd used to grow the pathogen *S. aureus*. He opened and examined each dish before tossing it into a cleaning solution. He noticed that one dish had grown contaminating mold, which in and of itself was not unusual in old plates, but all around the mold the staph bacteria had failed to grow (**Fig. 27.1A**). He took a sample of the mold and found it was from the penicillium family, later identified as *Penicillium notatum*. The mold appeared to have synthesized a chemical, now known as penicillin (**Fig. 27.1B**), that diffused through the agar, killing cells of *S. aureus* before they could form colonies. Fleming (**Fig. 27.1C**) presented his findings in 1929, but they raised little interest, since penicillin appeared to be unstable and would not remain active in the body long enough to kill pathogens.

As World War II began, an Oxford professor named Howard Florey (**Fig. 27.1D**), together with his colleague Ernst Chain, rediscovered Fleming's work, thought it held promise, and set about purifying penicillin. To their amazement, when the purified penicillin was injected into mice infected with staphylococci or streptococci, the majority of mice survived. Subsequent human trials also proved successful (**Fig. 27.1E**), and penicillin gained wide use, saving countless lives during the war. As a fitting tribute to serendipity, Fleming, Florey, and Chain received the 1945 Nobel Prize in Physiology or Medicine for their work. Duchesne's work, however, went unrecognized by the scientific community for decades.

Figure 27.2 The discoverers of sulfanilamide and streptomycin. A. Gerhard Domagk discovered sulfanilamide. **B.** Chemical structure of sulfanilamide, an analog of para-aminobenzoic acid (PABA), a precursor of the vitamin folic acid, necessary for growth. Sulfonilamide inhibits one of the enzymes that converts PABA into folic acid. **C.** Selman Waksman discovered streptomycin in 1944. **D.** Chemical structure of streptomycin.

The next landmark discovery in antibiotics was made by Gerhard Domagk (1895–1964), a German physician at the Institute of Experimental Pathology and Bacteriology who investigated antimicrobial compounds in the 1930s (**Fig. 27.2A**). In 1935, Domagk's 6-year old child was afflicted with a serious streptococcal infection induced by an innocent pinprick to the finger. The infection spread to the lymph nodes under her arm and became so severe that lancing and draining the pus 14 times did little to help.

The only remaining alternative was to amputate the arm. Unfortunately, even this drastic measure would probably not save her life. Frustrated, Gerhard Domagk took what would appear to be drastic measures. He administered a dose of an innocuous red dye he was investigating that, on agar plates (the usual medium for testing antibiotics), had shown absolutely no ability to inhibit the growth of streptococcus. Nevertheless, Domagk's daughter recovered completely.

How did Domagk conceive of such a therapy when the conventional method of screening for antibiotic activity on agar plates indicated that this compound (Prontosil) was useless? The answer lay in his prior use of laboratory animals to study the drug. When administered to mice, Prontosil was very effective at preventing infection. Had he not used live animals, Domagk would never have discovered that Prontosil was metabolized by the body into another compound, sulfanilamide, clearly lethal to the streptococcus. This finding led to an entire class of drugs, the sulfa drugs, which saved hundreds of thousands of lives, including that of his own child. Sulfanilamide is an analog of para-aminobenzoic acid (PABA), a precursor of folic acid, a vitamin necessary for nucleic acid synthesis (**Fig. 27.2B**). The drug stops bacterial growth by inhibiting the conversion of PABA to folic acid.

Folic acid is not synthesized by humans, but is a dietary supplement. Furthermore, bacteria do not transport folic acid, which explains why the sulfa drugs can inhibit bacterial growth in humans without affecting human cells.

In a dark turn, the pressing need for effective antibiotics during World War II dictated a change in the in vivo screening methods used by Domagk's German employer. Animal testing was abandoned in favor of human testing, but the humans were not volunteers. They were concentration camp prisoners intentionally infected with bacterial diseases, such as gangrene, and then treated with new chemical compounds. Domagk's possible participation in these experiments, even if unwilling, was a source of controversy that haunted him long after the war ended. Yet his contributions to medicine continued as he also developed the first effective chemotherapy for tuberculosis via the thiosemicarbazones and isoniazid, still used today.

During the same period of history, Selman Waksman (1888–1973) at Rutgers University began screening 10,000 strains of soil bacteria and fungi for an ability to inhibit growth or kill bacteria (**Fig. 27.2C**). In 1944, this Herculean effort paid off with the discovery of streptomycin, an antibiotic produced by the actinomycete *Streptomyces griseus* (**Fig. 27.2D**). Waksman's discovery of streptomycin triggered the antibiotic gold rush that is still under way.

TO SUMMARIZE:

- **The importance of antibiotics** in treating disease was recognized in the early 1940s.
- **Some antimicrobial agents are initially inactive** until converted by the body to an active agent.
- **Florey and Chain purified penicillin** and capitalized on Fleming's discovery of penicillin.

27.2 Basic Concepts of Antimicrobial Therapy

Antibiotics comprise the vast majority of chemotherapeutic agents used to treat microbial diseases. As already noted, the term *antibiotic* originally referred to any compound produced by one species of microbe that could kill or inhibit the growth of other microbes. Today, the term is also used for synthetic chemotherapeutic agents, such as sulfonamides, that are clinically useful but chemically synthesized. There are a large number of natural and synthetic compounds that affect microbial growth. However, their utility in a clinical setting is dictated by certain key characteristics.

Antibiotics Exhibit Selective Toxicity

As early as 1904, the German physician Paul Ehrlich (1854–1915) realized that a successful antimicrobial compound would be a "magic bullet" that selectively kills or inhibits the pathogen but not the host. This seemingly obvious premise was innovative at the time. Ehrlich made several discoveries based on this concept, the most celebrated of which was the arsenical compound known as salvarsan. Salvarsan proved to be quite active in killing the syphilis agent, *Treponema pallidum*. Syphilis, a sexually transmitted disease, had been untreatable and the source of considerable long-term suffering. Ehrlich's "magic bullet" concept is now known as **selective toxicity**.

Selective toxicity is possible because key aspects of a microbe's physiology are different from those of eukaryotes. For example, suitable bacterial antibiotic targets include peptidoglycan, which eukaryotic cells lack, and ribosomes, which are structurally distinct between the two domains of life. Thus, chemicals like penicillin, which prevents peptidoglycan synthesis, and tetracycline, which binds to bacterial 30S ribosomal subunits, inhibit bacterial growth but are essentially invisible to host cells, since they do not interact with them at low doses.

While their intended targets are bacterial cells, some antibiotics, particularly at high doses, can interact with elements of eukaryotic cells and cause side effects that harm the patient. For example, chloramphenicol, a drug that targets bacterial 50S ribosomal subunits, can interfere with the development of blood cells in bone marrow, a phenomenon that may result in aplastic anemia (failure to produce red blood cells). The toxicity of an antibiotic can also depend on the age of the patient. Tetracycline, for instance, can cause defects in human bone growth plates and should not be administered to children. Problems can even arise if the drug does not directly impact mammalian physiology. For example, many people develop an extreme allergic sensitivity toward penicillin, a situation in which the treatment of an infection may end up being worse than the infection itself. Physicians must be aware of these allergies and use alternative antibiotics to avoid harming their patients.

As a student of microbiology, it is important that you distinguish between drug *susceptibility* and drug *sensitivity*. A microbe is susceptible to the drug's action, but a human can develop an allergic sensitivity to the drug.

Antimicrobials Have a Limited Spectrum of Activity

No one antimicrobial drug affects all microbes. As a result, antimicrobial drugs are classified based on the type of organisms they affect. Thus, we have antifungal, antibacterial, antiprotozoan, and antiviral agents. The term antibiotic is usually reserved for antimicrobial compounds that affect bacteria. Even within a group, one agent might have a very narrow **spectrum of activity**, meaning it only affects a few species, while another antibiotic will inhibit many species. For instance, penicillin has a relatively narrow spectrum of activity, primarily killing gram-positive bacteria. However, ampicillin is penicillin with an added amino group that allows the drug to more easily penetrate the gram-negative outer membrane. As a result of this chemically engineered modification, ampicillin kills gram-positive and gram-negative organisms and is described as having a spectrum of activity broader than penicillin. There are also antimicrobials that exhibit extremely narrow activities. One example is isoniazid, which is clinically useful only against *Mycobacterium tuberculosis*, the agent of tuberculosis. **Table 27.1** presents the spectrum of activity of select antibiotics.

Antibiotics Are Classified as Bacteriostatic or Bactericidal

Nonscientists typically believe that all antibiotics kill their intended targets. This is a misconception. Many drugs simply prevent the growth of the organism and let the body's immune system dispatch the intruding microbe. Thus, antimicrobials are also classified on the basis of whether or not they kill the microbe. An antibiotic is **bactericidal** if it kills the target microbe; it is **bacteriostatic** if it merely prevents bacterial growth.

TO SUMMARIZE:

- **Antimicrobial agents** may be produced naturally or artificially.
- **Selective toxicity** refers to the ability of an antibiotic to attack a unique component of microbial physiology that is missing or distinctly different from eukaryotic physiology.
- **Antibiotic side effects** on mammalian physiology can limit the clinical usefulness of an agent.
- **Antibiotic spectrum of activity** refers to the range of microbes that a given drug affects.
- **Bactericidal antibiotics** kill microbes; **bacteriostatic antibiotics** inhibit their growth.

Table 27.1 Antibacterial activity (spectrum) of antimicrobial agents.

	Aerobic bacteria		Anaerobic bacteria		
Spectrum	Gram (+)	Gram (−)	Gram (+)	Gram (−)	Examples
Broad	+	+	+	+	Cefoxitin, chloramphenicol, imipenem, tetracyclines
Intermediate	+	+	+	±	Carbenicillin, ticarcillin, ceftiofur, amoxicillin/clavulanic acid, cephalosporins
	+	±	+	±	Ampicillin, amoxicillin
Narrow		+			Aztreonam, polymyxin
	+	±	+	±	Benzyl penicillin G
	+	+			Aminoglycosides, spectinomycin, sulfonamides, trimethoprim
	+	+			Fluoroquinolones
	+		+	+	Lincosamides, macrolides, pleuromutilins
	+		+		Bacitracin, vancomycin
			+	+	Nitroimidazoles

± variable activity, depending on species/strain

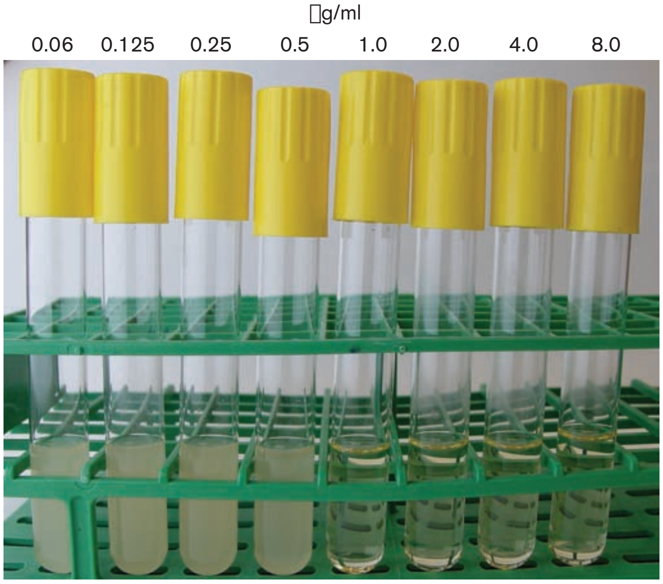
27.3 Measuring Drug Susceptibility

One critical decision a clinician must make when treating an infection is what antibiotic to prescribe for the patient. There are several factors to consider, including:

- The relative effectiveness of different antibiotics on the organism causing the infection. This includes learning whether the organism isolated from a specific patient has developed resistance to the drug.
- The average attainable tissue levels of each drug. An antibiotic may appear to work on an agar plate, but the concentration at which it affects bacterial growth may be too high to be safe in the patient. In fact, an important aspect of designing new antibiotics is to enhance the pharmacological activity of an existing drug—for example, modifying it so that the body does not break it down or quickly secrete it in urine.

Minimal Inhibitory Concentration Reflects Antibiotic Efficacy

The in vitro effectiveness of an agent is determined by measuring how little of it is needed to stop growth. This is classically measured in terms of an antibiotic's **minimal inhibitory concentration (MIC)**, defined as the lowest concentration of the drug that will prevent the growth of an organism. But the MIC for any one drug will differ among different bacterial species. For example, the MIC of ampicillin needed to stop the growth of *S. aureus* will be different from that needed to inhibit *Shigella dysenteriae*. The reasons that a drug may be more effective against one organism than another include the ease with which the drug penetrates the cell and the affinity of the drug for its molecular target.



John W. Foster

Figure 27.3 Determining minimal inhibitory concentration. In this series of tubes, tetracycline was diluted serially starting at 8 μg/ml (far right tube). Each tube was then inoculated with an equal number of bacteria. Turbidity indicates that the antibiotic concentration was not sufficient to inhibit growth. The MIC in this example is 1.0 μg/ml.

So how do we measure MIC? As shown in **Figure 27.3**, an antibiotic is serially diluted along a row of test tubes containing nutrient broth. After dilution, the organism to be tested is inoculated at low, constant density into each tube, and the tubes are usually incubated overnight. Growth of the organism is seen as turbidity. Note that in **Figure 27.3** the tubes with the highest concentration of drug were clear, indicating no growth. The tube containing the MIC is the tube with the *lowest* concentration of drug that shows no growth. However, the MIC does not tell whether a drug is bacteriostatic or bactericidal.

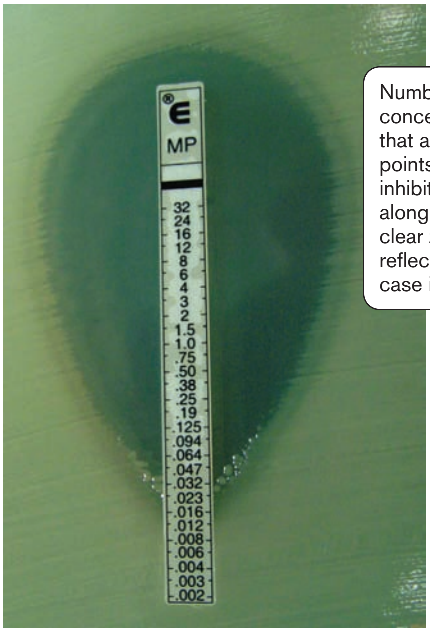
THOUGHT QUESTION 27.1 The drug tobramycin is added to a concentration of 1,000 μg/ml in a tube of broth from which serial twofold dilutions were made. Including the initial tube (tube 1), there are a total of ten tubes. Twenty-four hours after all the tubes are inoculated with *Listeria monocytogenes*, turbidity is observed in tubes 6–10. What is the MIC?

THOUGHT QUESTION 27.2 What additional test performed on an MIC series of tubes will tell you whether a drug is bacteriostatic or bactericidal?

MIC determinations are very useful for estimating a single drug's effectiveness against a single bacterial pathogen isolated from a patient but not very practical when trying to screen 20 or more different drugs. Dilutions take time—time that the technician, not to mention the patient, may not have. The time required to evaluate antibiotic effectiveness can be reduced by using a strip test (like the Etest® shown in **Fig. 27.4**) that avoids the need for dilutions. The strip, containing a gradient of antibiotic, is placed over a fresh lawn of bacteria spread on an agar plate. While the bacteria are trying to grow, the drug diffuses out of the disk and into the media. Drug emanating from the more concentrated areas of the strip will travel faster and farther through the agar than will drug from the less concentrated areas of the strip. Thus, the higher concentrations will kill or inhibit the growth of cells farther from the strip than the lower concentration areas. The result is a **zone of inhibition** where the antibiotic has stopped bacterial growth. The MIC is the point at which the elliptical zone of inhibition intersects with the strip.

Kirby-Bauer Disk Susceptibility Test

Although the strip test eliminates the time and effort needed to make dilutions, it would take 20 or more plates to test an equal number of antibiotics for just one bacterial



Numbers reflect the relative concentrations of antibiotic that are present at various points within the zone of inhibition. The concentrations along the periphery of the clear zone are equal, and reflect the MIC, which in this case is 0.047 μg/ml.

John W. Foster

Figure 27.4 An MIC strip test. The Etest® (AB Biodisk) is a commercially prepared strip that creates a gradient of antibiotic concentration (μg/ml) when placed on an agar plate. The MIC corresponds to the point where bacterial growth crosses the numbered strip.

isolate. Clinical labs can receive up to 100 or more isolates in one day, so individual MIC determinations are not practical. A simplified agar diffusion test, however, which can test 12 antibiotics on one plate, makes evaluating antibiotic susceptibility a manageable task.

Named for its inventors, the **Kirby-Bauer assay** uses a series of round filter paper disks impregnated with different antibiotics. A dispenser (**Fig. 27.5**) delivers up to 12 disks simultaneously to the surface of an agar plate covered by a bacterial lawn. Each disk is marked to indicate the drug used. During incubation, the drugs diffuse away from the disks into the surrounding agar and inhibit growth of the lawn to different distances. The zones of inhibition vary in width, depending on which antibiotic is used, the concentration of drug in the disk, and the susceptibility of the organism to the drug. The diameter of the zone correlates to the MIC of the antibiotic against the organism tested.

Correlations between MIC values and Kirby-Bauer zone sizes are made empirically. Every disk containing a given antibiotic is impregnated with a standard concentration of drug, and every antibiotic has a quantifiable MIC that will differ when tested against different bacterial species and strains. The outermost ring of the no-growth zone in a Kirby-Bauer disk test must, by

definition, contain the minimal concentration of drug needed to prevent growth on agar. Thus, if species A and B have MIC values for penicillin of 4 μg/ml and 40 μg/ml, respectively, then species A will exhibit a proportionally larger zone of inhibition than species B in the disk test. A graph plotting MIC on one axis and zone diameter on the other provides the correlation.

After incubating agar plates in the Kirby-Bauer test, the diameters of the zones of inhibition around each disk are measured, and the results are compared with a table listing whether a zone size is wide enough (meaning the MIC is low enough) to be clinically useful. **Table 27.2** shows susceptibility data for *S. aureus*. The concentration of antibiotic used and the zone size that is considered clinically significant are correlated with the average attainable tissue level for each antibiotic. For the antibiotic to remain effective in vivo, it is important that the tissue concentration of the drug remain above the MIC; otherwise, invading bacteria will not be affected.

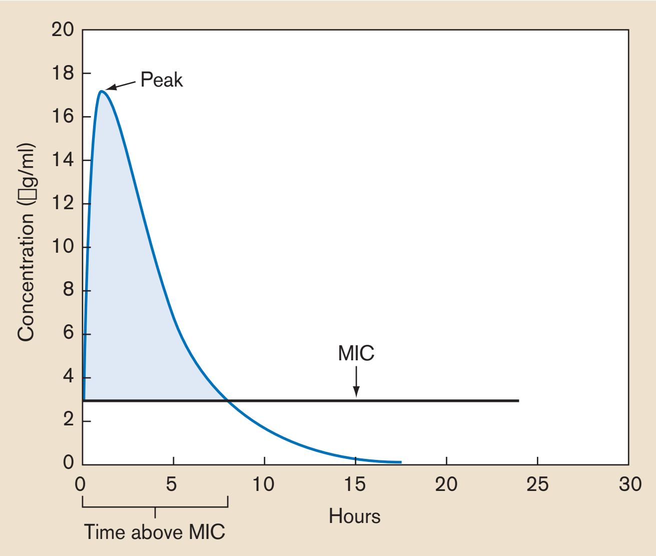

Figure 27.6 Correlation between MIC and serum or tissue level of an antibiotic. This graph illustrates the serum level of ampicillin over time. The important consideration here is how long the serum level of the antibiotic remains higher than the MIC. Once the concentration falls below the MIC, owing to destruction in the liver or clearance through the kidneys and secretion, the infectious agent fails to be controlled by the drug—in this case about 7–8 hours after the initial dose. To maintain a serum level higher than the MIC, a second dose would be taken. The shaded area of the curve represents time above MIC.

Correlating antibiotic MIC with tissue level. The average attainable tissue level for a drug depends on how quickly the antibiotic is cleared from the body via secretion by the kidney or destruction in the liver. It also depends on when side effects of the drug start to appear. As shown in **Figure 27.6**, as long as the concentration of the drug in tissue or blood remains higher than the MIC, the drug will be effective. The concentration can be kept at sufficient levels either by administering a higher dose, which runs the risk of side effects, or by giving a second dose at a time when the levels from the first dose have declined. This is why patients are told to take doses of some antibiotics four times a day and other antibiotics only once a day.

To ensure reproducibility, the Kirby-Bauer test was standardized a half century ago. Reproducibility means that results from a laboratory in California will match those in Alabama, Ohio, or any other state. The following are standardizations used to make the test reproducible and easier.

- **Size of the agar plate.** The plates used (150 mm) are larger than standard agar plates (100 mm) to accommodate more disks and to maintain sufficient distance between disks so that zones of inhibition do not overlap.
- **Depth of the media.** Antibiotics diffuse out of impregnated disks in not two, but three dimensions. Because diffusion cannot occur very far downward in a thinly poured agar, the drug is forced to move more laterally. Thus, the zone of inhibition measured from a thinly poured agar plate will be larger than the zone from a thick agar plate.
- **Media composition.** Media composition can also affect results. For example, most common laboratory media contain para-aminobenzoic acid (PABA), which is used by the cell to make folic acid, a vitamin needed for purine and pyrimidine synthesis.

Table 27.2 **Susceptibility results for *Staphylococcus aureus*.**

		Zone of inhibition diameter (mm)		
Antibiotic	**Quantity in disk (μg)**	**Resistant**	**Intermediate**	**Susceptible**
Ampicillin	10	<12	12–13	>13
Chloramphenicol	30	<13	13–17	>17
Erythromycin	15	<14	14–17	>17
Gentamicin	10	≤12.5		>12.5
Streptomycin	10	<12	12–14	>14
Tetracycline	30	<15	15–18	>18

Sulfonamides are analogs of PABA that competitively inhibit one of the enzymes needed to convert PABA to folic acid. Media containing PABA, such as standard nutrient agar, will flood the bacterial cell with PABA and limit the ability of the sulfa drugs to compete for the enzyme. Thus, even though the drug might be effective in vivo, on the agar plate there would be no zone of inhibition. The standardized media used for the Kirby-Bauer test is called **Mueller-Hinton agar**, which contains no PABA.

- **The number of organisms spread on the agar plate.** The number of organisms placed on an agar surface is inversely proportional to the size of the zone of inhibition. The more organisms there are, the smaller the zone. The reason for this is that there is a time lag between dropping a disk on a plate and the diffusion of the antibiotic. The more organisms there are on a plate, the less time it takes for them to form visible growth; so by the time the antibiotic gets to them, visible growth has already formed. As a result, a standard optical density solution of each organism is prepared, and a cotton swab is used to spread the entire agar surface.
- **Size of the disks.** A standard diameter of 6 mm means that all antibiotics start diffusing into agar at the same point.
- **Concentrations of antibiotics in the disks.** The higher the concentration of antibiotic in a disk, the faster the drug can diffuse through the plate and kill bacteria (or at least inhibit growth) before replicating cells are able to form visible growth. To avoid differences between labs, the concentration of each given drug impregnating a disk has been standardized.
- **Incubation temperature.** Incubation temperature will not affect growth and diffusion equally. To avoid differences, a temperature of 37°C is standard.

THOUGHT QUESTION 27.3 You are testing whether a new antibiotic will be a good treatment choice for a patient with a staph infection. The Kirby-Bauer test using the organism from the patient shows a zone of inhibition of 15 mm around the disk containing this drug. Clearly, the organism is susceptible. But you conclude from other studies that the drug would not be effective in the patient. What would make you draw this conclusion?

TO SUMMARIZE:

- **The spectrum of an antibiotic and the susceptibility** of the infectious agent are critical points of information required before prescribing antibiotic therapy.
- **Minimal inhibitory concentration (MIC)** of a drug, when correlated with average attainable tissue levels of the antibiotic, can predict the effectiveness of an antibiotic in treating disease.
- **MIC is measured** using tube dilution techniques but can be approximated using the Kirby-Bauer disk diffusion technique.

27.4 Mechanisms of Action

As noted earlier, selective toxicity of an antibiotic depends on enzymes or structures unique to the bacterial target cell. The following aspects of a microbe's physiology are classic targets:

- Cell wall
- Cell membrane
- DNA synthesis
- RNA synthesis
- Protein synthesis
- Metabolism

Table 27.3 summarizes the general targets of common antibiotics. Chapters 3, 7, and 8 describe these cellular components and provide the tools needed to understand how antibiotics work.

Cell Wall Antibiotics

Bacterial cell walls are an obvious structure that could be the basis for selective toxicity because peptidoglycan does not exist in mammalian cells; thus, antibiotics that target the synthesis of these structures should selectively kill bacteria. The following case history illustrates the use of two-cell-wall targeting antibiotics and also reveals how bacteria can evolve to escape destruction.

Case History: Meningitis

A 3-year-old child was brought to the emergency room crying, with a stiff neck and high fever. Gram stain of cerebral spinal fluid revealed gram-positive cocci, generally in pairs. The diagnosis is

Table 27.3 Mechanisms of action of antimicrobial agents.

Target	Antibiotic examples
Cell wall synthesis	Penicillins, cephalosporins, bacitracin, vancomycin
Protein synthesis	Chloramphenicol, tetracyclines, aminoglycosides, macrolides, lincosamides
Cell membrane	Polymyxin, amphotericin, imidazoles vs. fungi
Nucleic acid function	Nitroimidazoles, nitrofurans, quinolones, rifampin; some antiviral compounds, especially antimetabolites
Intermediary metabolism	Sulfonamides, trimethoprim

meningitis. The physician immediately prescribed intravenous ampicillin. Unfortunately, the child's condition worsened, so antibiotic treatment was changed to a third-generation cephalosporin (which will cross the blood-brain barrier). The patient began to improve within hours and was released after two days. A report from the clinical microbiology laboratory identified the organism as Streptococcus pneumoniae.

Both of the antibiotics used in this case kill bacteria by targeting cell wall synthesis. Synthesis of peptidoglycan is a complex process but is represented simply in **Figure 27.7**. Basically, sugar molecules called *N*-acetylglucosamine (NAG) and *N*-acetylmuramic acid (NAM) are made by the cell and linked together by a **transglycosylase** enzyme into long chains assembled at the cell wall. *N*-Acetylmuramic acid contains a short side chain of amino acids that is assembled enzymatically, not by a ribosome. Rigidity of the macromolecular structure, essential for maintaining cell shape, is achieved by cross-linking the side chains from adjacent strands. The enzyme **transpeptidase** (D-alanyl-D-alanine carboxypeptidase/transpeptidase) catalyzes the cross-link. **Figure 27.7** also indicates where several antibiotics target various stages of this assembly process.

Peptidoglycan is assembled outside the cell membrane. Before we can explain how cell wall antibiotics work, it is important to know how the cell wall is made. Synthesis of peptidoglycan starts in the cytoplasm with a uridine diphosphate (UDP)-NAM molecule. The amino acids L-alanine, D-glutamic acid, and L-lysine (or diaminopimelic acid in gram-negative organisms) are individually and sequentially added to NAM (**Fig. 27.7**, step 1); and then a dipeptide of D-alanine is attached (step 2). Next, the NAM-pentapeptide is transferred to a membrane-situated, 55-carbon, lipid molecule called bactoprenol (step 3) and UMP is released. Another sugar molecule, NAG, is then linked to NAM, once again through a UDP intermediate (step 4). All of this takes place on the cytoplasmic

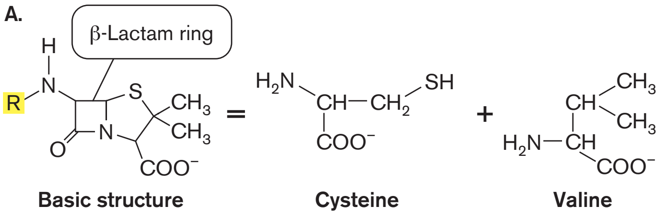
Figure 27.7 Peptidoglycan synthesis and targets of antibiotics. A series of small-molecular-weight compounds are joined to form a disaccharide unit that will be added to preexisting chains of this unit. Steps in the synthesis are described in the text. Red lines indicate inhibition. Cycloserine inhibits ligation of the two D-alanines (step 2). Bacitracin inhibits the linking of the disaccharide units, while vancomycin and the beta-lactams, such as penicillin, inhibit the peptide cross-linking of peptidoglycan side chains.

side of the membrane. Bactoprenol carrying NAM-NAG then moves to the outer side of the cytoplasmic membrane (step 5) where transpeptidases and transglycosylases (two so-called **penicillin-binding proteins**) bind to the D-ala-D-ala part of the pentapeptide. Transglycosylase attaches the new disaccharide unit to an existing peptidoglycan chain (step 6). Transpeptidase then links two peptide side chains with a pentaglycine cross-link (in *Staphylococcus aureus*). The pentaglycine connects L-lysine on one side chain and the penultimate D-ala on the other side chain (step 7). The terminal D-ala is removed in the process. Other bacteria do not use a pentaglycine cross-link but directly form a peptide bond between L-lysine (or DAP) and the penultimate D-ala. Cross-linking, which strengthens the cell wall, can take place between either the same strand or adjacent strands. In the last part of the cycle, one of the phosphates on the now liberated bactoprenol is removed and the lipid moves back to the cytoplasmic side of the membrane, ready to pick up and taxi another unit of peptidoglycan to the growing chain (step 8).

Penicillin and other beta-lactam antibiotics target penicillin-binding proteins. Penicillin is an antibiotic derived from cysteine and valine, which combine to form the beta-lactam ring structure shown in **Figure 27.8A**. Different R groups can be added to the basic ring structure to change the antimicrobial spectrum and stability of the derivative penicillin (**Fig. 27.8B**). Penicillin itself chemically resembles the D-ala-D-ala piece of peptidoglycan. This molecular mimicry allows the drug to bind transpeptidase and transglycosylase (which is why they are called penicillin-binding proteins), preventing their activities and halting synthesis of the chain. The consequence is a disaster for bacteria that are trying to grow larger and larger. Eventually, the growing cell bursts for lack of cell wall restraint. Penicillin, then, is a bactericidal drug (unless the treated organism is suspended in an isotonic solution). Penicillin is most effective against gram-positive organisms because the drug has difficulty passing through the gram-negative outer membrane. Ampicillin, which was used in the case history, is a modified version of penicillin that more easily penetrates this membrane and is more effective than penicillin against gram-negative microbes. Thus, ampicillin has a broader spectrum of activity than penicillin.



B. R groups

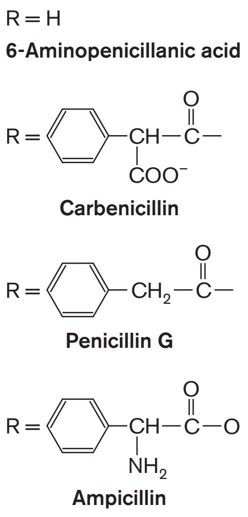


Figure 27.8 The structure of penicillins. A. Penicillanic acid (R = H) is derived from cysteine and valine. **B.** The R group marked in (A) can be any one of a number of different groups, some of which are shown here. Modifying this group changes the pharmacological properties and antimicrobial spectrum.

As noted earlier, antibiotic resistance is a growing problem throughout the world. Bacteria develop resistance to penicillin in two basic ways. The first is through inheritance of a gene encoding one of the beta-lactamase enzymes, which cleave the critical ring structure of this class of antibiotics. Beta-lactamase is transported out of the cell and into the surrounding media (for gram-positives) or the periplasm (for gram-negatives), where it can destroy penicillin before the drug even gets to the cell. Bacteria that produce beta-lactamase are still susceptible to certain modified penicillins and cephalosporins engineered to be poor substrates for the enzyme. Methicillin, for example, works well against beta-lactamase-producing microbes.

The second way a microbe can become resistant is through mutations in genes encoding key penicillin-binding proteins. Resistance occurs when the mutated gene produces an altered protein that no longer binds to the antibiotic. Methicillin-resistant bacteria use this strategy. Hospitals take special interest in methicillin-resistant *S. aureus* (MRSA) because very few drugs can kill it. One of the few remaining antibiotics effective against MRSA is vancomycin. Unfortunately, resistance to this drug is also developing. The penicillin-resistant *S. pneumoniae* in the preceding case history actually had an altered penicillin-binding protein. No beta-lactamase producing *S. pneumoniae* has ever been found.

Cephalosporins are another type of beta-lactam antibiotic originally discovered in nature but modified in the laboratory to fight microbes that are naturally resistant to penicillins (especially *Pseudomonas aeruginosa*). Over the years, the basic structure of cephalosporin has undergone a series of modifications to improve its effectiveness against penicillin-resistant pathogens. Each modification is increasingly more complex and produces what is referred to as a new "generation" of cephalosporins.

There are currently four generations of this semisynthetic antibiotic (**Fig. 27.9**). Unfortunately, the microbial world constantly adapts and eventually becomes resistant to new antibiotics. In the case of the cephalosporins, new beta-lactamases evolve that can attack the sterically buried beta-lactam rings in these molecules. It is also important to note that since the core feature of these drugs is the beta-lactam ring, persons who are sensitive to penicillins may also suffer a hypersensitivity reaction to cephalosporins.

Treatment note: The infecting strain of *S. pneumoniae* in the preceeding case history turned out to be resistant to ampicillin. If the patient had been an adult, a fluoroquinolone (discussed in Chapter 7) might have been the best secondary drug of choice because its target, a type II topoisomerase, is unrelated to cell wall synthesis. However, quinolones are not recommended for children, as in this case, due to potential side-effects. Other beta-lactam antibiotics, such as the third-generation cephalosporins, may still work on penicillin-resistant *S. pneumoniae* since the modified antibiotic often can still bind the altered PBP. Nevertheless, vancomycin or an oxazolidinone are the best last choices, since cephalosporin-resistant strains of *S. pneumoniae* are now appearing.

Representative examples. **A.** First generation: cephalexin (Keflex). **B.** Second generation: cefoxitin. **C.** Third generation: ceftriaxone. **D.** Fourth generation: cefepime. Note that with each successive generation, the side groups become more complex. Highlighted areas indicate the core structure of each of the cephalosporins, with beta-lactam rings.

> **NOTE:** Archaea peptidoglycan contains talosaminuronic acid instead of muramic acid and lacks the D-amino acids found in bacterial peptidoglycan. Because of this, archaea are insensitive to penicillins, which interfere with bacterial transpeptidases.

Cell wall antibiotics target other steps in peptidoglycan synthesis. Another antibiotic that affects cell wall synthesis is **bacitracin**, a large polypeptide molecule produced by *Bacillus subtilis* and *Bacillus licheniformis* (**Fig. 27.10A**). The antibiotic inhibits cell wall synthesis by binding to the bactoprenol lipid carrier molecule that normally transports monomeric units of peptidoglycan across the cell membrane and to the growing chain (see **Fig. 27.7**). Bacitracin binds to and inhibits dephosphorylation of the carrier, thereby preventing the carrier from accepting a new unit of UDP-NAM. Resistance to bacitracin can develop if the organism can rapidly recycle the phosphorylated lipid carrier molecule through dephosphorylation or if the organism possesses an efficient drug export system (discussed in Section 27.6). Normally, bacitracin is used only topically because of serious side effects, such as kidney damage, that can occur if it is ingested.

Cycloserine (made by *Streptomyces garyphalus*) is one of several antimicrobials used to treat tuberculosis (**Fig. 27.10B**). Relative to bacitracin, it acts at an even earlier step in peptidoglycan synthesis. Cycloserine inhibits the two enzymes that make the D-ala-D-ala dipeptide. As a result, the complete pentapeptide sidechain on *N*-acetylmuramic acid cannot be made (see **Fig. 27.7**). Without these alanines, cross-linking cannot occur and peptidoglycan integrity is compromised.

Vancomycin, a very large and complex glycopeptide produced by *Amycolatopsis orientalis* (**Fig. 27.10C**), binds to the D-ala-D-ala terminal end of the disaccharide unit and prevents the action of transglycosylase and transpeptidases (see **Fig. 27.7**). The mechanism of resistance is very different for vancomycin and penicillin. This difference makes vancomycin particularly useful against penicillin-resistant bacteria. To prevent development and spread of vancomycin-resistant bacteria, this antibiotic is typically used only as a drug of last resort. Resistance can develop when products from a cluster of *van* genes collaborate to make D-lactate and incorporate it into the ester D-ala-D-lactate to which vancomycin cannot bind. Another enzyme in the *van* gene cluster prevents the accumulation of D-ala-D-ala; as a result, the lactate version is incorporated into peptidoglycan. Peptidoglycan containing D-ala-D-lactate

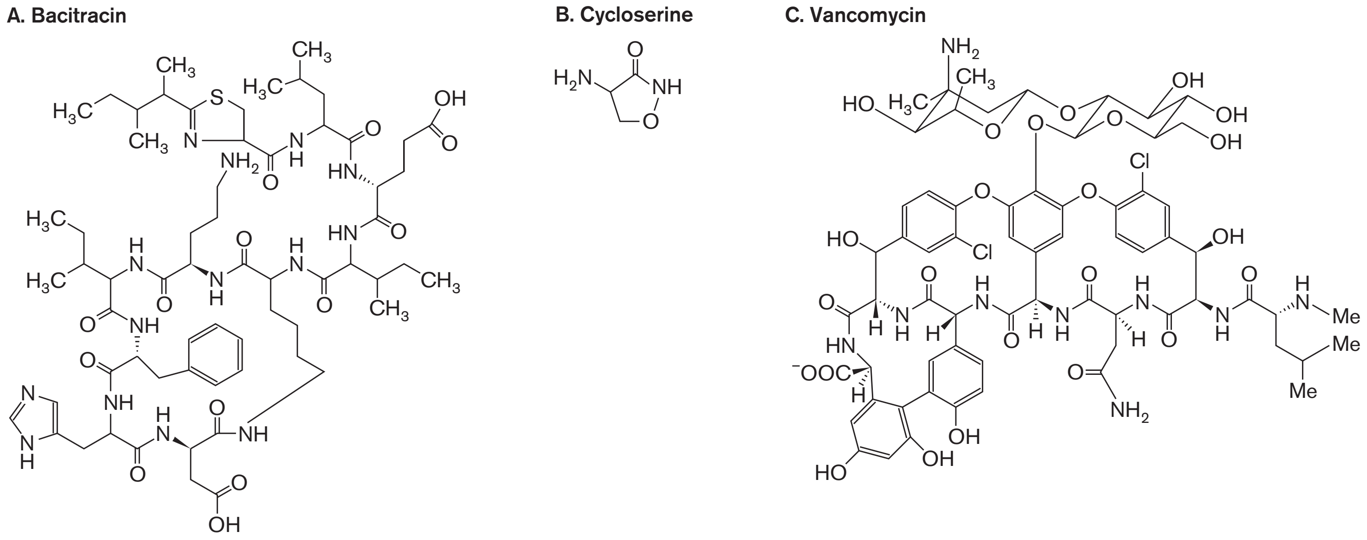

Figure 27.10 Other antibiotics that affect peptidoglycan synthesis. A. Bacitracin is produced by *Bacillus subtilis*. It is generally used only topically to prevent infection. **B.** Cycloserine, an analog of D-alanine, is one of several drugs used to treat tuberculosis. **C.** Vancomycin is a cyclic polypeptide made by *Amycolatopsis orientalis*, previously classified as a streptomycete. These antibiotics, especially bacitracin and vancomycin, are synthesized by exceedingly complex biochemical pathways in the producing organisms.

functions just fine, but since vancomycin cannot bind the D-lactate form, the organism is resistant to the antibiotic.

It is important to note that antibiotics targeting cell wall biosynthesis generally only kill *growing* cells. These drugs do not affect static or stationary phase cells because in this state the cell has no need for new peptidoglycan.

THOUGHT QUESTION 27.4 When treating a patient for an infection, why would combining a drug such as erythromycin with a penicillin be counterproductive?

Drugs That Affect Bacterial Membrane Integrity

Poking holes in a bacterial cytoplasmic membrane is an effective way to kill bacteria. There are a few compounds useful in this regard, among them a group called the peptide antibiotics, of which **gramicidin** is an example. Gramicidin, produced by *Bacillus brevis*, is a cyclic peptide composed of 15 alternating D- and L-amino acids. It inserts into the membrane as a dimer, forming a cation channel that disrupts membrane polarity (**Fig. 27.11**). Polymyxin (from *Bacillus polymyxa*), another polypeptide antibiotic, has a positively charged polypeptide ring that binds to the outer (lipid A) and inner membranes of bacteria, both of which are negatively charged. Its major lethal effect seems to be to destroy the inner membrane, much like a detergent. These antibiotics are used only topically to treat or prevent infection. Because they can also form channels across human cell membranes, they are never ingested. Polymyxin has been fused to some bandage materials used to treat burn patients who are particularly susceptible to gram-negative infections (e.g., *P. aeruginosa*).

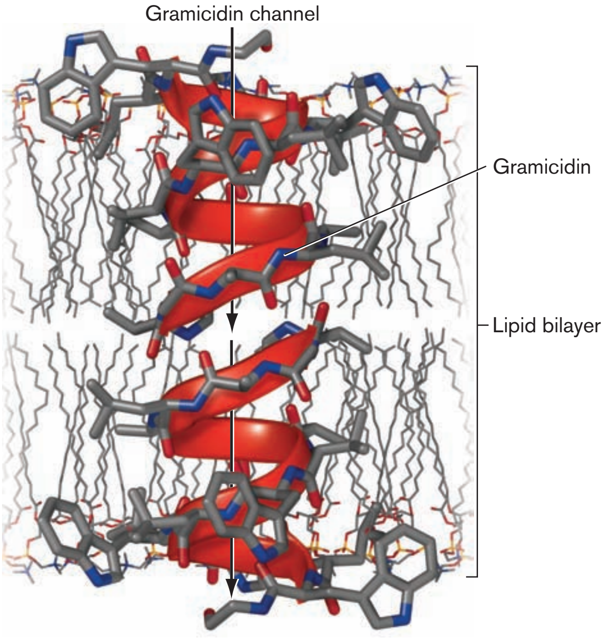

Figure 27.11 Gramicidin is a peptide antibiotic that affects membrane integrity. Gramicidin forms a cation channel through cell membranes through which H^+, Na^+, or K^+ can freely pass. (PDB code: 1grm)

Drugs That Affect DNA Synthesis and Integrity

Bacteria generally make and maintain their DNA using enzymes that closely resemble those of mammals. Thus, you might consider it impossible to selectively target bacterial DNA synthesis. As you will see, this is not the case.

Case History: Pneumonia Due to a Gram-Negative Anaerobe

A 23-year-old woman arrived at the emergency room by ambulance with fever, chills, and severe muscle aches. She developed a nonproductive cough, had difficulty breathing, had pleuritic chest pain, and became hypotensive (low blood pressure). An X-ray showed lower lobe infiltrate in the lungs, and the clinical laboratory reported the presence of the gram-negative anaerobe Fusobacterium necrophorum *in blood cultures. The patient was diagnosed with pneumonia and treated with metronidazole, a DNA-damaging agent specific for anaerobes. She fully recovered.*

There are several classes of drugs, including sulfa drugs, quinolones, and metronidazole, that selectively affect the synthesis or integrity of DNA in microorganisms.

Sulfa drugs. The sulfa drugs, originally discovered by Domagk, belong to a group of drugs known as antimetabolites because they interfere with the synthesis of metabolic intermediates. Ultimately, the sulfa drugs act to inhibit the synthesis of nucleic acids. Drugs such as sulfamethoxazole work at the metabolic level to prevent the synthesis of tetrahydrofolic acid (THF), an important cofactor in the synthesis of nucleic acid precursors (**Fig. 27.12**). All organisms use THF to synthesize nucleic acids, so why are the sulfa drugs selectively toxic to bacteria? The selectivity occurs because mammalians do not synthesize a precursor of THF called folic acid. Higher mammals generally rely on bacteria and green leafy vegetables as sources of folic acid. Bacteria make folic acid from the combination of PABA, glutamic acid, and pteridine. Sulfamethoxazole, a structural analog of PABA, competes for one of the enzymes in the bacterial folic acid pathway and inhibits both folic acid and THF production (**Fig. 27.12C**). Because humans lack that pathway, sulfa drugs are selectively toxic toward bacteria.

Quinolones. Another group of drugs inhibit DNA synthesis by targeting microbial topoisomerases such as DNA gyrase and topoisomerase IV (discussed in Section 7.2). Because these enzymes are structurally distinct from their mammalian counterparts, drugs can be designed to selectively interact with them without interfering with mammalian DNA metabolism. In 1963, one such drug, nalidixic acid, was discovered as a by-product of the synthesis of chloroquine, an antimalarial drug. Nalidixic acid, which targets DNA gyrase, has a very narrow antimicrobial spectrum, covering only a few gram-negative organisms. However, various chemical modifications, such as adding fluorine and amine groups, have increased its antimicrobial spectrum and its half-life in the bloodstream. The result is the class of drugs known as the **quinolones**. (The mode of action of quinolones and fluoroquinolones was discussed in Section 7.2.)

Metronidazole. Also known as Flagyl, metronidazole is an example of a drug that is harmless until activated, known as a prodrug. Metronidazole is activated after receiving an electron (is reduced) from the microbial protein cofactors flavodoxin and ferredoxin, found in microaerophilic and anaerobic bacteria such as *Bacteroides* (**Fig. 27.13**). Once activated, the compound begins nicking DNA at random, thus killing the cell. Because the etiological agent in our case history was an anaerobe, metronidazole was an effective therapy. Metronidazole is also effective against protozoans such as *Giardia* and *Entamoeba*. Aerobic microbes, although in possession of ferredoxin, are incapable of reducing metronidazole, presumably because oxygen is reduced in preference to metronidazole.

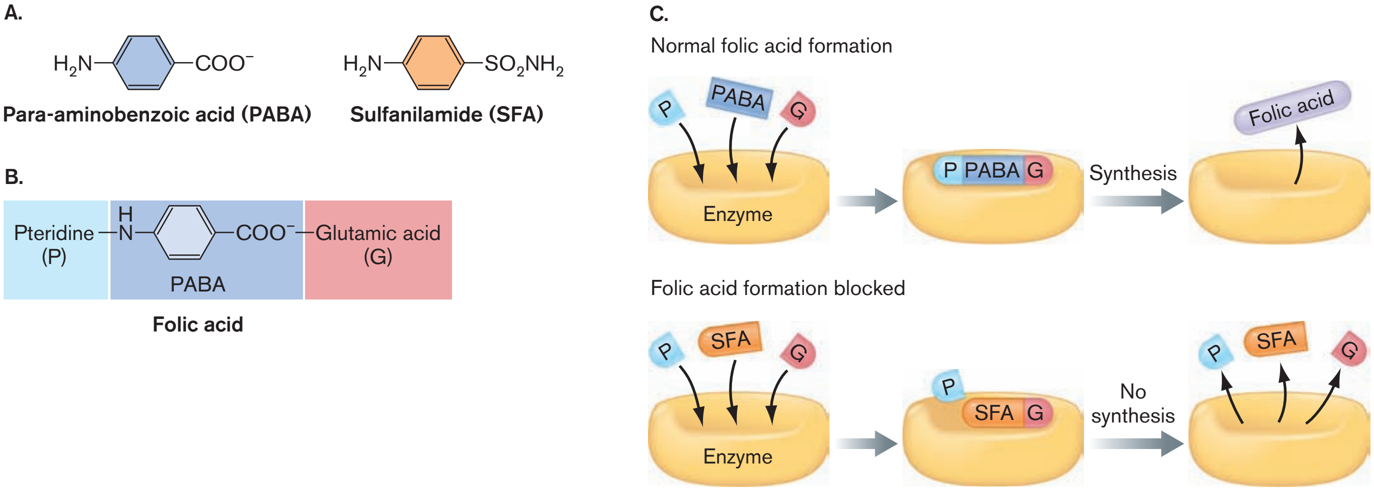

Figure 27.12 Mode of action of sulfanilamides. A. The structures of PABA and sulfanilamide are very similar. **B.** PABA, pteridine, and glutamic acid combine to make the vitamin folic acid. **C.** Normal synthesis of folic acid requires that all three components engage the active site of the biosynthetic enzyme. The sulfa drugs replace PABA at the active site. The sulfur group, however, will not form a peptide bond with glutamic acid, and the size of sulfanilamide sterically hinders binding of pteridine so folic acid cannot be made.

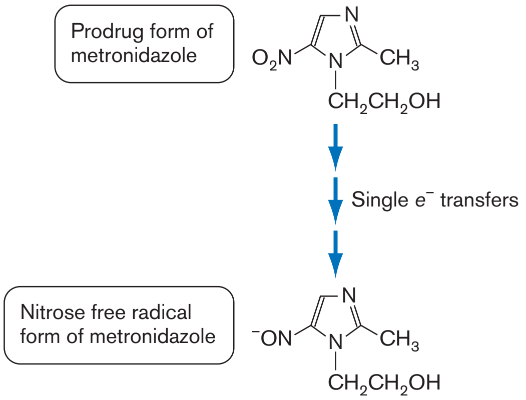

Figure 27.13 Activation of metronidazole. Single-electron transfers are made by ferredoxin and flavodoxin from anaerobes. Ferredoxin and flavodoxin are reducing agents capable of reducing very low redox potential compounds.

THOUGHT QUESTION 27.5 The enzyme DNA gyrase, a target of the quinolone antibiotics, is an essential protein in DNA replication. The quinolones bind to and inactivate this protein. Research has proved that quinolone-resistant mutants contain mutations in the gene encoding DNA gyrase. If the resistant mutants contain a mutant DNA gyrase and DNA gyrase is essential for growth, why are these mutations not lethal?

RNA Synthesis Inhibitors

Antibiotics that inhibit transcription, such as rifampicin and actinomycin D (**Fig. 27.14**), were described in Special Topic 8.1. These drugs are considered bactericidal in action and are most active against growing bacteria. The tricyclic ring of actinomycin D binds DNA from any source. As a result, it is not selectively toxic and not used to treat infections. Rifampin (also called rifampicin), on the other hand, does exhibit selective toxicity and is often prescribed for treatment of tuberculosis or meningococcal meningitis. Curiously, because rifampin is reddish orange, it turns bodily secretions, including breast milk, orange. The astute physician will warn the patient of this highly visible but harmless side effect to avoid unnecessary anxiety when the patient's urine changes color.

Protein Synthesis Inhibitors

The differences between prokaryotic and eukaryotic ribosomes account for the selective toxicity of antibiotics that specifically inhibit bacterial protein synthesis. How various antibiotics inhibit protein synthesis was discussed in Section 8.3. We recommend reviewing Chapter 8 for details. As a brief review, protein synthesis inhibitors can be classified into several groups based on structure and function (**Fig. 27.15**). Note that most of these antibiotics work by binding and interfering with the function of bacterial rRNA, which differs from eukaryotic rRNA. Also recall that protein synthesis inhibitors are, by and large, bacteriostatic.

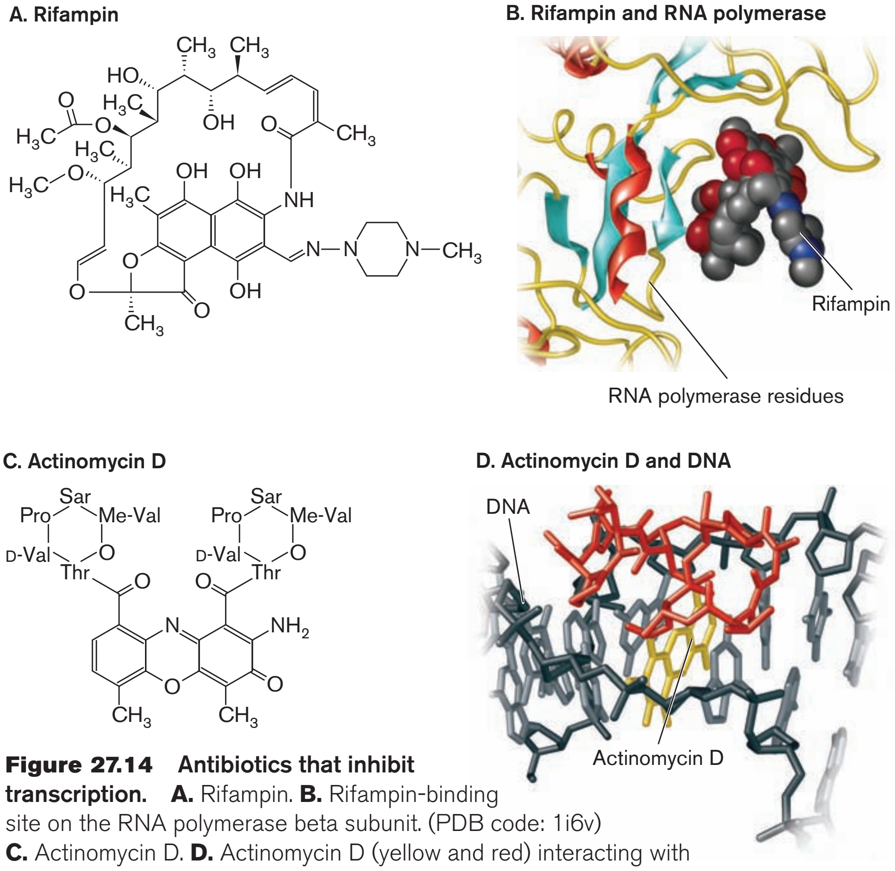

Figure 27.14 Antibiotics that inhibit transcription. A. Rifampin. **B.** Rifampin-binding site on the RNA polymerase beta subunit. (PDB code: 1i6v) **C.** Actinomycin D. **D.** Actinomycin D (yellow and red) interacting with DNA. Covalent intercalation of actinomycin interferes with DNA synthesis and transcription. (PDB code: 1DSC)

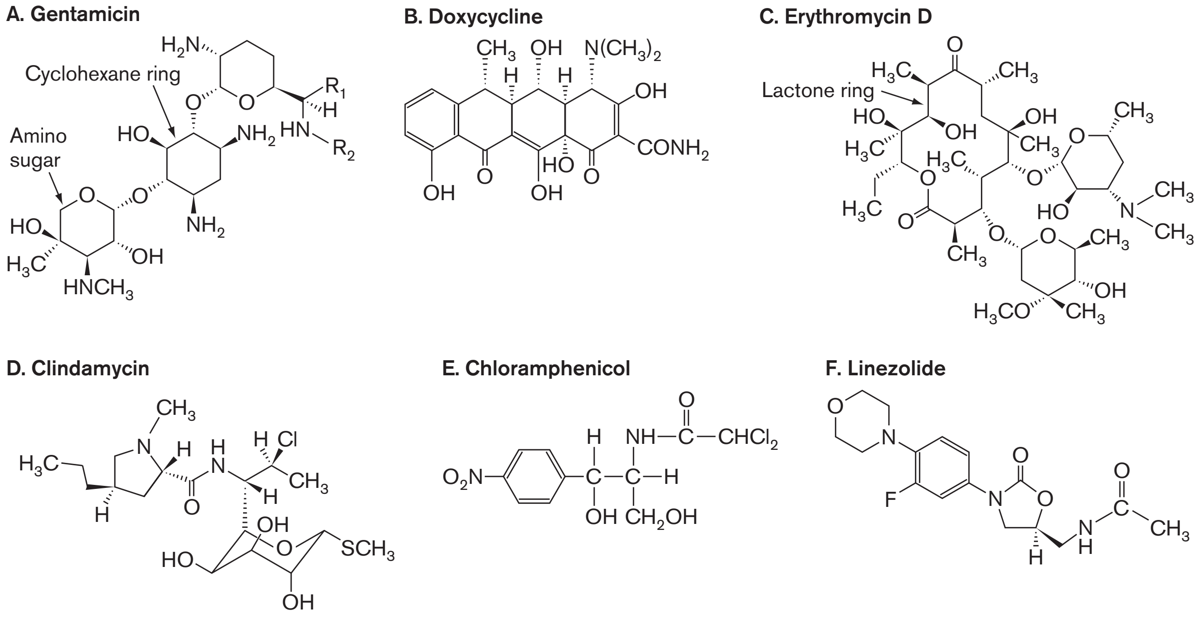
Case History: Erysipelas in a Penicillin-Sensitive Patient

Sixteen-year-old Jamal arrived at the emergency room after two days of fever, malaise, chills, and neck stiffness. His most notable symptom was a painful, red, rapidly spreading rash covering the right side of his face. The rash covered his entire cheek, which was swollen, and extended into his scalp. About seven days earlier, Jamal had a severe sore throat. However, since it subsided in two days, he was not clinically evaluated. Throat cultures taken on admission revealed group A Streptococcus pyogenes*, suggesting that the rash was a case of erysipelas caused by this organism. Although penicillin would be the drug of choice, Jamal is known to be allergic to this antibiotic.*



A. Gentamicin B. Doxycycline C. Erythromycin D D. Clindamycin E. Chloramphenicol F. Linezolide

Figure 27.15 Protein synthesis inhibitors. **A.** The aminoglycoside gentamicin. **B.** The tetracycline doxycycline. **C.** The macrolide antibiotic erythromycin. **D.** The lincosamide antibiotic clindamycin. **E.** Chloramphenicol. **F.** Linezolide.

When a patient is known to be immunologically sensitive to the usual drug of choice, a structurally distinct drug is best. Often, that drug will be one that inhibits protein synthesis; in this case, the drug chosen was the macrolide azithromycin. Drugs that inhibit protein synthesis can be subdivided into different groups based on their structures and on what part of the translation machine is targeted.

Drugs That Affect the 30S Ribosomal Subunit

The classification of antibiotics affecting protein synthesis is initially based on the bacterial ribosomal subunit targeted. Thus, one class of antibiotics interferes with 30S subunit function, and the other scrambles 50S subunit activities.

Aminoglycosides. There is considerable variation in structure among different aminoglycosides, but all contain a cyclohexane ring and amino sugars (**Fig. 27.15A**). The aminoglycosides are unusual among protein synthesis inhibitors in that they are bactericidal rather than bacteriostatic. Most of them bind 16S rRNA and cause translational misreading of mRNA, which is why these drugs are bactericidal. The resulting synthesis of jumbled peptides wreaks havoc with physiology and kills the cell. Streptomycin and gentamicin (see **Fig. 27.15A**) are two widely used drugs in this class. Ototoxicity (hearing damage) is a major, but uncommon, side effect of these antibiotics (approximately 0.5–3% of patients treated with gentamicin suffer from this toxicity). Hearing is generally affected at frequencies above 4,000 Hz.

Tetracyclines. Tetracycline antibiotics are characterized by a structure with four fused cyclic rings; hence the name. **Figure 27.15B** shows one frequently used example, called doxycycline. Tetracyclines are bacteriostatic and work by binding to and distorting the ribosomal A site that accepts incoming charged tRNA molecules. Doxycycline is used to treat early stages of Lyme disease (*Borrelia burgdorferi*), acne (*Corynebacterium acne*), and other infections. An important adverse side effect of tetracyclines is that they can interfere with bone development in a fetus or young child. Tetracycline use by pregnant mothers will also cause yellow discoloration of the infant's teeth. As a result, this drug is not recommended for pregnant women or nursing mothers.

Drugs That Affect the 50S Subunit

Five classes of drugs subvert translation by binding to the 50S ribosomal subunit. Most of these drugs were discussed in Chapter 8 and will be recapped here only briefly.

- **Macrolides**, all of which contain a 16-member lactone ring (**Fig. 27.15C**), inhibit translocation of the growing peptide (bacteriostatic action). Commonly prescribed examples are erythromycin and azithromycin. Azithromycin was the antibiotic used to treat the *S. pyogenes* infection in our case history, although other drugs could have been used. Because it is structurally dissimilar to any of the beta-lactam antibiotics, such as penicillin, it can be used safely in patients who are penicillin sensitive.

- **Lincosamides** (**Fig. 27.15D**), such as clindamycin, are similar to macrolides in function but have a different structure.
- **Chloramphenicol** (**Fig. 27.15E**) inhibits peptidyl transferase activity (bacteriostatic). Bone marrow depression leading to aplastic anemia is the most common serious side effect and limits its clinical use.
- **Oxazolidinones** (**Fig. 27.15F**) are a recently discovered class of antibiotics effective against many antibiotic-resistant microbes. In fact, this is the first new class of antibiotics discovered in over 35 years. Oxazolidinones such as linezolid bind to the 23S rRNA in the 50S subunit of the prokaryotic ribosome and prevent formation of the protein synthesis 70S initiation complex. This is a novel mode of action; other protein synthesis inhibitors either block polypeptide extension or cause misreading of mRNA. Linezolid binds to the 50S subunit near where chloramphenicol binds, but does not inhibit peptidyl transferase. Resistance is limited because most bacterial genomes have multiple operons encoding 23S rRNA. Usually more than one of these genes must mutate to confer high-level resistance. The more unmutated 23S rRNA genes there are, the more ribosomes susceptible to the antibiotic will be present. Oxazolidinones are useful primarily against gram-positive bacteria. Gram-negative bacteria are intrinsically resistant because of multidrug efflux pumps and decreased permeability due to the outer membrane.
- **Streptogramins** (**Fig. 27.16**), produced by some *Streptomyces* species, fall into two groups, A and B. Streptogramins belonging to group A have a large nonpeptide ring. Streptogramin B members are cyclic peptides. The two groups differ in their modes of action, although both inhibit bacterial protein synthesis by binding to the peptidyl transferase site. Group A streptogramins bound to the peptidyl transferase site distort the ribosome to prevent binding of tRNA to the ribosome A site. In contrast, group B streptogramins are thought to narrow the peptide exit channel, preventing exit of the peptide and thereby blocking translocation.

Natural streptogramins are produced as a mixture of A and B, the combination of which is more potent than either individual compound alone (an example of synergy). In tribute to this synergistic action, the drug combination is marketed under the name Synercid. Synergy between the two drugs occurs because the A type streptogramin alters the binding site for the B type drug, increasing its affinity. Bacteria can develop resistance either through ribosomal modification (the modification in 23S rRNA is the same one that provides resistance to macrolides), via the production of inactivating enzymes, or by active efflux of the antibiotic.

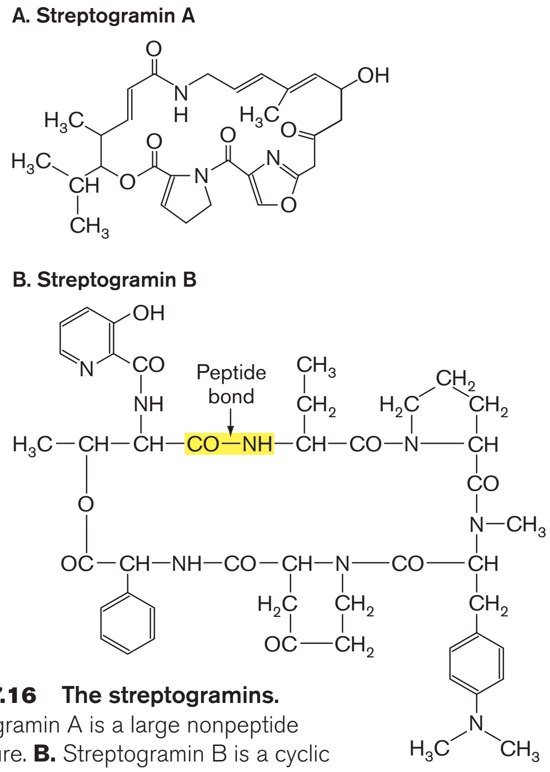


Figure 27.16 The streptogramins. **A.** Streptogramin A is a large nonpeptide ring structure. **B.** Streptogramin B is a cyclic peptide.

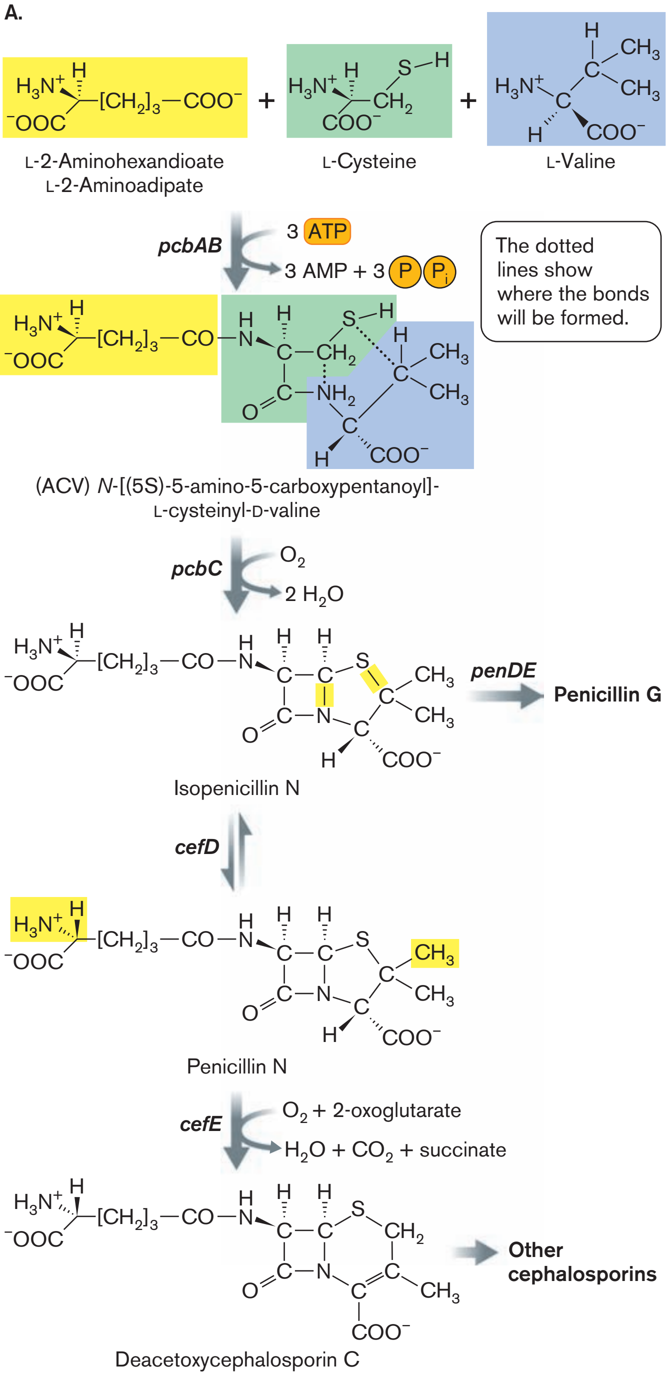
TO SUMMARIZE:

- **Antibiotic specificity** for bacteria can be achieved by targeting a process that occurs only in bacteria, not host cells; by targeting small structural differences between components of a process shared by bacteria and hosts; or by exploiting a physiological condition such as anaerobiosis present only in certain bacteria.
- **Antibiotic targets** include cell wall synthesis, cell membrane integrity, DNA synthesis, RNA synthesis, protein synthesis, and metabolism.
- **Antibiotics targeting the cell wall** bind to the transglycosidases, transpeptidases, and lipid carrier proteins involved with peptidoglycan synthesis and cross-linking.
- **Antibiotics interfering with DNA** include the antimetabolite sulfa drugs that inhibit nucleotide synthesis, quinolones that inhibit DNA topoisomerases, and a drug, metronidazole, that, when activated, randomly nicks the phosphodiester backbone.
- **Inhibitors of RNA synthesis** target RNA polymerase (rifampin) or bind DNA and inhibit polymerase movement (actinomycin D).
- **Aminoglycosides and tetracyclines** bind the 30S subunit of the prokaryotic ribosome.
- **A variety of antibiotics** bind the 50S ribosomal subunit and inhibit translocation (macrolides, lincosamides), peptidyl transferase (chloramphenicol), formation of 70S complex (oxazolidinones), or peptide exit through the ribosome exit channel (streptogramins).

Figure 27.17 Core biosynthetic pathway for penicillin and the cephalosporins. **A.** Penicillin and cephalosporins share a biochemical pathway. The *pcbAB*, *pcbC*, and *penDE* genes encode ACV synthetase, IPN synthase, and IPN acyltransferase, respectively. CefD is required to make penicillin N, a precursor of the cephalosporins, and CefE is a synthase that makes the first cephalosporin structure in the biosynthetic sequence.



27.5 Antibiotic Biosynthesis

Antibiotics are considered **secondary metabolites** because they often have no apparent use in the producing organism. This most likely means a purpose has yet to be identified. Although the production of antibiotics is thought to help one microbe compete with another in nature, growth inhibition may not have been the original purpose of secondary metabolite production. The relative complexity of the biosynthetic pathways suggests a more immediate purpose—for example, cell-cell signaling—that evolved into cross-species inhibition. Antibiotic biosynthetic pathways are sometimes relatively simple (as in penicillin) and sometimes quite complex. **Figure 27.17A** outlines the relatively straightforward biosynthetic pathway used to make penicillin and the related cephalosporins, all of which contain a beta-lactam ring. Note that the ring results from the joining of two amino acids, cysteine and valine. Several different types of fungi can produce these drugs. All use similar pathways and evolutionarily related genes (**Fig. 27.17B**).

Polyketide antibiotics such as erythromycin (**Fig. 27.15D**) are synthesized in a modular fashion by modular polyketide synthase enzymes (discussed previously in Special Topic 15.2). The synthesis strategy is reminiscent of the way fatty acids are made. Malonyl-ACP units containing different R groups are successively condensed by modular subunits of the polyketide synthase complex until elongation is terminated by the thioesterase. The repeating forms of polyketides enable these long-chain molecules to be synthesized by a small number of enzymes.

Curiously, the peptide antibiotics such as bacitracin or the gramacidins are not synthesized using ribosomes. Complex biosynthetic pathways are involved that do not rely on mRNA. Nonribosomal synthesis of peptide antibiotics is discussed in Section 15.6 and Special Topic 15.3.

One theory of why certain microbes make antibiotics is that they prevent the growth of competing organisms, but how do microbes that make antibiotics avoid committing suicide? Fungi that make penicillin do not face any consequence for having done so because the organism does not contain peptidoglycan. Actinomycetes that produce compounds such as streptomycin or chloramphenicol, however, could be susceptible to their own secondary metabolite. Ribosomes isolated from *Streptomyces griseus*, for example, are fully sensitive to the streptomycin produced by this organism. *S. griseus* avoids killing itself in two ways. First, the organism synthesizes an inactive precursor of streptomycin, 6-phosphorylstreptomycin, which is secreted from the cell and, once outside the mycelium, becomes activated by a specific phosphatase. In addition, this streptomycete has an enzyme that inactivates any streptomycin that may leak back into the mycelium. Other organisms protect themselves by methylating key residues on their rRNA to prevent drug binding or set up permeability barriers that thwart reentry of the antibiotic.

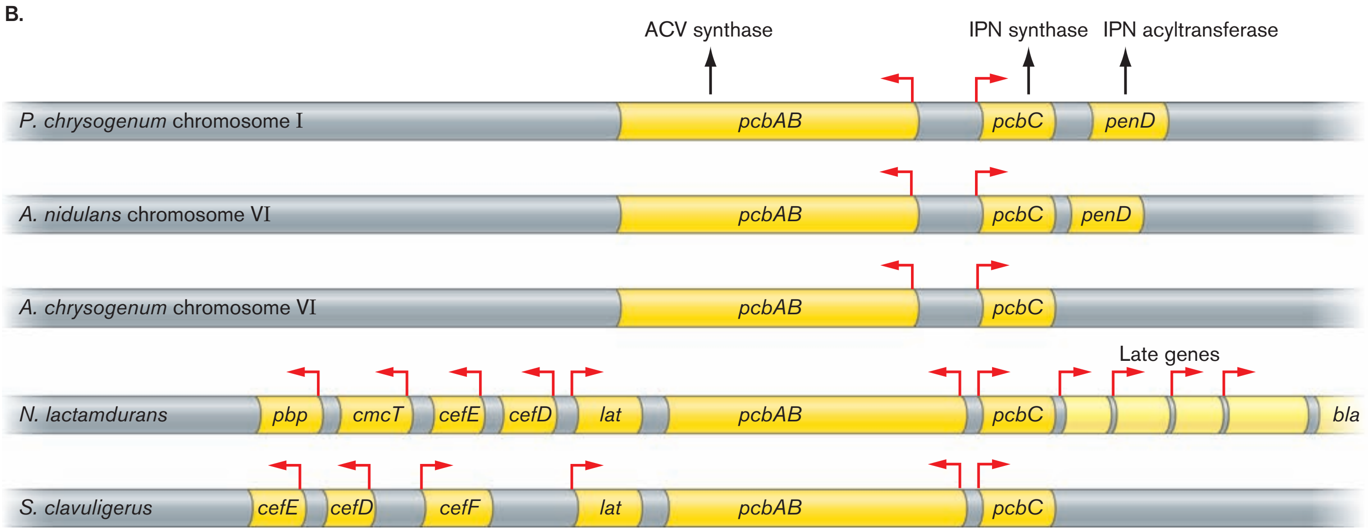


Figure 27.17 **(*continued*)** **B.** Penicillin gene clusters in various fungi that synthesize penicillins and cephalosporins. The arrows indicate the orientation of the genes. Note that the *pcbAB-pcbC* promoter region is transcribed bidirectionally. Genes involved in cephalosporin synthesis are labeled *cef.* The *bla* gene encodes a beta-lactamase that protects the producing organism *Nocardia lactamdurans* and appears to serve as an ancestral homolog to *bla* genes found in clinical pathogens.

THOUGHT QUESTION 27.6 Why might a combination therapy of an aminoglycoside antibiotic and cephalosporin be synergistic?

THOUGHT QUESTION 27.7 Could genomics ever predict the drug resistance phenotype of a microbe? If so, how?

TO SUMMARIZE:

- **Antibiotics are synthesized as secondary metabolites.**
- **Microbes may make antibiotics** to eliminate competitors in the environment.
- **Antibiotic producers prevent self-destruction** by various antibiotic resistance mechanisms.

27.6 The Challenges of Antibiotic Resistance

In this section, we discuss the various ways microbes can become resistant to antibiotics and explore the evolutionary road to resistance. In addition, we address how resistance moves between species and how we can deal with the spread of resistance throughout the world.

Case History: Multiple-Drug-Resistant Pneumonia

A 14-year-old boy with fever (39°C), chills, and left-sided pleuritic chest pain was referred to a hospital emergency department by his general practitioner. A chest X-ray showed left lower lobe pneumonia. The boy reported that he was allergic to amoxicillin and cephalosporins (as a child he had developed a rash to these agents) and had been taking daily doxycycline (tetracycline) for the previous three months to treat mild acne. He was admitted to the hospital and treated with intravenous erythromycin because of his reported beta-lactam allergies, but he continued to feel sick. The day after admission, both sputum and blood cultures grew Streptococcus pneumoniae*. After 48 hours, antibiotic susceptibility results indicated that the microbe was resistant to penicillin, erythromycin, and tetracycline. Armed with this information, the clinician immediately changed antibiotic treatment to vancomycin. The boy's fever resolved over the next 12 hours, and he made a slow but full recovery over the next week.*

Unfortunately the scenario presented in this case is far too common and has become an extremely serious concern. **Figure 27.18** illustrates the rapid rise of penicillin resistance among *S. pneumoniae* in the world. Another instance of emerging antibiotic resistance is unfolding in Europe and the Far East. The non-Enterobacteriaceae gram-negative rod *Acinetobacter baumanii* is increasingly seen as a dangerous cause of nosocomial infections. It commonly colonizes hospitalized patients, particularly those in intensive care units. Before 1998, there were almost no cases of multidrug-resistant *A. baumanii*. The rate is now as high as 8%. The organism is resistant to drugs as diverse as ciprofloxacin (a quinolone), amikacin (an aminoglycoside), penicillins, third-generation cephalosporins, tetracycline, and chloramphenicol. Imipenem, a relatively new class of beta-lactam drugs, is currently useful, but resistance to it is also likely to develop.

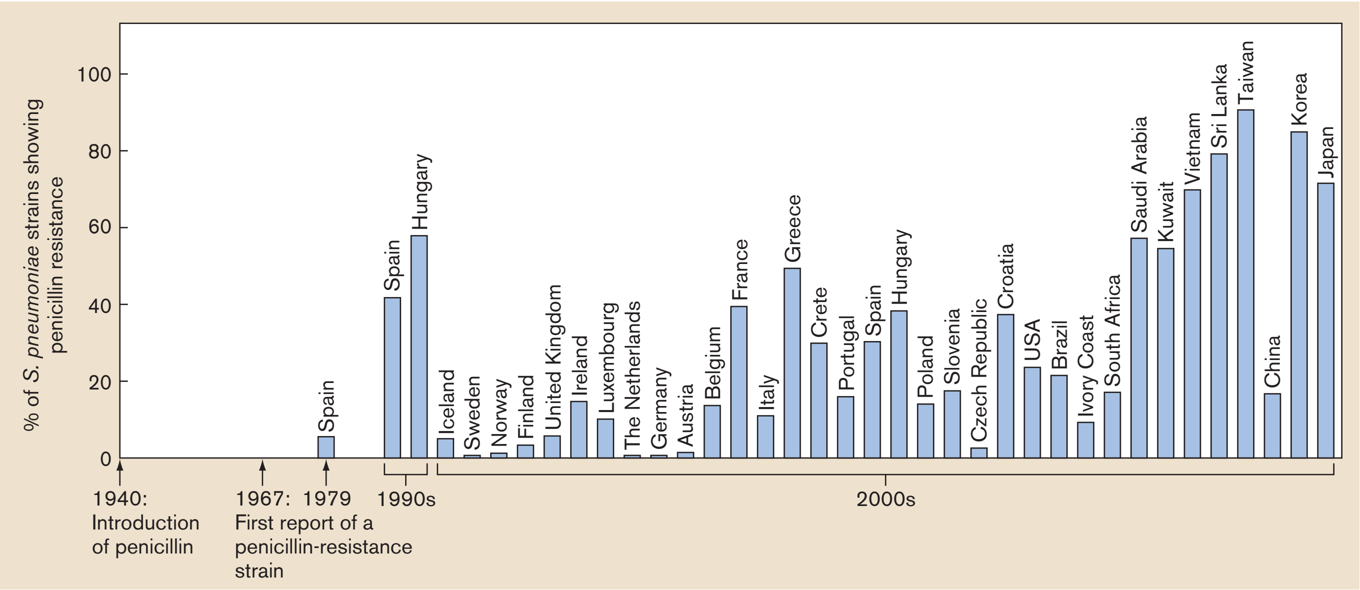

Figure 27.18 **The rise of penicillin-resistant *Streptococcus pneumoniae* throughout the world.** Numbers reflect the number of penicillin-resistant strains among clinical isolates (strains of disease-causing bacteria isolated from patients).

There are four basic forms of antibiotic resistance. The resistant organism can:

- **Modify the target so that it no longer binds the antibiotic.** Mutations in key penicillin-binding proteins and ribosomal proteins, for instance, can confer resistance to methicillin and streptomycin, respectively. These mutations occur spontaneously and are not typically transferred between organisms.
- **Destroy the antibiotic before it gets into the cell.** One example is the enzyme beta-lactamase (or penicillinase), which is made exclusively to destroy penicillins. The sites of ring cleavage and structure of the enzyme are illustrated in **Figure 27.19**.
- **Add modifying groups that inactivate the antibiotic.** For instance, there are three classes of enzymes that modify and inactivate aminoglycoside antibiotics. The results of these types of enzyme modifications are illustrated for kanamycin in **Figure 27.20**.
- **Pump the antibiotic out of the cell using specific (for example, tetracycline export) and nonspecific transport proteins.** This strategy works because the pumps bail drugs out of the cell faster than the drugs can get in. Some are single-component pumps present in the cytoplasmic membrane of gram-negative and gram-positive bacteria (for example, NorA in *S. aureus,* PmrA in *S. pneumoniae,* and the TetA and B proteins in gram-negatives). Other drug efflux pumps are multicomponent systems present in gram-negative bacteria only (discussed shortly). Efflux in either case is usually energized by proton motive force.

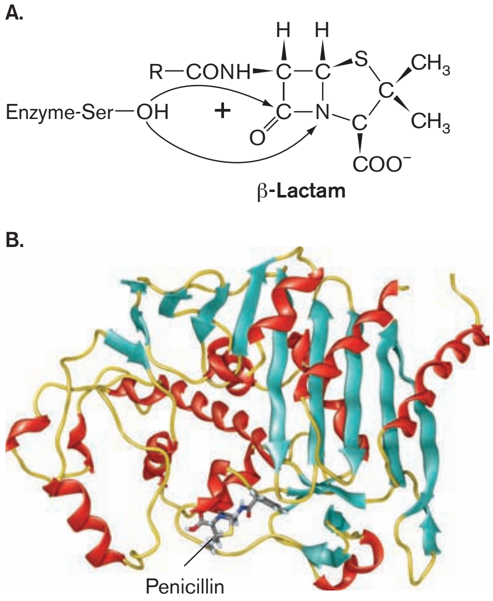

Figure 27.19 **Destroying penicillin.** **A.** Beta-lactamase (or penicillinase) cleaves the beta-lactam ring of penicillins and cephalosporins. There are two types of penicillinases, based on where the enzyme attacks the ring. In either type, a serine hydroxyl group launches a nucleophilic attack on the ring. **B.** Structure of a beta-lactamase and location of the penicillin-binding site. (PDB code: 1XX2)

THOUGHT QUESTION 27.8 Fusaric acid is a cation chelator that normally does not penetrate the *E. coli* membrane, which means *E. coli* is typically resistant to this compound. Curiously, cells that develop resistance to tetracycline become *sensitive* to fusaric acid. Resistance to tetracycline is usually the result of an integral membrane efflux pump that pumps tetracycline out of the cell. What might explain the development of fusaric acid sensitivity?

THOUGHT QUESTION 27.9 Mutations in the ribosomal protein S12 (encoded by *rpsL*) confer resistance to streptomycin. Given a cell containing both *rpsL*$^+$ and *rpsL*^{R} genes, would the cell be streptomycin resistant or sensitive? (Recall that genes encoding ribosome proteins for the small subunit are designated *rps*. A + indicates the wild-type allele, while R indicates a gene whose product is resistant to a certain drug.)

Figure 27.21 Basic structure of a multidrug efflux pump in gram-negative bacteria. These efflux systems have promiscuous binding sites that can bind and pump a wide range of drugs out of the bacterial cell.

A particularily dangerous type of drug resistance is mediated by what are called **multidrug resistance (MDR) efflux pumps** (**Fig. 27.21**). A single pump in this class can export many different kinds of antibiotics with little regard for structure. MDR pumps of gram-negative microbes are similar to the ABC export systems described in Section 4.2. They include three proteins: an inner membrane pump protein (fueled by proton motive force, a distinction from true ABC exporters), an outer membrane channel connected to the pump protein, and an accessory protein that may link the other two proteins. For instance, the ArcB transporter, shown in **Figure 27.22**, almost indiscriminately binds antibiotics in a large central cavity (a promiscuous binding site) and uses proton motive force to move those compounds through a pore and out of a funnel that connects to an outer membrane channel, TolC.

Antibiotic efflux pumps are now believed to contribute significantly to bacterial antibiotic resistance because of the very broad variety of substrates they recognize and because of their expression in important pathogens. Strains of the pathogen *M. tuberculosis*, for instance, have developed multiple drug resistance phenotypes due in part to MDR pumps. Approximately 2 million people die from tuberculosis annually, mostly in developing nations. What is even more alarming is that an increasing number of *M. tuberculosis* strains isolated from patients exhibit multidrug resistance. Although most of the antibiotic resistance in most *M. tuberculosis* multidrug resistant strains is due to the accumulation of independent mutations in several genes, MDR pumps are thought to increase the level of resistance. Chemists typically try to tweak the structure of an antibiotic to overcome a specific type of resistance mechanism; but the MDR pumps act on an exceptionally wide range of antibiotics, almost without regard to structure.

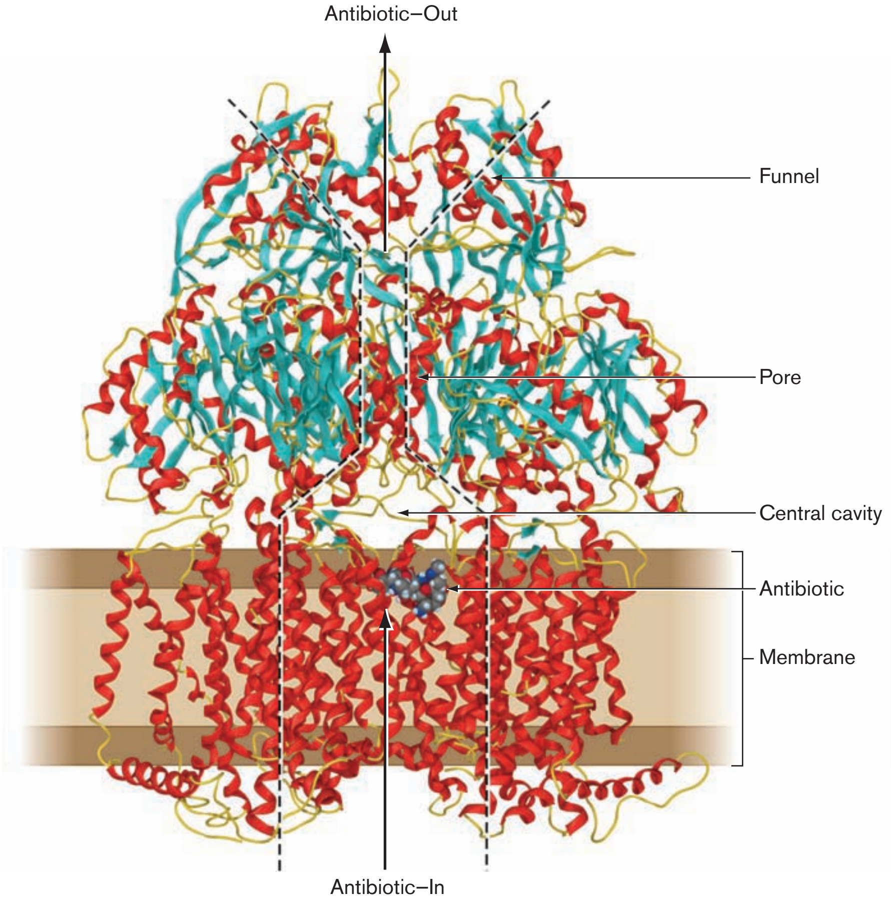

Figure 27.22 Structure of the *E. coli* ArcB multidrug resistance efflux pump. The structure is trimeric and driven by proton motive force. Dotted lines outline the central cavity, pore, and efflux funnel through which the drug is pumped. Connection to TolC in the outer membrane is not shown. (PDB code: 2GIF)

How Does Drug Resistance Develop?

As discussed in earlier chapters, nature has engineered a certain degree of flexibility in the way genomes are replicated and passed from one generation to the next. DNA repair pathways involving lesion bypass polymerases (for example, UmuDC; see Section 9.5) are thought to play a large role in randomized adaptive and evolutionary processes. For instance, at some point during evolution, gene duplication and mutational reshaping generated a gene product able to cleave the beta-lactam ring, creating an organism resistant to penicillin.

However, antibiotic resistance in all species does not occur de novo through gene duplication and/or mutation. Why reinvent the wheel—or, in this case, drug resistance? Gene transfer mechanisms such as conjugation, described in Chapter 9, can move antibiotic resistance genes from one organism to another and from one species to another. In fact, several drug resistance genes found in pathogenic bacteria actually had their start in the chromosomes of the drug-producing organisms and were passed on through gene swapping. For instance, *Streptomyces clavuligerus* produces a beta-lactamase (encoded by the *bla* gene) that protects this organism from the penicillin it produces. Transfer of a drug resistance gene is particularly evident if the gene has been incorporated into a plasmid and that plasmid is found in a new species.

An interesting case study of antibiotic resistance is provided by the gram-positive bacterium *Enterococcus faecalis*, a natural inhabitant of the mammalian gastrointestinal tract that can cause life-threatening disease if granted access to other body sites (as in subacute bacterial endocarditis; see Section 26.7).

E. faecalis is naturally resistant to numerous antibiotics, which makes disease treatment particularly challenging.

Vancomycin is one of the last lines of defense for treating serious *E. faecalis* infections. Unfortunately, increasing numbers of vancomycin-resistant strains have arisen in recent years. The completed genome sequence of one vancomycin-resistant strain illustrates the reason. The organism has an incredible propensity for incorporating mobile genetic elements that encode drug resistance. About a quarter of the genome consists of mobile or exogenously acquired DNA. These include 7 probable phages, 38 insertion elements, numerous transposons, and integrated plasmid genes. One such mobile element encodes vancomycin resistance in the sequenced strain.

Recently, multidrug resistance in various microbes (for example, *Salmonella enterica*) has also been attributed to the presence of integrons. Integrons are gene expression elements that account for rapid transmission of drug resistance because of their mobility and ability to collect resistance gene cassettes (see Special Topic 9.2).

We should note that the development of antibiotic resistance is not without consequence to the bacterium. Altering one aspect of an organism's physiology for the better may weaken another area. Bacteria may become resistant to a certain antibiotic, but that resistance comes at a price. For example, the altered DNA gyrase that affords resistance to quinolones may not function as well as the "normal" gyrase. Thus, in a situation where both resistant and susceptible organisms cohabit the same environment, the wild-type (sensitive) strain may grow faster and eventually overwhelm the mutant strain—unless fluoroquinolone is present, of course.

How Did We Get into This Mess?

Consider the following case: A young mother brings her 4-year-old child to the physician. The child is screaming because he has an extremely painful sore throat. Simply looking at the throat is not diagnostic. The raw tissue could mean the child is suffering from a bacterial infection, in which case antibiotics are needed. Alternatively, a virus could be the cause, a situation where antibiotics do nothing but pacify the parent. More often than not, the clinician will prescribe an antibiotic without ever knowing the cause of disease. The problem is this: the more an antibiotic is used, the more opportunities there are to select for an antibiotic-resistant organism. The presence of drug does not *cause* resistance but will kill off or inhibit the growth of competing bacteria that are sensitive, thereby allowing the resistant organism to grow to high numbers.

When *should* antimicrobials be administered? Certainly, in life-threatening situations where time is of the essence, antibiotics should be administered even before knowing the cause of the infection. On the other hand, the most prudent course to take when a patient has a simple infection is to confirm a bacterial etiology, and then prescribe. An exception to this may be in an elderly or otherwise immunocompromised individual, who may be more susceptible to secondary bacterial infections that can occur subsequent to viral disease.

Another proposed source of antibiotic resistance is the widespread practice of adding antibiotics to animal feed. No one quite knows why, but feeding animals antibiotics in their food makes for larger, and therefore more profitable, animals. Some estimates suggest that 70% of all antibiotics used in the United States is fed to healthy livestock. The consequence of this is that the animals may serve as incubators for the development of antibiotic resistance. Even if the resistance develops in nonpathogens, the antibiotic genes produced can be transferred to pathogens. Efforts have been under way since the 1960s to curb this practice.

Fighting Drug Resistance

Several strategies are being used to stay one step ahead of drug-resistant pathogens. In some instances, dummy target compounds that inactivate resistance enzymes have been developed. Clavulanic acid, for example, is a compound sometimes used in combination with penicillins such as amoxicillin. Clavulanic acid, a beta-lactam compound with no antimicrobial effect, competitively binds to beta-lactamases secreted from penicillin-resistant bacteria. Because the enzyme releases bound clavulanic acid very slowly, the amoxicillin remains free to enter and kill the bacterium. Another strategy is to alter the structure of the antibiotic in a way that sterically hinders the access of modifying enzymes. **Figure 27.23** illustrates how adding a side chain to gentamicin, converting it to amikacin, blocks the activity of various aminoglycoside-modifying enzymes. Of course, we are now seeing resistance to amikacin develop (this resistance is ribosome based, involving mutational alteration of the S12 protein or 16S rRNA).

Linking antibiotics is another strategy currently used to limit resistance. Recent advances have been made in linking a quinolone to an oxazolidinone to form a hybrid antibiotic with dual modes of action (**Fig. 27.24**). Because it has two modes of action, this hybrid antibiotic may limit the development of antibiotic resistance. Here's why: The rate of spontaneous resistance to a given antibiotic is roughly 1 out of 10^7 cells. For spontaneous resistance to develop to two antibiotics, that probability rises to 1 out of 10^{14}, making it very unlikely that an organism can become doubly drug resistant. However, multidrug resistance efflux pumps, integron cassettes, and plasmids carrying multiple antibiotic resistance genes can overwhelm that approach.

TO SUMMARIZE:

- **Antibiotic resistance** is a growing problem worldwide.
- **Mechanisms of antibiotic resistance** include modifying the antibiotic, destroying the antibiotic, altering the target to reduce affinity, and pumping the antibiotic out of the cell.
- **Multidrug resistance pumps** use promiscuous binding sites to bind antibiotics of diverse structure.
- **Antibiotic resistance can arise spontaneously** through mutation, can be inherited by gene exchange mechanisms, or can arise de novo through gene duplication and mutational reengineering.
- **Indiscriminate use of antibiotics** has significantly contributed to the rise in antibiotic resistance.
- **Measures to counter antibiotic resistance** include chemically altering the antibiotic, using combination antibiotic therapy, and adding a chemical decoy.

27.7 The Future of Drug Discovery

Is humankind doomed to a future where antibiotics will no longer work? The general consensus is no. Through prudent use of current antibiotics and innovative approaches for finding new ones, humans should continue to effectively control evolving bacterial pathogens.

How does one screen for new drugs that target specific proteins? Certainly the classic approach in which microbes, plants, and even animals collected from around the world are screened for their abilities to make new antibiotics is still valid and remains the most fruitful source of new drugs. However, the ability to search for novel bacterial drug targets or validate theoretical targets has been revolutionized by genome sequence analysis and associated genetic techniques. Powerful computational and bioinformatic methods are required in the initial identification and selection of molecular targets, followed by a series of postgenomic approaches to validate and characterize the targets, devise screens for effective inhibitor molecules, and pursue structure-based drug design to handle the inescapable emergence of future resistance.

The modern drug discovery process can be outlined as follows:

1. Identify new targets (such as unique essential enzymes) based on genomics.
2. Find or design compounds that inhibit the target in vitro and show that the inhibitory compound has actual antibacterial activity.
3. Show that the target within the bacterial cell is the same as the in vitro target.

4. Optimize the MICs against susceptible species by altering the compound's structure.
5. Examine the compound's spectrum of activity (gram-positive, gram-negative, aerobe, anaerobe, etc.) and the rate at which antibiotic resistance develops in pathogens.
6. Determine the new drug's toxicity to animals and humans, and its pharmacological properties (for instance, how long does it stay at therapeutic levels in a patient).

The functions of genes that constitute potential new drug targets fall into three broad categories: those required only for growth of bacteria in laboratory media (in vitro expressed genes), those required only for bacterial infection in vivo (the in vivo induced genes, discussed in Section 25.6), and those required for bacterial growth both in vitro and in vivo (housekeeping genes). Products of novel and essential genes falling into the second and third categories constitute new potential drug targets.

Take, for example, the case of *S. pneumoniae*. Twenty years ago, *S. pneumoniae* was uniformly sensitive to penicillin. Today, a growing number of strains have become resistant (as illustrated in the multiple-drug-resistant pneumonia case history presented earlier; also see **Fig. 27.18**). The discovery of proteins within this microbe that could potentially be targeted by new antibiotics would offer hope of future treatments. Recently, a computer-assisted strategy has helped identify several potential drug targets in this pathogen. The search consisted of scanning the pneumococcal genome for sequence motifs commonly found in cell-surface-exposed or virulence-related proteins of other bacteria.

One such motif, called the choline-binding domain (CBD), is used by a variety of bacteria to interact with host cells. These domains consist of repeats of 2–10 amino acids. The rationale used to find potential drug targets in the pneumococcus was to look for pneumococcal proteins that contain these domains. It was already known that various streptococcal species had one such protein, CbpA, which functions as a surface adhesin and plays an important role in nasopharyngeal colonization. By performing genome-wide searches with the C-terminal choline-binding region of *cbpA*, Khoosheh Gosink and his collaborators at St. Jude Children's Hospital (Memphis, TN) identified six genes predicted to encode CBD-containing proteins ranging from 20 to 80 kDa (CbpD, E, F, G, I, and J). They constructed mutations in each gene and tested the mutants for pathogenicity. Mutants defective in CbpG adhered poorly to nasopharyngeal cells and were less virulent in a mouse infection model. Therefore, CbpG appears to play an important role in invasion and infection of the mucosa and the bloodstream. Its structural similarity to proteases suggests that it may be an excellent candidate for target-based drug development because numerous chemical inhibitors of proteases already exist.

Another advance in drug design utilizes a combination of genomic and proteomic approaches. The basis of this technique is to develop fluorescent molecules that bind only to *active* proteins of a given family of proteins. The probes can be created by rational design in which knowledge of the active site structure allows chemists to engineer chemicals that interact with that site. A true inhibitor of that protein and thus, a potential antibiotic, will prevent binding of the tagged probe, an event that can be viewed after directly blotting cell extracts on a membrane filter, much like a Western blot. In the absence of inhibitor, the probe will bind the spot, which will fluoresce. However, the presence of an inhibitor that binds well to the active site will prevent binding of the probe and the spot will not fluoresce.

Alternatively, if the probe binds to more than one protein, the same test can be performed using gel electrophoresis separation techniques. Proteins are separated on a nondenaturing gel so that the protein in question will retain its shape and its ability to bind probe. Tagged probe, with or without a potential inhibitor, is added to duplicate gels or a blot of those gels. The protein band will fluoresce in the absence of inhibitor or in the presence of a poor inhibitor. The band will not light up if an effective inhibitor is present.

The inhibitors are often made using more or less random combinatorial chemistry techniques, in which random variations of a molecule are created and tested. A library of these related compounds, which could number in the thousands, is robotically screened for inhibitory activity.

Genomic and combinatorial chemistries are certainly the cutting edge of antibiotic discovery. However, the old brute force screening of natural products was recently used in a novel way to discover a promising new class of antibiotic. Merck scientists screened 250,000 natural product extracts for an ability to specifically inhibit bacterial fatty acid biosynthesis. Fatty acid biosynthesis is an attractive target for antibiotic development because the process and proteins involved are different from those of eukaryotes. The strategy specifically targeted the protein FabF because it is an essential component of fatty acid synthesis and is conserved among key pathogens such as *S. aureus*.

Scientists engineered a strain of *S. aureus* to contain a gene expressing an antisense RNA to *fabF* mRNA. When the antisense RNA was induced, it bound to *fabF* mRNA and prevented efficient translation. As a result, the level of FabF protein in the cell decreased. The strain could still grow but would be exquisitely sensitive to any compound that targeted the remaining FabF protein. Fewer molecules of FabF present per cell means that fewer molecules of an active ingredient in a natural product are needed to stop fatty acid synthesis. Thus, zones of inhibition on an agar plate will be wider than they would be if cells produced normal amounts of FabF.

This novel targeted screening method led to the discovery of the antibiotic platensimycin, made by *Streptomyces platensis*, an organism isolated from South African soil. Platensimycin was subsequently shown to bind FabF and exhibit bacteriostatic, broad-spectrum activity, acting on gram-positive and gram-negative bacteria. It is only the third entirely new antibiotic developed in the last four decades. The novel chemical structure of platensimycin and its unique mode of action provide a great opportunity to develop a new class of critically needed antibiotics—a class that selectively targets fatty acid synthesis. More information on fatty acid biosynthesis and inhibitors can be found in Chapter 15.

Another type of rationale for developing new antimicrobial compounds is presented in **Special Topic 27.1**.

TO SUMMARIZE:

- **Potential targets for rational antimicrobial drug design** include proteins expressed only in vivo or proteins expressed both in vivo and in vitro.
- **Candidate antimicrobial compounds** can be designed to interact at the active site of a known enzyme and inhibit its activity.
- **Combinatorial chemistry** is used to make random combinations of compounds that can be tested for enzyme inhibitory activity and antimicrobial activity.

27.8 Antiviral Agents

A father pleading with a physician to give his child antibiotics when the infant is suffering with a cold is an all too common dilemma faced by the general practitioner, but there is nothing of substance the physician can do. The common cold is caused by the rhinovirus, and no antibiotic designed for bacteria can touch it. So why are there so few antiviral agents in the clinician's arsenal? The reason is that applying the principle of selective toxicity is much harder to achieve for viruses than it is for bacteria. Viruses routinely usurp host cell functions to make copies of themselves. Thus, a drug that hurts the virus is likely to also harm the patient. Nevertheless, there are several useful antiviral agents in which selective viral targets have been found and exploited. Some of these agents are listed in **Table 27.4**. Select examples are discussed in this section. Note that all of the molecular mechanisms of viruses presented in Chapter 11 are studied as potential drug targets.

Antiviral Agents That Prevent Virus Uncoating or Release

Membrane-coated viruses are vulnerable at two stages: when the virus is invading the host cell and after viral propagation, when the progeny viruses release from the host cell. The flu virus presents a good example of both.

Case History: Antiviral Treatment of Infant Influenza

A 9-month-old infant arrived at the Johns Hopkins Hospital with an acute onset of fever, cough, regurgitation from his gastrostomy feeding tube, and dehydration. This illness occurred following a series of chronic problems, including respiratory syncytial virus bronchiolitis (infection and inflammation of the bronchioles) and neonatal group B streptococcal sepsis. [Neonatal sepsis is often caused by Lancefield group B Streptococcus agalactiae *described in Chapter 28.] Physical*

Table 27.4 Examples of antiviral agents.

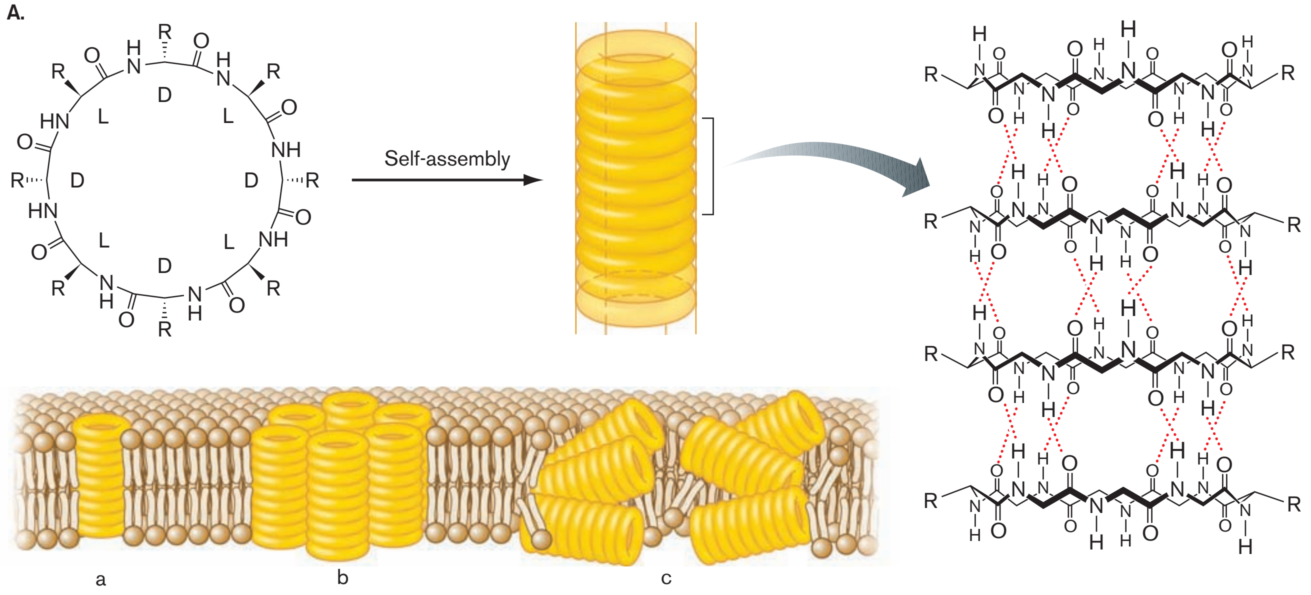
Virus	Agent	Mechanism of action	Result
Influenza	Amantadine	Inhibits viral M2 protein	Prevents viral uncoating
	Zanamivir	Neuraminidase inhibitor	Prevents viral release
Herpes simplex virus and varicella-zoster virus (shingles)	Acyclovir	Guanosine analog	Halts DNA synthesis
	Famciclovir	Prodrug of penciclovir a guanosine analog	Halts DNA synthesis
Cytomegalovirus	Gancyclovir	Similar to acyclovir	
	Foscarnet	Analog of inorganic phosphate	Binds and inhibits virus-specific DNA polymerase
Respiratory synticial virus and chronic hepatitis C	Ribavirin	RNA virus mutagen	Causes catastrophic replication errors
HIV	Zidovudine (AZT)	Nucleoside analog, resembles thymine	Inhibits reverse transcriptase
	Nevirapine	Binds to allosteric site	Inhibits reverse transcriptase
	Nelfinavir	Protease inhibitor	Prevents viral maturation

Special Topic 27.1 Poking Holes with Nanotubes: A New Antibiotic Therapy

Reza Ghadiri and his colleagues at the Scripps Research Institute have designed tiny peptide molecules that will self-assemble within bacterial membranes to form lethal nanotubes that puncture the cell surface (**Fig. 1A**). The component parts of the tube are six- and eight-residue cyclic D, L alpha peptides. Built with alternating right- and left-handed amino acids joined end to end, the peptides expose their amino acid side chains outside of the ring. (In nature, the great majority of peptides contain only left-handed L-amino acids, but synthetic peptides can use both right- and left-handed forms.) This alternating D and L configuration allows adoption of a planar ring structure and stacking of rings to form a tube. Ghadiri and his colleagues were able to design the amphipathic peptides to insert themselves selectively into bacterial cell membranes (differences in the phospholipid content of mammalian and bacterial membranes enables selective toxicity). Once the peptides enter the charged environment of the bacterial membrane, they become sticky and form hollow, antiparallel, hydrogen-bonded stacks (**Fig. 1B**).

These nanotubes effectively poke holes in the membrane and disrupt the normal electrical potential and ion gradients that bacteria use to maintain homeostasis, generate energy, and carry out chemical reactions necessary for survival. By forming nanotubes and poking holes in the cells, cyclic peptides disrupt these gradients and kill the cells. This is not just a theoretical whimsy. The authors have found these peptides to be highly effective in curing methicillin-resistant *S. aureus* infections in mice. Questions of selectivity and toxicity have yet to be addressed, so it will be years before the use of nanotubes in humans can be realized.

Sources: Fernandez-Lopez, S., H.-S. Kim, E. C. Choi, M. Delgado, J. R. Granja, et al. 2001. Antibacterial agents based on the cyclic D, L-α-peptide architecture. *Nature* 412:452–455. Dartois, V., J. Sanchez-Quesada, E. Cabezas, E. Chi, C. Dubbelde, et al. 2005. Systemic antibacterial activity of novel synthetic cyclic peptides. *Antimicrobial Agents and Chemotherapy* 49:3302–3310.



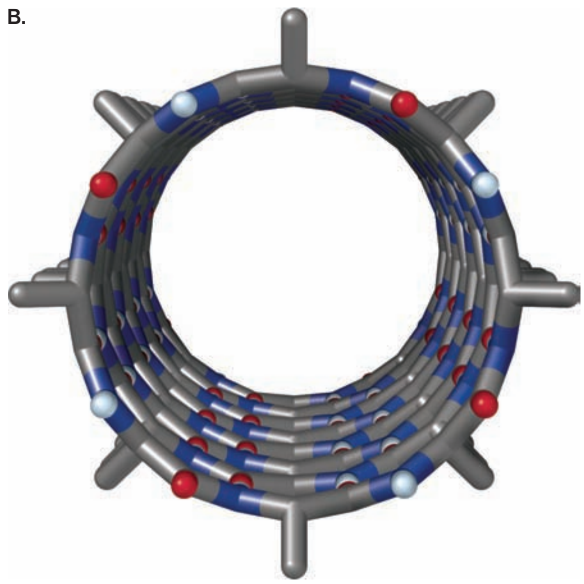


Figure 1 Antibiotic nanotubes. A. The diagram on the left illustrates the cyclic nature of peptides that form nanotubes. R groups define different amino acids shown as single letter designations inside the ring. The cyclic peptides possess outward facing side chains that allow them to stack via hydrogen bonds (red dotted lines) within a membrane structure to form penetrating nanotubes. The lower figure shows a bacterial membrane under nanotube attack. (Cyclic peptides are depicted as ring structures. There are three possible sequence-dependent modes of membrane permeation; a, intramolecular pore; b, barrel stave; and c, carpet-like). Nanotubes operating through the carpet-like mode of action would have a greater potential for membrane discrimination because of its polyvalent display of surface-exposed hydrophilic side chains for potential interactions with various membrane constituents. **B.** A top view down a nanotube.

exam revealed fever, a severe cough resulting in respiratory distress, a rapid heart rate, and moderate dehydration. Nasopharyngeal aspirate was positive for influenza A antigen. The patient was treated with amantadine when influenza was diagnosed. He gradually improved and was discharged home four days after admission.

An unusually severe form of influenza spread across the United States in 2003. Most states reported a higher than normal number of influenza-related deaths of children and young adults. Several factors, however, helped keep the outbreak from becoming an epidemic of larger proportions. First, the administration of flu vaccine afforded the population what is called herd immunity (discussed in Section 26.9). Herd immunity occurs even when only a fraction of a population is immunized. This fraction of individuals will not become infected and so cannot spread the disease to others. At the very least, this slows progression of infection throughout the population. (It is impossible to immunize all humans against any given disease. However, it is estimated that immunizing two-thirds of a population can eliminate the disease by cutting off transmission. Even this, however, is rarely achieved.)

The second factor that prevented an influenza pandemic was the availability of antiviral agents that can limit the disease course. As a result of studying the molecular biology of influenza, scientists discovered two selective targets. Influenza virus (200 nm) is encased in a membrane envelope donned when the virion buds from an infected cell. As described in Section 11.4, the envelope contains the viral proteins neuraminidase and hemagglutinin. Spikes of hemagglutinin bind to glycoprotein receptors on the host cell and trigger receptor-mediated endocytosis. The virus ends up inside the resulting endosome. After the endosome is formed, proton pumps in the membrane acidify endosomal contents. The drop in pH changes the structure of hemagglutinin on the viral membrane so it can now bind to receptors on the endocytic membrane. The result is fusion of the two membranes and release of the virion into the cytoplasm. For this change in hemagglutinin structure to occur, it is essential that the *interior* of the enveloped virion also be acidified, and this is facilitated by the formation of a channel by the virus-encoded M2 envelope protein. Amantadine (**Fig. 27.25A**), a drug that has been used to treat some strains of the flu virus, is a specific inhibitor of the influenza M2 protein; however, it is useful against the influenza type A viral strains only. It is also effective against the avian H5N1 strain that has occasionally infected humans and is feared as the source of a future influenza pandemic. Unfortunately, amantadine-resistant strains are circulating in Asia due in part to the widespread use of amantadine by Chinese poultry farmers.

The second target of the influenza virus is the envelope protein neuraminidase. The newer antiflu drugs, such as zanamivir (Relenza), are **neuraminidase inhibitors** that act against types A and B influenza strains (**Figs. 27.25B** and **C**). Neuraminidase on the viral envelope allows virus particles to leave the cell in which they were made. Neuraminidase inhibitors prevent this release and cause the virus particles to aggregate at the cell surface, reducing the number of virus particles released. The contributions of different NA and HA genes on the severity of influenza are discussed in **Special Topic 27.2**.

Amantadine and the neuraminidase inhibitors, when used within 48 hours of disease onset, decrease shedding and reduce the duration of influenza symptoms by approximately one day. However, flu symptoms generally last only from three to ten days. While this does not sound like a substantial benefit, in the elderly, shortening the course of the flu can minimize damage to the lungs, which in turn reduces the chance of developing life-threatening secondary bacterial infections such as pneumonia and bronchitis.

Antiviral DNA Synthesis Inhibitors

Most antiviral agents work by inhibiting viral DNA synthesis. These drugs chemically resemble normal DNA nucleosides, molecules containing deoxyribose and analogs of

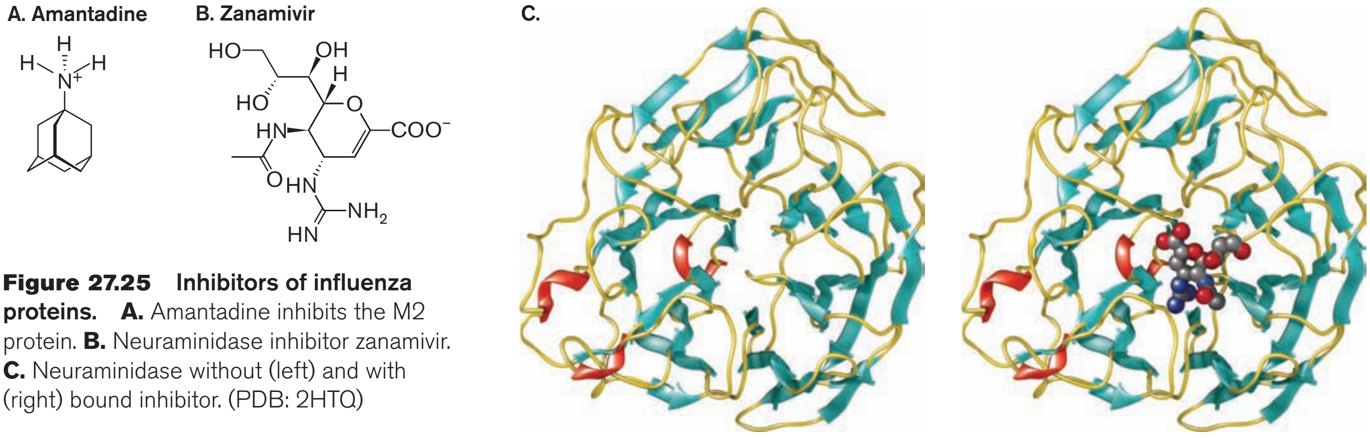

Figure 27.25 Inhibitors of influenza proteins. A. Amantadine inhibits the M2 protein. **B.** Neuraminidase inhibitor zanamivir. **C.** Neuraminidase without (left) and with (right) bound inhibitor. (PDB: 2HTQ)

Special Topic 27.2 Critical Virulence Factors Found in the 1918 Strain of Influenza Virus

As Chapter 26 describes, the influenza virus that swept the globe from 1918 to 1919 took the lives of 20–40 million people, making it a killer greater than the first World War. One might wonder whether today's drugs could prevent a similar disaster should that virus strain reemerge after all these years. This question may now have been answered.

A team of scientists working in a fortresslike biohazard research facility has used forensic molecular biology techniques to partially re-create that deadly virus. Their initial goal was to determine why the 1918 virus was so lethal compared with typical influenza strains, but they also wanted to learn if the antivirals on hand today could avert a 1918-like disaster.

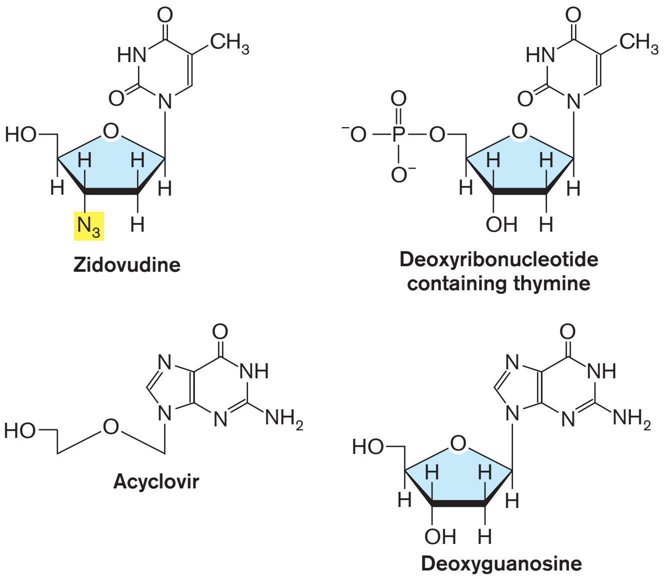
Christopher F. Basler, of the Mount Sinai School of Medicine in New York, and his colleagues incorporated several genes from the 1918 flu into an influenza strain that was adapted to kill mice. The viral genes introduced included those that encode hemagglutinin (HA), neuraminidase (NA), and protein M2. The team actually expected that those genes would *reduce* the virulence of the mouse-adapted virus. This was because flu viruses isolated from people rarely prove lethal to rodents, and genes from human-adapted strains typically weaken the rodent-adapted viruses. Not so for the HA and NA genes of the 1918 flu.

The engineered virus containing both of the 1918 HA and NA genes efficiently killed mice, but the presence of only one or the other of the two genes lowered virulence. This suggests that the *specific combination* of HA and NA may underlie the 1918 flu disaster. Even more remarkable was that treating the recombinant virus-infected mice with an NA inhibitor prevented 90% of the mice from dying. Furthermore, all mice infected with a recombinant flu strain carrying the 1918 gene for M2 survived when treated with M2 inhibitors, even if treatment began 6 hours after infection. The conclusion is that HA and M2 are critical components of influenza virulence. Thus, the currently available flu drugs targeting HA and M2 may help prevent a new pandemic of the 1918 influenza strain or a similar flu, such as the H5N1 avian flu.

adenine, guanine, cytosine, or thymine. Viral enzymes then add phosphate groups to these nucleoside analogs to form DNA nucleotide analogs. The DNA nucleotide analogs are then inserted into the growing viral DNA strand in place of a normal nucleotide. Once inserted, however, new nucleotides cannot attach to the nucleoside analogs, and DNA synthesis stops (**Fig. 27.26**). These DNA chain-terminating analogs are selectively toxic because viral polymerases are more prone to incorporate nucleotide analogs into their nucleic acid than are the more selective host cell polymerases. Antiviral DNA synthesis inhibitors work on DNA viruses or retroviruses, but not on viruses such as influenza with its RNA genome.

Case History: Treatment of HIV

A married couple come to the community clinic for prenatal care. He is 20 years old. She is 19 and reportedly two months pregnant with her first child. She denies intravenous (IV) drug use or a history of other sexual partners and has no history of sexually transmitted disease; however, a routine prenatal HIV antibody screen is reported as positive for HIV-1. Careful questioning of the patient and her husband elicits from him a history of IV drug use five years earlier. An HIV antibody screen for him is also positive. The laboratory results indicate that the wife may not yet require therapy (she has a low viral load—that is, less than 1,000 copies per milliliter of blood—and a high CD4 T-cell count), but since she is pregnant, a short course of antiretroviral therapy (AZT) will be helpful in preventing the transmission of the virus to her child. The husband had an HIV viral load of 10,000 copies per milliliter and was started on protease inhibitor treatment.



Zidovudine

Deoxyribonucleotide containing thymine

Acyclovir

Deoxyguanosine

Figure 27.26 **Antiviral inhibitors that prevent DNA synthesis.** Zidovudine (AZT) and acyclovir are analogs of thymine and guanine nucleotides, respectively. Because the analogs have no 3′ OH to which another nucleotide can add, chain elongation ceases.

Nucleoside and Nonnucleoside Reverse Transcriptase Inhibitors

Human immunodeficiency virus (HIV) is an RNA retrovirus that uses a reverse transcriptase to make DNA that then integrates into host nuclear DNA to form a provirus (discussed in Section 11.5). The antiretroviral drug zidovudine (abbreviated ZDV or AZT), which was used in the case history, is a nucleoside analog recognized by reverse transcriptase. Once incorporated into a replicating HIV DNA molecule, the DNA chain-terminating property of AZT prevents further DNA synthesis. Because HIV transmission from the mother to the neonate can occur at delivery or by breast-feeding, treatment of the mother and the child are important steps to prevent transmission.

There are also nonnucleoside reverse transcriptase inhibitors. For example, the drug delavirdine binds directly to reverse transcriptase and allosterically inactivates the enzyme.

Because HIV can mutate rapidly and become resistant to single-drug therapies, treatment usually involves administering combinations of three or more antiretroviral drugs.

Protease Inhibitors

To make optimum use of its limited provirus DNA sequence, HIV makes long nonfunctional polypeptide chains that are proteolytically cleaved to make the actual proteins and enzymes used to replicate and produce new virions. For example, the *gag* and *pol* genes reside next to each other in the HIV genome and are transcribed as a single mRNA molecule (discussed in Chapter 11). The Gag and Pol open reading frames overlap but are offset from one another by one base. This mRNA produces two polyproteins called Gag and Gag-Pol, the latter being the result of a shift in reading frames that takes place during translation. Once made, both polyproteins are cleaved by HIV protease. The Gag protein is proteolytically cleaved to make different capsid components (p17, p24, and p15, which is further cleaved to make nucleocapsid protein p7), while Gag-Pol is cleaved to make reverse transcriptase and integrase (**Fig. 27.27A**). Protease inhibitors such as Viracept® and Lopinavir® are a powerful new class of drugs that block the HIV protease (**Fig. 27.27B**). When the protease is inactivated, even though new virus particles are made, the polyproteins remain uncleaved and the virus cannot mature. Because immature HIV particles cannot infect other cells, progress of the disease stalls. It is important to note that protease inhibitors do not cure AIDS; they can only decrease the number of infectious copies of HIV.

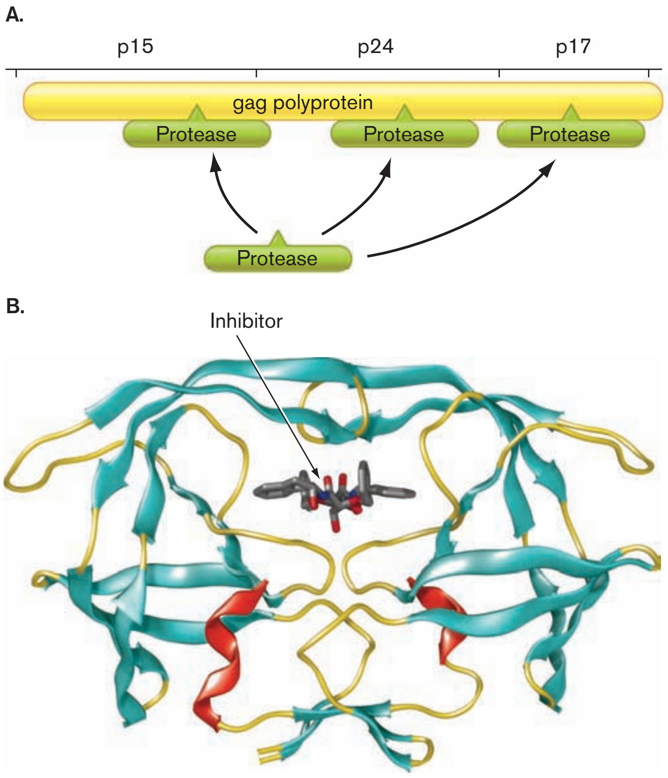


Figure 27.27 HIV protease inhibitor. A. Representation of HIV protease cleavage of a single gag polyprotein into multiple, smaller proteins. **B.** The protease enzyme is shown as a ribbon structure, while the protease inhibitor BEA 369 is shown as a stick model. (PDB code: 1EBY)

Antiviral therapy with protease inhibitors is recommended for patients with symptoms of AIDS and for asymptomatic patients with viral loads above 30,000 copies per milliliter. Treatment should be considered even for patients with viral loads above 5,000 copies per milliliter, as for the husband in the case history presented earlier.

TO SUMMARIZE:

- **Fewer antiviral agents** are available when compared to antibacterial agents because it is harder to identify viral targets that provide selective toxicity.
- **Preventing viral attachment to, or release from, host cells** are mechanisms of action for antiviral agents such as amantadine and Zanamivir used to treat influenza virus.
- **Inhibiting DNA synthesis** is the mode of action for most antiviral agents, although they only work for DNA viruses and retroviruses.
- **HIV treatments** include reverse transcriptase inhibitors that prevent synthesis of DNA and protease inhibitors that prevent the maturation of viral polyproteins into active forms.

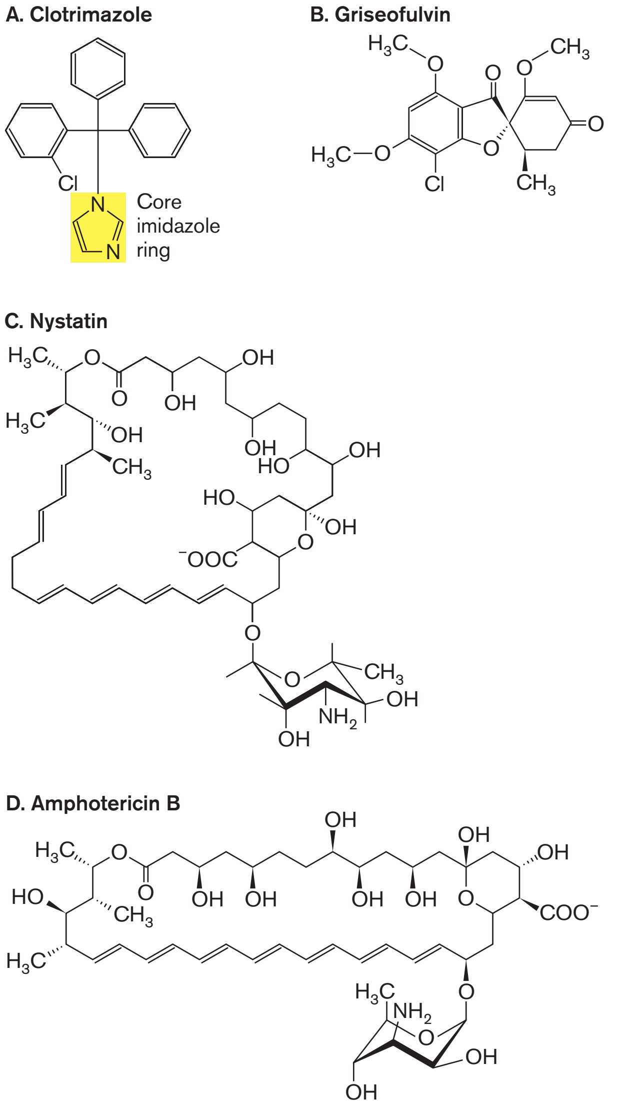
27.9 Antifungal Agents

Fungal infections are much more difficult to treat than bacterial infections in part because fungal physiology is more similar to that of humans than is bacterial physiology. The other reason is that fungi have an efficient drug detoxification system that modifies and inactivates many antibiotics. Thus, to have a fungistatic effect, repeated applications of antifungal agents are necessary to keep the level of unmodified drug above MIC levels.

Case History: Blastomycosis

A 37-year-old male presented to the emergency department of a Florida hospital with persistent fever, malaise, and a painful right arm mass. He denied trauma to the arm. White blood cell count was elevated at 27,000/µl, and chest X-ray revealed a left lung infiltrate. Bronchoscopy revealed granulomatous inflammation containing a single yeast-like mass. Incision and drainage was performed on the arm mass and cultures obtained. Serum cryptococcal antigen tests were negative, as were tests for Bartonella henselae *and* Toxoplasma. *Cultures from the right arm grew out a fungal form similar to that identified from the bronchoscopy specimens. A tentative diagnosis of* Blastomyces dermatitides *was confirmed using PCR. The patient was placed on amphotericin B, and his fevers and leukocytosis subsequently subsided. His medication was changed to fluconazole for a recommended duration of six months.*

Superficial **mycoses** (fungal infections), such as athlete's foot, and systemic mycoses, such as blastomycosis, require very different treatments. Imidazole-containing drugs (clotrimazole, miconazole) are often used topically in creams for superficial mycoses (**Fig. 27.28A**). Others, such as itraconazole, are administered orally. Superficial mycoses include infections of the skin, hair, and nails, as well as *Candida* infections of moist skin and mucous membranes (for example, vaginal yeast infections). The imidazole-containing drugs appear to disrupt the fungal membrane by inhibiting sterol synthesis. More chronic dermatophytic infections typically require another antifungal agent called **griseofulvin**, produced by a *Penicillium* species (**Fig. 27.28B**). Griseofulvin disrupts the mitotic spindle and derails cell division (called metaphase arrest). This does not kill the fungus, but as the hair, skin, or nails grow and are replaced, the fungus is shed. Vaginal yeast infections caused by *Candida* are often treated with **nystatin**, a polyene antifungal agent synthesized by *Streptomyces* that forms membrane pores (**Fig. 27.28C**). The name *nystatin*, by the way, came about because two of the people who discovered it worked for the New York State Public Health Department.



A. Clotrimazole

B. Griseofulvin

C. Nystatin

D. Amphotericin B

Figure 27.28 Examples of antifungal agents. **A.** Clotrimazole belongs to the group of imidazole antifungals, which are so named because they all contain an imidazole ring. **B.** Griseofulvin is produced by *Penicillium griseofulvum*. **C.** Nystatin is a polyene macrolide produced by *Streptomyces noursei*. **D.** Amphotericin B is a polyene produced by *Streptomyces nodosus*.

The serious, sometimes fatal consequences of systemic mycoses require more aggressive therapy. The drugs used in these instances include **amphotericin B** (produced by *Streptomyces*; see **Fig. 27.28D**) and fluconazole. Amphotericin B binds to the sterols in fungal membranes and destroys membrane integrity. It has a high affinity for ergosterol, which is prevalent in fungal, but not mammalian, membranes. Fluconazole, on the other hand, inhibits the synthesis of ergosterol. Thus, fungal cells grown in the presence of fluconazole make defective membranes. Typically, curing systemic fungal infections

requires long-term treatment to prevent disease relapse. **Table 27.5** lists a number of other commonly used antifungal agents.

TO SUMMARIZE:

- **Fungal infections** are difficult to treat because of similarities in human and fungal physiologies.
- **Imidazole-containing** antifungal agents inhibit sterol synthesis.
- **Griseofulvin** inhibits mitotic spindle formation.
- **Nystatin** produces membrane pores.
- **Amphotericin B** binds to membranes and destroys membrane integrity.

Concluding Thoughts

Antibiotics have done much to improve the health and well-being of people and animals around the globe. Although they have successfully kept at bay infectious diseases dreaded for centuries (such as the plague and tuberculosis), a crisis of antibiotic resistance looms because of the irresponsible use of antimicrobial agents. The fact that very few new, clinically useful antimicrobials have been discovered over the last quarter century should give us pause. Redoubling efforts to find new drugs combined with the responsible use of existing antibiotics are required to maintain our advantage over constantly evolving pathogens.

CHAPTER REVIEW

Review Questions

1. What is selective toxicity? Provide examples.
2. Explain the difference between antibiotic susceptibility and antibiotic sensitivity.
3. What does the term *spectrum of antibiotic activity* mean?
4. Provide examples of bacteriostatic and bactericidal antibiotics.
5. What is the Kirby-Bauer test? Does it tell whether a drug is bacteriostatic or bactericidal?
6. Give examples of drugs that target cell wall synthesis; RNA synthesis; protein synthesis; DNA replication. What are their modes of action?
7. What is the mechanism by which peptide antibiotics are synthesized by the producing organism?

Clinical application				
	Opportunistic mycoses

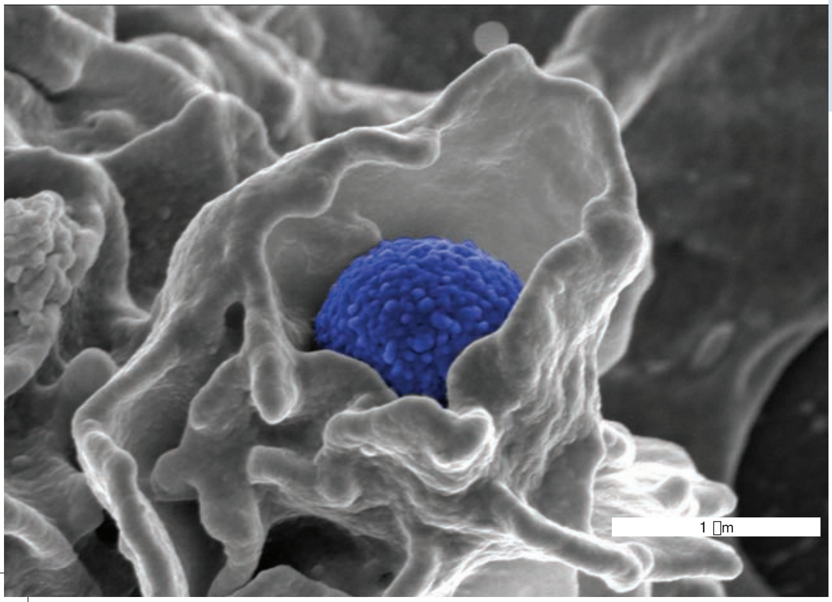
Chapter 28

Clinical Microbiology and Epidemiology

28.1 Principles of Clinical Microbiology
28.2 Approaches to Pathogen Identification
28.3 Specimen Collection
28.4 Biosafety Containment Procedures
28.5 Principles of Epidemiology
28.6 Detecting Emerging Microbial Diseases

Throughout history, infectious diseases have killed more people than all of our wars combined. Our present success in controlling the spread of disease is due in large part to worldwide surveillance agencies that are equipped to detect outbreaks quickly, before major epidemics develop. These agencies rely on smaller clinical microbiology laboratories scattered throughout the world. These laboratories help clinicians diagnose infectious diseases.

This chapter discusses the principles of clinical microbiology and epidemiology that are used to identify, treat, and contain outbreaks. How do clinical laboratories know what organisms to suspect in a given case? And what tests will unequivocally identify the right pathogen? How are the *real* pathogens found among the normal flora? Finding the *source* of an outbreak is also critical. How do epidemiologists identify "patient zero" and recognize and contain emerging diseases? Last but not least, we'll consider bioterrorism. Clinical scientists and epidemiologists are trained to detect bioterrorist attacks using the same principles they employ to detect naturally occuring infectious diseases.



Community-acquired methicillin-resistant *S. aureus* (in blue) destroys a neutrophil attempting to phagocytose it, thus breaching the body's first line of defense. Recent outbreaks of community-acquired MRSA have become a serious health problem.

Wilfrid Saintilus lay immobile on a straw mat when first seen by Dr. Paul Farmer in 1996. The 33-year-old peasant farmer had been sent home without hope by health care workers in a small clinic near his village in Haiti. He was pronounced "paralyzed from the waist down"; it was said that "nothing more could be done." Farmer, however, quickly realized that Wilfrid's problem was not paralysis but a long-term *Salmonella* infection, very likely contracted from an unclean drinking water supply—a problem for 80% of Haiti's population. Farmer realized that, while normally a gastrointestinal pathogen, *Salmonella* can occasionally disseminate via the bloodstream and infect bones, causing a painful disease called osteomyelitis. The microbe had infected Wilfrid's hip, causing pain so severe he could not move. His leg muscles had atrophied over time, and he now weighed under 100 pounds. Contrary to prediction, Wilfrid did not die. Dr. Farmer's diagnostic skills and antibiotics saved his life.

Thousands of stories like this, most with more tragic outcomes, underscore the integral roles that clinical microbiology and epidemiology have in health care. In Wilfrid's case, a simple laboratory test would have revealed a fully treatable *Salmonella* infection and prevented his enormous physical and emotional pain.

As in Chapters 24–27, we use case histories in this chapter to introduce various strategies and methodologies used by modern medicine to diagnose infectious diseases. The approach is, by necessity, selective. Not all techniques, nor all diseases, can be described. Our goal is not to catalog the many kinds of infectious diseases but to demonstrate general principles and problem-solving approaches used in identifying disease-causing microbes. It will become apparent in the process that modern tools of clinical microbiology are indispensable in the diagnosis and treatment of infectious disease.

28.1 Principles of Clinical Microbiology

As in any good detective mystery, the first step in investigating an infectious disease is to identify the most likely suspects. This can be accomplished, in part, from observing the disease symptoms in a patient and knowing what organisms typically produce those symptoms. It also helps if the physician is aware of a similar disease outbreak under way in the community. Beyond these clues, the etiological agent must be identified through biochemical, molecular, serological, or antigen detection strategies.

Why Take the Time to Identify an Infectious Agent?

This is the first question many students ask when contemplating the effort and expense required to identify the genus and species of an organism causing an infection. Why not simply treat the patient with an antibiotic and be done with it? While this approach sounds appealing, there are several compelling reasons for identifying an infectious agent.

Many bacteria are resistant to certain antibiotics. As discussed in Chapter 27, antibiotic resistance is an increasingly serious global problem. Characterizing a microbe's antibiotic resistance profile is thus part of any microbial identification process. Understanding which antibiotics are effective in treating an infectious agent will help the physician avoid prescribing an inappropriate drug. Furthermore, knowing which drugs are ineffective enables health organizations to track the spread of antibiotic-resistant strains. For example, before 1970, most strains of *Neisseria gonorrheae* were susceptible to penicillin. Today, most are penicillin resistant, due in part to the widespread use of penicillin to treat gonorrhea during and after the Vietnam War, when U.S. soldiers first contracted penicillinase-producing *N. gonorrhoeae* (PPNG).

There are strain-specific disease complications. Many diseases have serious complications that are common to a given organism or strain of organism. For example, children whose sore throats are caused by certain strains of *Streptococcus pyogenes* can develop serious complications affecting the heart and kidney long after the infection has resolved. These complications are the immunological consequence of bacterial and host antigen cross-reactivity; they are called **sequelae** because they occur *after* the infection itself is over. Life-threatening sequelae such as rheumatic fever and acute glomerular nephritis caused by certain strains of *S. pyogenes* produce severe damage to the heart and kidney, respectively. Knowing early on that *S. pyogenes* has caused a child's sore throat allows the physician to prescribe antibiotics that will quickly eradicate the infection and prevent development of the sequelae.

NOTE: Penicillin or a penicillin-like antibiotic is the usual treatment for *S. pyogenes* infection. Contrary to what you might expect, *S. pyogenes* has not developed any penicillin-resistant strains.

Tracking the spread of a disease can lead to its source. Consider a situation in which ten infants scattered throughout a city develop bloody diarrhea. The clinical laboratory identifies the same strain of *Shigella sonnei*, a gram-negative bacillus, as the cause in each case. Finding the same strain in all cases suggests they probably originated from the same source. Shigellosis is transferred from person to person by what is called the fecal-oral route. Carriers of *Shigella* will shed this organism in their feces. Inadequate hand washing after defecation will leave bacteria on their hands, which can then transfer the pathogen to foods or utensils or to another person by touching. Uninfected persons can become infected after eating the contaminated food or placing their fingers in their mouth.

Public health officials, armed with the knowledge that all the patients had the same strain of *Shigella*, then question the parents and learn that all of the children attend the same day-care center. By testing the other children and workers in that center, officials can stop the infection, called shigellosis, from spreading. This investigative process, called epidemiology, is covered more completely later in this chapter.

TO SUMMARIZE:

Identifying a pathogen enables us to:

- Use appropriate **antibiotics**, if necessary.
- Anticipate possible **sequelae**.
- **Track the spread** of the disease.

28.2 Approaches to Pathogen Identification

Pathogens can be identified on the basis of a variety of observations, including the patient's symptoms, finding organisms in stained clinical specimens, biochemical clues, and serology (the presence in a patient's serum of antibodies reactive against a specific microbe).

Bacterial Pathogen Identification Requires Knowledge of Microbial Physiology and Genetics

Thousands of bacterial species are capable of causing disease. How can a laboratory quickly, sometimes within hours, identify which one causes a given infection? The solution, in part, comes from knowing the biochemical and enzymatic features of these bacteria. Because no two species have the same biochemical "signature," the clinical lab can look for reactions, or combinations of reactions, that are unique to a given species.

The same is now true at the genetic level. In the current genomics-dominated era, DNA sequences of many pathogens have been completely elucidated. This has enabled design of polymerase chain reaction (PCR) primers that rapidly detect species-specific genes or even genes that are unique to highly pathogenic strains within a species. One example of such a gene is the attaching and effacing locus (*eae*) that is present in enterohemorrhagic, but not commensal, strains of *E. coli*. Finding *E. coli* in a fecal stool sample is not unusual. Finding *E. coli* with the *eae* gene, however, indicates that it is a pathogen.

Case History: Medical Detective Work

A 38-year-old woman with no significant previous medical history came to the emergency room complaining of a mild sore throat persisting for three days. Her symptoms included arthralgia (joint pain), myalgia (muscle pain), and low-grade fever. The day before, she had a severe headache with neck stiffness, nausea, and vomiting. She was not taking any medications, had no known drug allergies, and did not smoke. She lived with her husband and two children, all of whom were well. Cerebral spinal fluid (CSF) was collected from a spinal tap. The CSF appeared cloudy (it should be clear) and contained 871 white blood cells per microliliter (normal is 0–10/μl); the glucose level was 1 mg/dl (normal is 50–80 mg/dl); and the total protein level was 417 mg/dl (normal is under 45 mg/dl). Gram stain of a CSF smear revealed gram-negative rods. The CSF sample was sent to the diagnostic laboratory for microbial identification.

As discussed in Thought Question 26.6, low glucose and elevated protein levels in CSF are indicators of *bacterial* infection, not viral. The increase in white blood cells revealed that the woman's immune system was trying to fight the disease. The presence of gram-negative rods in the CSF smear confirmed a diagnosis of bacterial meningitis, since CSF should be sterile. Now it was up to the clinical laboratory to determine the etiological agent.

Clinical Laboratories Use Problem-Solving Algorithms to Identify Bacteria

How does a clinical microbiology laboratory handle incoming specimens such as the one considered here? What are the first steps toward identifying the etiological agent of a disease? Over the years, clinical microbiologists have developed algorithms (step-by-step problem-solving procedures) that expose the most likely cause of a given infectious disease. For instance, there are only a limited number of microbes known to cause meningitis. The microbiologist poses a series of binary "yes" or "no" questions about the clinical specimen in the form of biochemical or serological tests. Typical questions in this case might include: "Is an organism seen in the CSF of a patient with symptoms of meningitis?" "Is the organism gram-positive or gram-negative?" "Does it stain acid-fast?" Answers to a first round of questions will then dictate the next series of tests to be used.

Because speed is of the essence in deciding how to treat the patient, a series of tests is not always carried out sequentially. To save time, a slew of tests are carried out simultaneously, but the results are *interpreted* sequentially based on the algorithm. In our case history, for instance, consider the most common causes of bacterial meningitis: *Neisseria meningitidis*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Escherichia coli*. The CSF sample was

Gram-stained by a microbiologist and simultaneously plated onto three media—chocolate agar, blood agar, and Hektoen agar. Chocolate agar is an extremely rich medium that looks brown owing to the presence of heat-lysed red blood cells (**Figs. 28.1A** and **B**). Because it is so nutrient-rich, all four organisms will grow on chocolate agar. However, nutritionally fastidious organisms such as *N. meningitidis* and *H. influenzae* will not grow well, if at all, on ordinary blood agar because these bacteria cannot lyse red blood cells and release required nutrients. Less fastidious organisms, such as *S. pneumoniae* and *E. coli*, will grow on blood agar, but only *E. coli* can grow on Hektoen agar (**Figs. 28.1C–E**), which is a selective and differential medium for enteric gram-negative rods. Differential and selective media are described in Section 4.3.

In our case history, the Gram stain of the CSF revealed gram-negative rods, which ruled out *Neisseria* (a gram-negative diplococcus) and *Streptococcus pneumonia* (a gram-positive diplococcus). The organism in CSF did grow on blood agar, which eliminated *Haemophilus influenzae* (a gram-negative, nonenteric rod) as a candidate. It also grew on Hektoen, where it produced orange lactose-fermenting colonies. Thus, the organism was a gram-negative, enteric rod and likely *E. coli*. Additional biochemical tests confirming the identity of the organism had to be carried out, but this simple example shows how simultanteous tests can be interpreted.

Identifying gram-negative bacteria. The gram-negative bacterium in this case was subjected to a battery of biochemical tests packaged as 20 separate chambers in a patented analytical profile index (API 20E) strip that can be used for pathogen identification (**Fig. 28.2**). The strip

Figure 28.1 Chocolate agar and Hektoen agar; two widely used clinical media. A. Uninoculated chocolate agar. Its color is due to gently lysed red blood cells that provide a rich source of nutrients for fastidious bacteria. **B.** Chocolate agar inoculated with a species of *Neisseria*. This organism will not grow well on typical blood agar because important nutrients remain locked within intact red blood cells. **C.** Uninoculated Hektoen agar, which contains lactose, peptone, bile salts, thiosulfate, an iron salt, and the pH indicators bromthymol blue and acid fuchsin. The bile salts prevent growth of gram-positive microbes. **D.** Hektoen agar inoculated with *Escherichia coli*. This organism ferments lactose to produce acidic fermentation products that give the medium an orange color owing to the pH indicators acid fuchsin and bromphenol blue. **E.** Hektoen agar inoculated with *Salmonella enterica*. This organism does not ferment lactose but instead grows on the peptone amino acids. The amines produced are alkaline and produce a more intense blue color with bromthymol blue. *Salmonella* species also produce hydrogen sulfide gas from the thiosulfate. Hydrogen sulfide reacts with the medium's iron salt to produce an insoluble, black iron sulfide precipitate visible in the center of the colonies.

Figure 28.2 API 20E strip technology for the biochemical identification of Enterobacteriaceae. A. Uninoculated API strip. Each well contains a different medium that tests for a specific biochemical capability. The color of the media after 24-hour incubation indicates a positive or negative reaction (see Table 28.1). **B.** API results for *E. coli*. Plus (+) and minus (–) indicate positive and negative reactions, respectively. **C.** API results for *Proteus mirabilis*.

requires overnight incubation and tests whether the organism can ferment a series of carbon sources. It also provides evidence of specific end products produced as a result of fermentation. The results appear as different-colored reactions in each chamber and are scored as positive or negative, depending on the color (**Table 28.1**). For example, in the indole chamber (ninth well from the left in **Fig. 28.2B**), a red reaction is positive and indicates that the organism can produce indole from tryptophan. A colorless chamber would be a negative result. Similar API strips are available for the identification of gram-positive bacteria and yeasts.

The results of the API chambers can be interpreted in two ways. First, as a dichotomous key, a stepwise interpretation can be done by lab personnel starting with a key reaction, such as lactose fermentation. The reaction is read as positive or negative based on the color. Then, following a printed flowchart, the technician would go to the next key reaction, indole production, and read it as positive or negative. If the organism was a lactose fermentor and the indole test was positive, the choices have been narrowed to *E. coli* or *Klebsiella* species. Another reaction is read to distinguish between the remaining choices. The process continues until a single species is identified. A simplified example is shown in **Figure 28.3** using a limited number of enteric gram-negative species. In reality, many more reactions than the 11 shown have to be used to make a definitive identification because of species differences with respect to a single reaction. For example, Figure 28.3 shows that *K. pneumoniae* and *K. oxytoca* exhibit opposite indole reactions,

Figure 28.3 **Simplified biochemical algorithm to identify gram-negative rods.** The diagram presents a dichotomous key using a limited number of biochemical reactions and selected organisms to illustrate how species identifications can be made using biochemistry. Abbreviations and reactions: Lactose fermentation to produce acid, ONPG (orthonitrophenyl beta-D-galactoside, cleaved by beta-galactosidase); sorbitol fermentation to produce acid, indole production from tryptophan; VP (Voges-Proskauer test) indicates production of acetoin or 2,3-butanediol; LDC (lysine decarboxylase) cleaves lysine to produce CO_2 and cadaverine; ODC (ornithine decarboxylase) cleaves ornithine to make CO_2 and putrescine; ADH (arginine dihydrolase) is the stepwise degradation of arginine to citrulline and ornithine; citrate utilization as a carbon source; H_2S is the production of hydrogen sulfide gas; urease produces CO_2 and ammonia from urea. (*Note*: "Neg" for *Pseudomonas* in terms of glucose indicates an inability to ferment glucose. *Pseudomonas* can still use glucose as a carbon source.)

even though they are of the same genus. Even within a given species, only a certain percentage of strains might be positive for a given reaction. The inherent danger in using a dichotomous key is that one anomolous result can lead to an incorrect identification.

In a second approach, the API strips can be used to generate a seven-digit identification number that points to the identity of the bacterium. To generate this number, individual reactions are given numerical values based on whether they give a positive or negative result, and then the number values from three reactions are added to produce a single digit. Because there are 21 reactions (the 21st reaction is an oxidase test performed on colonies), the end result will be a seven-digit number. The example in **Figure 28.4A** shows how this is done. Once the number is generated, it is compared to a database of numbers generated by computer. The database was compiled by taking all possible test results and applying them to all species of Enterobacteriaceae. Each species has a known probability of being positive for a given reaction. As discussed in Section 17.3, taking each species and multiplying the probabilities for the results generated by the test organism will generate a probability score. The test organism is identified as the species with the highest score. This probability approach is considerably more accurate than the dichotomous key.

Most clinical laboratories in the United States and Europe now use automated identification systems that are even more sophisticated than API. These include BioMerieux's *VITEC*, Dade Behring's *WalkAway*, and Becton, Dickinson and Company Phoenix systems (**Fig. 28.4B**). All of them use cards or plates with 30 or more biochemical or enzymatic reactions. As with the API chambers, the results appear as colored reactions that can be read by computer. The BD Phoenix system, for example, will convert the results into a 10-digit code that is used to identify genus and species.

Identifying nonenteric gram-negative bacteria. The procedures we have outlined will accurately identify members of Enterobacteriaceae, but pathogenic gram-negative bacilli can also be found in other phylogenetic

Figure 28.4 Generating an identification number from the API 20E strip. **A.** Results from Figure 28.2C were used to generate an identification number. The 20 reactions in the API plus an oxidase reaction performed separately are divided into seven reaction triplets. Each reaction within a triplet is given a value (1, 2, or 4). If the reaction is positive, that value is added to the value of any other positive reaction in that group, and the resulting number is placed in the oval. The result is a seven-digit number that will be unique to a given genus and species of enteric microorganism. Note that because of biochemical diversity within different strains of a species, several different numbers may be generated; but because of the way the test is designed, the numbers will still be unique to the species. **B.** Automated microbiology system. The BD Phoenix™ system uses plates with numerous reaction wells and a computerized plate reader to automatically identify pathogenic bacteria. The numbers and their evaluation can be done automatically using this type of instrument.

families. One possibility in the preceding case history is that the gram-negative bacillus seen in CSF smears would *not* grow on blood agar or on the other selective media, but would grow as small, glistening colonies on chocolate agar. This result would implicate the gram-negative rod *Haemophilus influenzae*. Meningitis caused by *H. influenzae* was a major problem prior to 1988, before the introduction of vaccinations with *H. influenzae* type b capsule material. Growth of *H. influenzae* requires hemin (X factor) and NAD (V factor), so confirming the identity *H. influenzae* involves growing the organism on agar medium containing hemin and NAD. This can be done by placing small filter paper disks containing these compounds on a nutrient agar surface (not blood agar) that has been covered with the organism. *H. influenzae* will only grow around a strip containing both X and V factors. Alternatively, X and V factors can be incorporated into Mueller-Hinton agar, as shown in **Fig. 28.5A**. The organism grows on chocolate medium because the lysed red blood cells release these factors. Although XV growth

Figure 28.5 ***Haemophilus influenzae*** **growth factors and** ***Neisseria meningitidis*** **oxidase reaction.** **A.** *H. influenzae* will grow on an agar plate (here, Mueller-Hinton agar) only when the medium has been fortified with both X factor (hemin) and V factor (NAD), but not either one alone. **B.** Oxidase positive reaction for *Neisseria meningitidis*. Oxidase reagent was dropped onto colonies of *N. meningitidis* grown on chocolate agar. The test is called the cytochrome oxidase test, but it really tests for cytochrome *c*.

phenotype is still used for identification, fluorescent antibody staining is more specific (discussed shortly).

A completely different identification scheme would have been used in the preceding meningitis case if the laboratory had discovered the organism to be a gram-negative diplococcus (rather than a gram-negative rod). A gram-negative diplococcus would suggest *Neisseria meningitidis*. *N. gonorrhoeae* is also possible, but less likely because the gonococcus lacks the protective capsule meningococci used to survive in the bloodstream. Without this capsule, *N. gonorrhoeae* is not as resistant to serum complement and cannot disseminate to the meninges.

The first test to determine if the organism is a species of *Neisseria* is the cytochrome oxidase test (**Fig. 28.5B**). In this test, a few drops of the colorless reagent N,N,N′,N′-tetramethyl-p-phenylenediamine dihydrochloride are applied to the suspect colonies. The reaction, which only takes place if the organism possesses both cytochrome oxidase and cytochrome *c*, turns the p-phenylenediamine reagent (and the colony) a deep purple/black. While many bacteria possess cytochrome oxidase, *Neisseria* is one of only a few genera that also contain cytochrome *c* in their membranes. Oxidase-positive organisms use cytochrome oxidase to oxidize cytochrome *c*, which then oxidizes p-phenylenediamine. Other oxidase-positive bacteria include *Pseudomonas*, *Haemophilus*, *Bordetella*, *Brucella*, and *Campylobacter* species—all of them gram-negative rods. None of the Enterobacteriaceae, however, are oxidase-positive because they lack cytochrome *c*.

An oxidase-positive, gram-negative diplococcus is very likely a member of *Neisseria*. Differentiation between species of *Neisseria* is based on their ability to grow on certain carbohydrates; or it can be determined using immunofluorescent antibody staining tests that test for the presence of different capsule antigens in *N. meningitidis*.

Identifying gram-positive pyogenic cocci. Recall the case of the woman with necrotizing fasciitis (see Section 26.2). How did the laboratory determine that the etiological agent was *Streptococcus pyogenes*? A sample algorithm, or flowchart (**Fig. 28.6**), shows how it was done. The physician sends a cotton swab containing a sample from a lesion to the clinical laboratory. The laboratory technician streaks the material onto several media: (1) blood agar (which will grow both gram-positive and gram-negative organisms), (2) blood agar containing the inhibitors colistin and naladixic acid (called a CNA plate, this agar will grow *only* gram-positives), and (3) MacConkey agar (which will grow only gram-negative organisms (see Section 4.3). The suspect organism in this case grows on the CNA and blood plates. Because they grow in the presence of the gram-negative inhibitory compounds in CNA, one would immediately suspect the organism to be gram-positive, an assumption borne out by the Gram stain.

NOTE: Though the skin is normally populated by many different microorganisms (normal flora), samples from an infected lesion are overwhelmingly populated by the etiological agent. This occurs because the pathogenic microbe outgrows normal flora. Using selective media to isolate the infectious agent will further simplify diagnosis by reducing growth of any normal flora that may still be present.

The algorithm tells the laboratory technician that since the organism is a gram-positive coccus, the next step is to test for catalase production. Catalase, which converts hydrogen peroxide (H_2O_2) to O_2 and H_2O, clearly distinguishes staphylococci from streptococci (remember, Gram stain morphology alone is insufficiently reliable to make that distinction). The catalase test is performed by mixing a colony with a drop of H_2O_2 on a glass slide. Effusive bubbling due to the release of oxygen indicates catalase activity (see **Fig. 28.6**). Staphylococci are catalase-positive, while the streptococci are catalase-negative. Note that many other organisms possess catalase activity, including the gram-negative rod *E. coli*. However, based on the algorithm, *E. coli* would not be considered, since it does not grow on CNA agar and is not gram-positive.

NOTE: When performing a catalase test from colonies grown on blood agar, be sure not to transfer any of the agar, since red blood cells also contain catalase.

Having established that the organism is catalase-negative, the technician examines the blood plate for evidence of hemolysis. Three types of colonies are possible: nonhemolytic, alpha-hemolytic, and beta-hemolytic. Nonhemolytic streptococci do not produce any lytic zone. Alpha-hemolytic strains produce large amounts of hydrogen peroxide that oxidize the heme iron within intact red blood cells to produce a green product. As a result, alpha-hemolytic streptococci produce a green zone around their colonies called alpha hemolysis—even though the red blood cells remain intact. (For example, *S. mutans*, a cause of dental caries and subacute bacterial endocarditis, is alpha-hemolytic.) Still other streptococci produce a completely clear zone of true hemolysis surrounding their colony. This is called beta hemolysis. Complete hemolysis of red blood cells occurs owing to the export of enzymes, called hemolysins, that lyse red cell membranes. The flowchart indicates that the organism from the case history was beta-hemolytic.

The final relevant test in this flowchart involves susceptibility to the antibiotic bacitracin, which identifies the

most pathogenic group of beta-hemolytic streptococci. The beta-hemolytic streptococci are subdivided into many different groups, known as the Lancefield groups, based on differences in the composition of their carbohydrate peptidoglycans. These cell wall differences are distinguished from each other immunologically and divide the streptococci into Lancefield groups A through U. Rebecca Lancefield, for whom the classification scheme is named, was the first to use immunoprecipitation to group the streptococci (**Fig. 28.7**). The vast majority of streptococcal diseases are caused by group A beta-hemolytic streptococci (also called GAS), defined as the species *Streptococcus pyogenes*.

Unfortunately, the Lancefield classification procedure is somewhat time-consuming and not readily amenable as a rapid identification method. However, the group A beta-hemolytic streptococci are uniformly susceptible to the antibiotic bacitracin. Thus, a simple antibiotic disk susceptibility test can be used to indicate the group A beta-hemolytic streptococci (that is, *S. pyogenes*). But beware; many bacteria are bacitracin sensitive, so like the catalase test, the bacitracin test must be used in conjunction with an algorithm to be useful for identification. The technician must follow the appropriate algorithm before assigning importance to this or any other test result. It is irrelevant, for instance, if an alpha-hemolytic organism is bacitracin susceptible. Some of these may exist, but they are not associated with disease.

Marine Biological Laboratory

Figure 28.7 Rebecca Lancefield. In 1918, Dr. Lancefield joined the Rockefeller Institute for Medical Research in New York City, where she studied the hemolytic streptococci, known then as *Streptococcus haemolyticus*. She was the first to use serum precipitation methods to classify *S. haemolyticus* into groups according to differences in cell wall carbohydrate antigens. The basic technique is still used today and is known as the Lancefield classification scheme in her honor.

The organism in our case of necrotizing fasciitis, however, was beta-hemolytic, so bacitracin susceptibility indicated that the organism was *S. pyogenes*.

The other tests named in Figure 28.6 are equally important for the identification of gram-positive infectious agents. For example, *Streptococcus pneumoniae* is an important cause of pneumonia. Like *S. pyogenes*, *S. pneumoniae* is a catalase-negative, gram-positive coccus; but unlike *S. pyogenes*, it is alpha-hemolytic. Optochin susceptibility is a property closely associated with *S. pneumoniae* while other alpha-hemolytic strains of streptococci are resistant to this compound. Thus, an optochin susceptibility disk test is a useful tool for identifying *S. pneumoniae*.

Coagulase is a key reaction used to distinguish the pathogen *Staphylococcus aureus*, which causes boils and bone infections, from other staphylococci, such as the normal skin species *S. epidermidis*. To conduct a coagulase test, a tube of plasma is inoculated with the suspect organism. If the organism is *S. aureus*, it will secrete the enzyme coagulase. Coagulase will convert fibrinogen to fibrin and produce a clotted, or coagulated, tube of plasma. Coagulase-negative staphylococci can still be medically important, however. *S. saprophiticus*, for instance, is an important cause of urinary tract infections. It can be distinguished from *S. epidermidis* based on resistance to novobiocin.

THOUGHT QUESTION 28.1 Use **Figure 28.6** to identify the organism from the following case. A sample was taken from a boil located on the arm of a 62-year-old man. Bacteriological examination revealed the presence of gram-positive cocci that were also catalase-positive, coagulase-positive, and novobiocin resistant.

Pathogen Identifications Based on Molecular Genetics

Many diagnostic laboratories have implemented DNA-based methods to detect and type bacteria and viruses. Molecular detection methods for bacteria are often more rapid than the traditional culture-based methods described earlier. DNA detection (for example, PCR) takes only a few hours, while culture-based identification takes days to weeks. DNA/RNA detection methods are especially useful for viruses, which otherwise require elaborate electron microscopy to view morphology or serology to detect an increased presence of antiviral antibodies. The problem with serology is that by the time these antibodies become detectable in blood, the patient is already recovering from the disease. It is also important to note that molecular detection techniques may provide the *only* means of identifying newly recognized, or emerging, pathogens.

The polymerase chain reaction (PCR) is the most widely used molecular method in the clinical laboratory's diagnostic arsenal. DNA primers that bind to unique genes in a pathogen's genome can be used to specifically amplify DNA or RNA present in a clinical specimen. Successful amplification is visualized as an appropriately sized fragment in agarose gels following electrophoresis.

Why is PCR needed to detect the presence of these nucleic acids? Without the PCR amplification steps, clinical samples usually provide too little nucleic acid from infecting microorganisms to be detected. For example, *Mycobacterium tuberculosis*, the cause of tuberculosis, can take weeks to grow on standard bacteriological media. Detecting the presence of its DNA in the specimen, however, would allow a very rapid diagnosis. Unfortunately, the amount of bacterial DNA present in the sample is infinitesimal, too little to detect by standard techniques such as Southern blot. By amplifying *M. tuberculosis* nucleic acid by PCR, however, one copy of DNA will become billions of copies.

PCR is very quick. Preparing a clinical specimen for PCR by extracting the DNA or RNA usually takes less than an hour. PCR itself is completed in 2–3 hours. Detection of the PCR-amplified DNA by DNA gel electrophoresis takes an additional 1–2 hours. So, what might take two to three days (or sometimes weeks) using biochemical algorithms may take less than a day by molecular strategies. Most clinical laboratories are now equipped with thermocyclers (the instrument used to precisely and rapidly cycle temperature for PCR reactions) and can carry out this type of identification protocol for organisms for which specific primers are available.

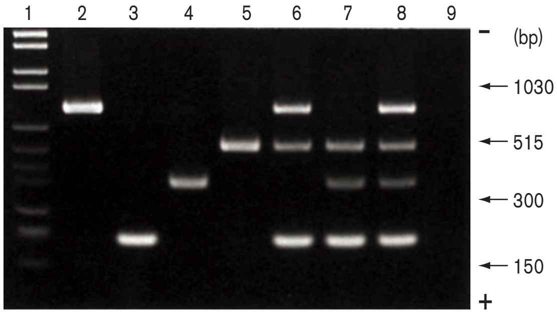
Table 28.2 lists several instances in which DNA detection tests are useful. A specific example presented in **Figure 28.8** illustrates the use of PCR to type different strains of the anaerobic pathogen *Clostridium botulinum*, the cause of food-borne botulism. These organisms are not typed serologically, as is the case for *S. pneumoniae*. *C. botulinum* is divided into different types based on what neurotoxin genes they possess. In this example, **multiplex PCR** was used to simultaneously search for these toxin genes. Multiplex PCR uses multiple sets of primers, one pair for each gene, combined in a single tube with a specimen. Care must be taken to be sure that the primers chosen make different-sized products, do not interfere with each other, and do not produce artifactual products that can confuse interpretation. Multiplex PCR can help identify sets of specific genes present in a single species or can screen for the presence of multiple pathogens in a clinical sample. In the latter, primer sets are designed to amplify genes unique to each pathogen.

Case History: Outbreak of Hospital-Acquired Wound Infections in New Delhi

*From August through December, 45 patients in the pediatric surgery unit of a New Delhi hospital developed postoperative wound infections. Of these, 42 were outpatients, while 3 were inpatients who had undergone major surgery. The diseases ranged from chronic ear infections to bacteremia associated with the use of hemodialysis equipment. Thirty-two clinical samples of pus and wound exudates were tested for acid-fast bacilli by the Ziehl-Neelsen method (***Fig. 28.9A***).*

Table 28.2 Some DNA-based detection tests.

Test	Intended use	Specimen for PCR	Transport conditions
Detection of HIV proviral DNA	Diagnosis of HIV infection in newborns; to resolve indeterminate serologic results	>2 ml whole blood in EDTA tube. EDTA prevents coagulation by chelating (binding) ions	Room temperature, within 24 hours after collection
Detection of *Bordetella pertussis*	Diagnosis of whooping cough (pertussis)	Nasopharyngeal swab	Room temperature, within 24 hours after collection
Detection of *Borrelia burgdorferi*	Diagnosis/surveillance of Lyme disease	Tick	Wrap in moist tissue in small plastic bag
		Skin biopsy; >1 ml spinal fluid; or urine	4°C (cold packs); within 24 hours after collection
Detection of *Rickettsia rickettsii*	Diagnosis/surveillance of Rocky Mountain spotted fever	Tick	Wrap in moist tissue in small plastic bag
		>2 ml whole blood in EDTA tube	Blood: room temperature
		Skin biopsy	Skin lesion biopsy within 24 hours after collection; skin: 4°C
Detection of *Ehrlichia chaffeensis*	Diagnosis/surveillance of human monocytic ehrlichiosis	Tick	Wrap in moist tissue in small plastic bag
		>2 ml whole blood in EDTA tube	Room temperature, within 24 hours after collection
Detection of Norwalk and other small round-structured viruses	Diagnosis of viral gastroenteritis; investigation of food-borne and waterborne outbreaks	>1 ml diarrheal stool in sterile container	4°C (cold packs) within 72 hours after collection
Typing of *Mycobacterium tuberculosis*	Determine relatedness of *M. tuberculosis* isolates/investigation of suspected outbreaks	Sputum, urine	Room temperature
Typing of various gram-negative and gram-positive bacteria	Determine relatedness of isolates/investigation of suspected nosocomial or food-borne outbreaks	Food, feces	4°C (cold packs), within 24 hours after collection (if *Campylobacter* suspected, transport at room temperature)



School of Veterinary Medicine, UC Davis

Figure 28.8 Multiplex PCR identification of *Clostridium botulinum*. *C. botulinum* cells are not typed serologically based on surface antigens, but on the basis of what toxin genes a strain possesses. Typing isolates can be done by a single PCR reaction that uses primer pairs specific for each of the four major toxin genes: Type A, B, E, and F. Because multiple products are sought in a single reaction, this is called multiplex PCR. Each lane in the agarose gel was loaded with multiplex products from different isolates of *C. botulinum* and subjected to electrophoresis. The slower-moving fragments (toward top of gel) are larger than those moving farther down the gel toward the positive pole. Lane 1, DNA size markers; lane 2, type A (*cntA*); lane 3, type B (*cntB*); lane 4, type E (*cntE*); lane 5, type F (*cntF*); lane 6, type A, B, and F; lane 7, type B, E, and F; lane 8, type A, B, E, and F.

*The same smear samples were cultured on Lowenstein-Jensen slants (***Fig. 28.9B***) and examined for growth over a course of several weeks. Biochemical tests indicated that the organism was a mycobacterium in each case. The slow-growing organism,* Mycobacterium abscessus*, was identified by PCR. Based on the DNA fingerprint, the source of the outbreak was traced to the tap water in the operating room and to a defective autoclaving process (the result of a leaking vacuum pump and faulty pressure gauge in the autoclave).*

This case history points out an underlying problem with some biochemical identifications. It took weeks to grow enough organisms to perform these biochemical tests. An alternative PCR test that probed for mycobacterium-specific genes encoding 16S rDNA could have been performed directly on the clinical specimen and would have confirmed the diagnosis immediately, much sooner than by biochemical methods. The PCR test that was done was not performed until *after* the cells were grown in the laboratory.

M. tuberculosis can be presumptively diagnosed in the clinical laboratory by the acid-fast stain, a technique first described in 1882 (called the Ziehl-Neelsen stain) that is used to find the tubercle bacillus in a patient's sputum (**Fig. 28.9A**). The acid-fast stain enables a technician to visualize bacteria such as *Mycobacterium* species that are *not* stained by the Gram stain. Mycobacteria have a very waxy outer coat composed of mycolic acid that resists penetration by most dyes, an obstacle the acid-fast stain was designed to overcome. The original Ziehl-Neelsen acid-fast stain used phenol and heat to drive carbol fuchsin (a red dye) into mycobacterial cells on glass slides. Destaining with an acid alcohol solution removes the stain from all cell types *except* mycobacteria. The slide is subsequently counterstained with methylene blue, after which the mycobacteria will be seen as curved, red rods (called acid-fast bacilli), while everything else will appear blue. A more modern version of the acid-fast stain uses the fluorochrome auramine O to stain the mycolic acid. This dye also resists removal by an acid alcohol wash, so when observed under a fluorescence microscope, the mycobacteria will fluoresce bright yellow.

Although the acid-fast stain is very useful, sometimes organisms cannot be found in a sputum sample; and even if they are found, confirmatory tests are needed for a definitive diagnosis. Relying on growth of the organism means that diagnosis may not be clear for several weeks. For our case history, a rapid DNA-based method would have made the job of determining species much easier. This test probes a 383-bp DNA sequence located at the end of a heat-shock gene that is highly conserved among all mycobacterial species. As a result, the sequence can be amplified by PCR regardless of the strain. However, fragments amplified from different species will have somewhat different DNA sequences. The alterations in DNA sequence can be exposed by restriction digestion. Sequences from different species will produce unique digestion fragment patterns that can then be used for identification. The clinical laboratory compared the restriction patterns produced from mycobacteria isolated from different areas throughout the hospital in the case history. The results allowed the infection control staff to trace the source of all the infections to the tap water in the operating room.

In addition to PCR, restriction fragment length polymorphisms (RFLPs), a form of DNA fingerprinting, can be used to track a given strain during the course of an epidemic. This technique relies on small differences in sequence that occur between strains of a single species. Because of these small differences in sequence, the number and location of restriction enzymes sites in the chromosome will differ. In the example in Figure 28.9, DNA from a strain of *Mycobacterium tuberculosis* is cut with restriction enzymes, and the digested fragments are separated by gel electrophoresis (**Figs. 28.9C** and **D**). The gel is then probed with a radioactively labeled fragment of insertion sequence IS6110 (a fluorescent probe can also be used). IS6110 is a repetitive DNA sequence present at multiple sites in the chromosome. The radioactive probe can hybridize only to DNA fragments that contain IS6110 sequences. Strains of

Figure 28.9 Morphology, growth and DNA fingerprinting of *Mycobacterium tuberculosis*. A. Acid-fast stain of *M. tuberculosis*. **B.** Lowenstein-Jensen medium enables growth of mycobacterial species, some of which grow extremely slowly. The colonies have a “bread-crumb-like” appearance. **C.** Genetic fingerprinting of *Mycobacterium tuberculosis* isolates. Fragments containing IS6110 are marked yellow. **D.** Fragments containing IS6110 hybridize to the specific radioactive probe. A characteristic banding pattern (fingerprint) appears for each isolate. Isolates with similar banding patterns are assigned the same number in this example.

M. tuberculosis obtained from different outbreaks would likely display different hybridization patterns. Strains isolated from the same outbreak would look very similar, if not identical.

Case History: West Nile Virus

A 55-year-old man was admitted to a local hospital complaining of headache, high fever, and neck stiffness. The man appeared confused and disoriented. He also complained of muscle weakness. History indicated he had received several mosquito bites approximately two weeks previously. A blood specimen was sent to the laboratory. The report the following day indicated that the patient was suffering from West Nile virus.

West Nile virus is primarily an infection of birds and culicine mosquitoes (a group of mosquitoes that can transmit human diseases), with humans and horses serving as incidental, dead-end hosts. Replication of virus in this bird-mosquito-bird cycle begins when adult mosquitoes emerge in early spring and continues until fall. Among humans, the incidence of disease peaks in late summer and early fall. Birds provide an efficient means of geographical spread of the virus. As a result, over the past several years, the virus has spread throughout much of the United States.

Isolating a disease-causing virus is extremely challenging. Most laboratories are not equipped for the special tissue culture techniques required to grow viruses. Consequently, most viral infections, including human West Nile virus infections, are usually diagnosed by measuring the antibody response of the patient. For instance, the presence of West Nile virus–specific IgM in cerebrospinal fluid is a good indicator of current West Nile virus infection, but it is indirect and not conclusive. Real-time PCR is a molecular test that can quickly reveal the presence of the virus itself.

Real-time quantitative PCR (RTQ-PCR, or qPCR) is used routinely for the high-throughput diagnosis of viral pathogens such as West Nile virus. Because West Nile virus (Flaviviridae family) contains single-stranded RNA, its RNA must first be converted to DNA using reverse transcriptase before PCR can be attempted. The quantitative advantage of RTQ-PCR is that you can estimate the number of virus particles present in the sample based on the number of viral RNA molecules there.

The basic technique is as follows: RNA is first extracted from the sample. A subsequence of viral RNA is then converted to cDNA using a single primer and reverse transcriptase (**Fig. 28.10**). The more virus particles there are in the sample, the more viral RNA will be present and the more cDNA product is made. The cDNA is then amplified by PCR using two specific primers and Taq polymerase (see Section 12.3; Fig. 12.15). The trick for quantitation is in the method used to detect amplification. In one method, a third, fluorescent oligonucleotide (called the probe) is added to the PCR reaction (see Fig. 12.15A). The probe contains a fluorescent dye at the 3′ end and a chemical dye at the 5′ end that quenches (that is, absorbs) energy emitted from the fluorescent dye. As long as the two chemicals are kept in close proximity by the intact probe, no light is emitted. The probe is designed to anneal to a sequence in between the binding sites of the two other primers (modifications on the ends of the probe prevent it from being used as a primer). So in a successful amplification, Taq polymerase will synthesize DNA from the two outside primers and degrade the probe oligonucleotide as it passes through that area. This cleavage separates the dye from the quencher, and the dye begins to fluoresce. The greater the amount of cDNA there was to begin with, the fewer cycles it takes to register a fluorescence increase over background (**Fig. 28.11**).

Figure 28.10 Reverse transcriptase synthesis of DNA. Reverse transcriptase (RT) uses mRNA as a template to make DNA. The DNA can then be amplified using standard PCR methods. Molecules of eukaryotic and viral mRNA usually contain poly-A tails at their 3′ ends. An oligonucleotide poly-T primer added to the reaction tube will anneal to the poly-A tail and allow RT to synthesize the first strand of a complementary DNA (cDNA). A second primer specific to the viral gene is then used to prime RT synthesis of the opposite strand (second-strand synthesis), using the first DNA strand as template. Subsequent amplification by PCR requires the addition of a thermostable DNA polymerase (Taq) that can withstand the denaturing and DNA synthesis temperatures required for amplifying the cDNA.

THOUGHT QUESTION 28.2 Why does finding IgM to West Nile virus indicate current infection? Why wouldn't finding IgG do the same?

A.

Cycle number	Amount of DNA

B.

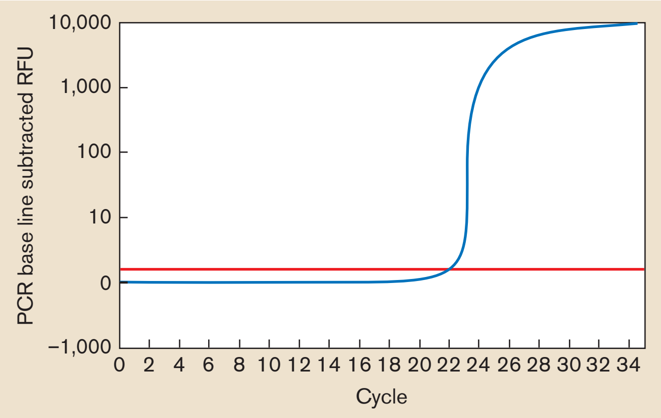

Figure 28.11 **Results of real-time PCR.** **A.** The exponential increase in PCR products after each cycle of hybridization and polymerization. The switch to yellow indicates the point where the increase in product plateaus because the primers have been exhausted. **B.** Increase in relative fluorescence units (RFU) as the fluorescent dye is released from the dual-labeled probe during real-time PCR. The blue curve representing PCR product is flat for the first 22 cycles because the amount of DNA made, and therefore level of fluorescent dye released, remains below background level (red line). The more starting DNA there is, the sooner RFU values will increase over background (that is, fewer cycles are needed to see the increase over background). The slope eventually decreases because the fluorescent probe has become limiting.

Identifications Based on Serology

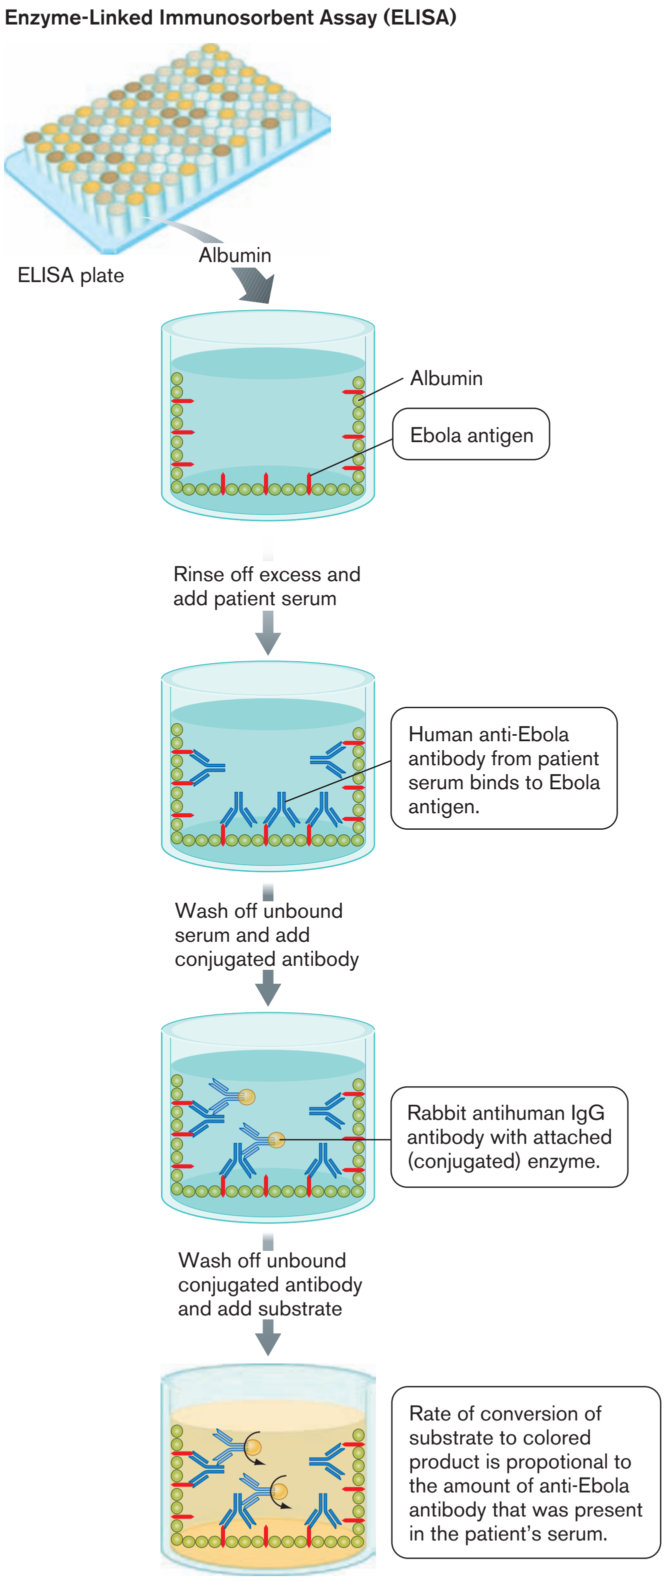
Case History: Ebola

Between October and November 2000, 62 residents of a small village north of Gulu, a town in Uganda, became ill with high fever, diarrhea, headache, vomiting, and gastrointestinal bleeding from the rectum. As many as 36 patients died. By January, 425 cases were reported, of whom 224 died. The presumptive diagnosis was Ebola. Laboratory confirmation tests included viral antigen detection and antibody ELISA tests. Laboratory-confirmed Ebola patients were defined as patients who were either positive for Ebola virus antigen or Ebola IgG antibody. Once identified, rigorous quarantine mechanisms were implemented to limit spread of the disease to other villages.

What are these tests?

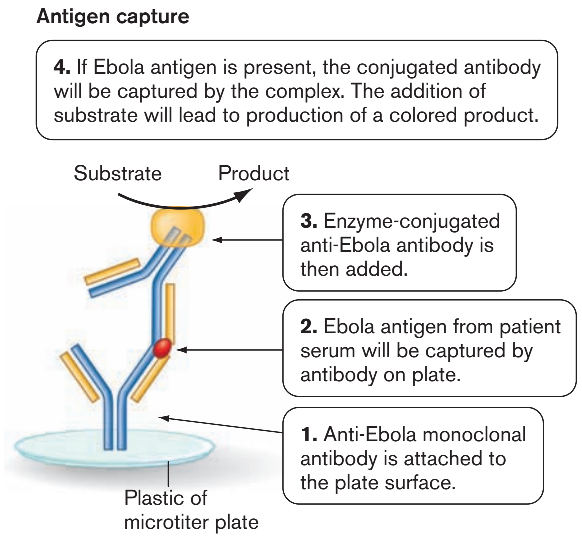
The ELISA test detects antibodies indirectly or antigens directly. The **enzyme-linked immunosorbent assay (ELISA)** can detect antigens or antibodies present in nanogram and picogram quantities. One form of ELISA detects serum antibodies. It is carried out in a 96-well microtiter plate, which allows multiple patient serum samples to be tested simultaneously. An antigen from the virus (Ebola in this case) is attached (or adsorbed) to the plastic of the wells (**Fig. 28.12**). Albumin or powdered milk is used to block the remaining sites on the plastic that could result in false positives. Patient serum is then added. Ebola-specific antibodies present in the serum will react with the antigen attached to the microtiter plate. The antigen-antibody complex is then reacted with goat-antihuman IgG to which an enzyme has been attached, or conjugated (for example, horseradish peroxidase). This forms an antibody "sandwich" that attaches the enzyme to the well. The chromogenic substrate for the enzyme is added next (for example, tetramethylbenzidine). If enzyme-conjugated antibody has bound to any human IgG, the enzyme will convert the substrate to a colored product (blue for tetramethybenzidine). Enzyme activity can be measured with an ELISA plate reader. The amount of colored product formed, detected as absorbance with a spectrophotometer, will be an indication of the amount of anti-Ebola antibody present in the patient sample.

THOUGHT QUESTION 28.3 Why does adding albumin or powdered milk prevent false positives in ELISA?



Enzyme-Linked Immunosorbent Assay (ELISA)
ELISA plate
Albumin
Albumin
Ebola antigen
Rinse off excess and add patient serum
Human anti-Ebola antibody from patient serum binds to Ebola antigen.
Wash off unbound serum and add conjugated antibody
Rabbit antihuman IgG antibody with attached (conjugated) enzyme.
Wash off unbound conjugated antibody and add substrate
Rate of conversion of substrate to colored product is propotional to the amount of anti-Ebola antibody that was present in the patient's serum.

Figure 28.12 Enzyme-linked immunosorbent assay (ELISA). ELISA to detect anti-Ebola antibodies circulating in patient serum. The 96-well plate can be used to make dilutions of a single patient's serum to more precisely determine the amount of anti-Ebola antibody, or it can be used to test samples from multiple patients.



Antigen capture
4. If Ebola antigen is present, the conjugated antibody will be captured by the complex. The addition of substrate will lead to production of a colored product.
Substrate
Product
3. Enzyme-conjugated anti-Ebola antibody is then added.
2. Ebola antigen from patient serum will be captured by antibody on plate.
1. Anti-Ebola monoclonal antibody is attached to the plate surface.
Plastic of microtiter plate

Figure 28.13 Antigen capture ELISA. ELISA technique to capture Ebola antigens circulating in patient serum.

Antigen capture is another ELISA technique, but in this instance, anti-Ebola antibody, not viral antigen, is absorbed to the wells of a microtiter plate (**Fig. 28.13**). Patient serum is then added to the wells. If the serum contains Ebola antigen, the antigen will be captured by the antibody in the well. Then a second, enzyme-conjugated antibody against the Ebola antigen is added. The more antigen present in the serum, the more enzyme-linked antibody will affix to the well. Addition of the appropriate chromogenic substrate will produce a colored product that can be measured.

Antibody against Ebola may be easier to detect than viral antigen because antibodies will be present at higher levels than the virus itself. But because there is a delay between the time when the virus is first present in serum and when the body manages to make antibody, a speedier diagnosis can be made by directly detecting viral antigen.

While bacterial infections are commonly diagnosed by growing the infecting organism on artificial medium in the clinical laboratory, viral diseases are usually diagnosed by immunological means. Viruses are more difficult to grow than bacteria and do not exhibit the biochemical diversity so useful for identifying different bacterial species. In addition to immunological tests, viral diseases can be diagnosed using molecular approaches, such as PCR, to identify viral DNA or RNA sequences.

THOUGHT QUESTION 28.4 Specific antibodies against an infectious agent can persist for years in the bloodstream. So how is it possible that antibody titers can be used to diagnose diseases such as infectious mononucleosis?

Figure 28.14 Fluorescent antibody stain. **A.** *S. pneumoniae* capsule (cells approx. 0.8 µm, fluorescence microscopy). The capsule is the green halo. The center of the halo is the cell. **B.** *Legionella pneumophila* (approx. 1 µm in length) from a respiratory tract specimen.

Fluorescent Antibody Staining

Chapter 27 presents a case history involving an 80-year-old nursing home resident who contracted pneumonia caused by *Streptococcus pneumoniae*. The laboratory diagnosis was probably made using the biochemical algorithm previously described. However, there are over 80 serological types of *S. pneumoniae*, each one containing a different capsular antigen. How can the lab identify which antigenic type has caused the infection? One way is to stain the organism with antibodies.

Figure 28.14A illustrates the result of staining a smear of the isolated streptococcus with fluorescently tagged antibodies directed against a specific antigenic type of capsule. Viewed under a fluorescence microscope, the organism is "painted" green when the right antibody binds to the capsule. In the case of pneumonia, this knowledge probably will not help in the treatment of the individual patient, but its broader value is in determining if a *single type* of organism is responsible for an outbreak of pneumonia, which in turn is of epidemiological value for identifying the source of the bacterium.

On the other hand, fluorescent antibody staining techniques are critically important for rapidly identifying organisms that are difficult to grow. Infected tissues can be subjected to direct fluorescent antibody staining. **Figure 28.14B**, for example, shows a direct fluorescent antibody stain of pleural fluid from a patient with Legionnaires' disease.

Other Microbes

Space does not permit a complete listing of the various diseases and the methods used to identify the etiological agents, but **Table 28.3** presents some additional examples. In general, bacteria that are easily cultured are grown in the laboratory, after which biochemical tests are performed. Bacterial, viral, and fungal species that are difficult to grow are typically identified using immunological techniques. These tests either identify antigen from the microbe in infected tissues or measure a rise in antibody titer. As noted earlier, DNA-based methodologies are gaining increasing acceptance. Eukaryotic microbial parasites such as *Plasmodium* species (the cause of malaria), *Giardia lamblia* (which causes giardiasis, a diarrheal disease), and *Entamoeba histolytica* (the cause of amebic dysentery) can be identified via their telltale morphologies under the microscope, making biochemical tests unnecessary.

TO SUMMARIZE:

- **Selective media** are used to inhibit growth of one group of organisms while permitting the growth of others (such as gram-positive bacteria versus gram-negative bacteria). This technique is often used to prevent growth of normal flora while permitting the growth of pathogens.
- **Differential media** exploit the unique biochemical properties of a pathogen to distinguish it from similar-looking nonpathogens.
- **Identification of bacterial species** can be accomplished with biochemical analyses, molecular techniques (for example, PCR), and/or immunological methods (for example, ELISA).
- **Viral diseases are often diagnosed using immunological tests,** such as ELISA, that measure the presence of antibody or antigen, or by real-time quantitative PCR.
- **Fluorescent antibody staining** can rapidly identify organisms or antigens present in tissues.

Table 28.3 Identification procedures for selected diseases.

Agent	Disease	Identification
Corynebacterium diphtheriae	Diphtheria	Material from nose and throat cultured on a special medium; in vivo or in vitro tests for toxin
Bordetella pertussis	Pertussis (whooping cough)	Smears of nasopharyngeal secretions stained with fluorescent antibody; ELISA for toxin in respiratory secretions; culture on special media
Legionella pneumophila	Legionellosis, Legionnaires' disease, Pontiac fever	Culture on special medium is preferred method; antigen detection by ELISA; *Legionella* nucleic acid can be identified in clinical material using PCR and nucleic acid probes
Campylobacter spp.	Campylobacteriosis	Isolate bacteria on selective media incubated at 42°C in atmosphere of nitrogen containing 5% oxygen and 10% carbon dioxide; then biochemical testing performed
Leptospira interrogans	Leptospirosis	Serological tests early in the illness and after 2–3 weeks to detect rise in antibody titer
Listeria monocytogenes	Listeriosis	Culture of blood and spinal fluid; selective and enrichment cultures performed on food samples to grow potential pathogens; DNA probe for rapid identification of colonies
Chlamydia trachomatis	Chlamydial genital infections	Identification of *C. trachomatis* antigen in urine or pus using monoclonal antibody; nucleic acid probes
Treponema pallidum	Syphilis	Direct fluorescent antibody staining; serological tests
Francisella tularensis	Tularemia	Cultures using cysteine-containing media; fluorescent antibody stain of pus; detection of rise in antibody titer
Yersinia pestis	Plague	Identification of capsular antigen using fluorescent antibody or ELISA
Viruses		
Rhinovirus	Common cold	Strain identification requires use of specific antibodies
Influenza	Flu	Tests comparing influenzal antibody levels in blood samples taken during acute and convalescent stages of illness
Hantavirus	Hantavirus pulmonary syndrome	Antigen detection in tissues using electron microscopy or monoclonal antibody; ELISA and Western blot tests for IgG and IgM antibodies in victim's blood
Herpes simplex	Different strains cause cold sores, ocular lesions, and genital lesions	Identifying the viral antigen in clinical material using fluorescent antibody or DNA probes
Mumps	Mumps	Rise in antibody titer, or presence of IgM antibody to mumps virus in victim's blood
Rotavirus	Diarrhea	Electron microscopy or ELISA of diarrheal stool for virus
HIV	AIDS	Detection of antibody to HIV-1 in patient's blood
Fungi		
Coccidioides immitis	Coccidioidomycosis, infection of lung; can disseminate to almost any tissue	Observation of large, thick-walled, round spherules from clinical specimens; PCR identification
Histoplasma capsulatum	Histoplasmosis, intracellular infection of lung; sometimes disseminates	Stained material from pus, sputum, tissue, etc., examined for intracellular *H. capsulatum* yeast phase; blood tests for antibody to the organism

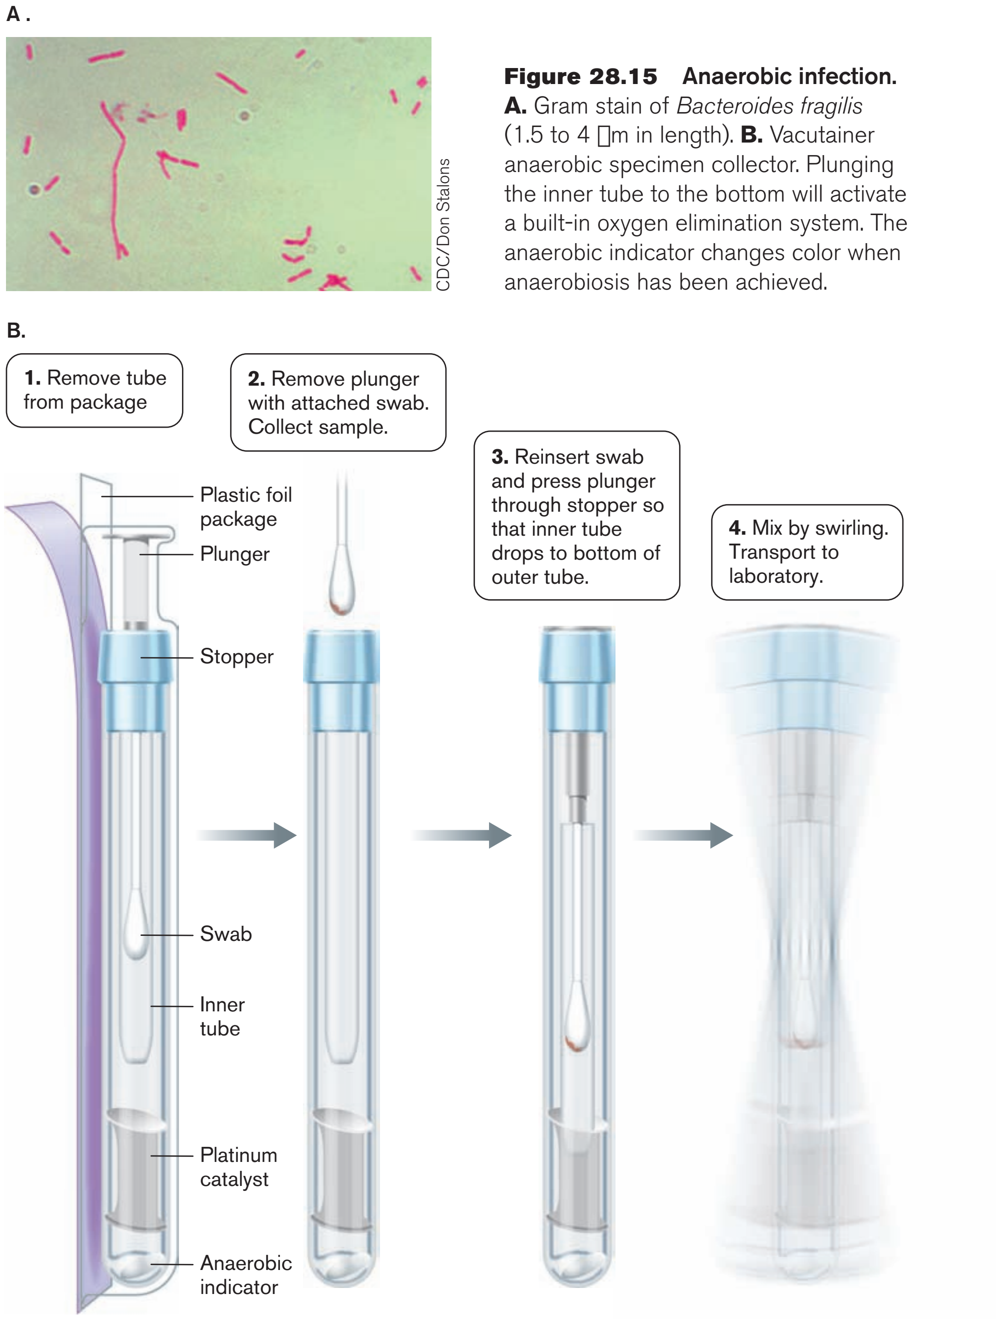
28.3 Specimen Collection

Physicians must collect, and the laboratory must process, a wide variety of clinical specimens. Types of specimens range from simple cotton swabs of sore throats, in which the swab is placed into a liquid transport medium before being sent to the laboratory, to urine and fecal samples that are transported directly. Tables 28.2 and 28.3 outline some of these samples and the techniques used to collect them.

Case History: Abdominal Abscess

A 4-year-old boy was admitted to the hospital for evaluation and treatment of persistent pain in the rectal area. His problem began about one week earlier with ill-defined pain in the same area. He had a white blood cell count of 24,900 with 87% granulocytes. An abdominal computed tomography scan revealed an abscess adjacent to his rectum. A needle aspiration drained 20 mL of yellowish, foul-smelling fluid from the abscess. Aerobic cultures of this specimen plated on blood and MacConkey agars were negative. Why didn't the infectious agent grow?

The problem in this instance is related to specimen collection and processing. Internal abscesses located near the gastrointestinal tract are often anaerobic infections, in this case caused by the gram-negative rod *Bacteroides fragilis*, a strict anaerobe (**Fig. 28.15A**).



CDC/Don Stalons

1. Remove tube from package

2. Remove plunger with attached swab. Collect sample.

3. Reinsert swab and press plunger through stopper so that inner tube drops to bottom of outer tube.

4. Mix by swirling. Transport to laboratory.

Figure 28.15 Anaerobic infection. **A.** Gram stain of *Bacteroides fragilis* (1.5 to 4 μm in length). **B.** Vacutainer anaerobic specimen collector. Plunging the inner tube to the bottom will activate a built-in oxygen elimination system. The anaerobic indicator changes color when anaerobiosis has been achieved.

Intestinal microbes, the majority of which are anaerobic, can sometimes escape the intestine if the organ is damaged in some way. The specimen in this instance should have been collected under anaerobic conditions by aspiration into a nitrogen-filled tube prior to transport to the clinical laboratory. Alternatively, a swab of the abcess material can be inserted into a special transport tube that has a built-in oxygen elimination system (**Fig. 28.15B**). Because it was collected, transported, and handled in air, many anaerobic microbes were probably killed by the oxygen.

Because *B. fragilis* has a stress response system that permits survival of this anaerobe for one or two days in oxygen, some of the bacteria may have survived transport. The laboratory still had a chance to find the organism, which raises the second problem in the case. Once the lab received the specimen, they cultured it only under aerobic conditions. The laboratory should have also incubated a series of plates anaerobically (see Section 5.6; Figure 5.22). This case, therefore, illustrates the importance of both proper specimen collection and proper processing.

Some body sites should not contain any microorganisms when collected from a healthy individual. These include blood, cerebral spinal fluid, and urine from the bladder. Because these sites are sterile, specimens can be plated onto nonselective agar media as well as selective media. Nonselective media, such as blood or chocolate agars, can be used because any organism found in these specimens is considered significant.

Urine collection can be problematic, however. When collected from a catheterized patient, urine should be sterile (**Fig. 28.16A**). Catheterization involves passing a thin, sterile tubing through the urethra and directly into the bladder. (Catheterization is primarily used to assist urination by immobilized patients, but it also provides a convenient way to collect urine for bacteriological examination.) Collections made from the tube should be sterile unless an infection is present. Unfortunately, the simple process of inserting the catheter through the non-sterile urethra can sometimes introduce organisms into the bladder and precipitate an infection. Also, the urine should be collected from the catheter, never from the collection bag. Urine may sit for hours in the collection bag, so organisms initially present at low numbers have time to replicate to high numbers even if the patient does not have a urinary tract infection (UTI).

When a catheter is not in place, urine is most commonly collected by what is called a midstream clean-

Figure 28.16 Specimen collection. **A.** Urinary catheter showing placement in the urethra. **B.** Throat swab. **C.** Sputum collection. A TB patient has coughed up sputum and is spitting it into a sterile container. (The patient is sitting in a special sputum collection booth that prevents the spread of tubercle bacilli. The booth is decontaminated between uses.) **D.** Lumbar puncture to obtain cerebral spinal fluid.

catch technique, which is performed by the patient. In this procedure, the external genitals are first cleaned with a sterile wipe containing an antiseptic. The patient then partially urinates to wash as many organisms as possible out of the urethra and then collects 5–15 ml of the midstream urine in a sterile cup. This urine sample will not usually be sterile because of urethral contamination, but the number of bacteria will be low. The clinical laboratory determines how many organisms per milliliter are present in the midstream catch and informs the physician as to whether an infection is present. Finding more than 100,000 organisms per milliliter of urine from a midstream clean catch is considered indicative of an infection even in an asymptomatic patient; 10,000 or fewer is considered normal. If the patient actually has symptoms of a UTI, however, then any count greater than 1,000 CFUs/ml of a single species is considered significant and should be treated.

Identifying pathogens present at sites that contain normal flora is more challenging. A stool or fecal sample, for instance, is normally teaming with microbial flora. These specimens are typically plated onto selective media (for example, MacConkey, Hektoen, CNA agar) to eliminate or decrease the number of normal flora that might contaminate the specimen. The following represent techniques used to collect specimens from sterile and nonsterile body sites:

Collections from sites with normal flora:

Swabs	Throat swabs (**Fig. 28.16B**), for example, should be placed in specialized liquid nutrient transport medium
Sputum	Deep lung secretions expectorated for oral collection (**Fig. 28.16C**)
Stool samples	Cup or rectal swab; for identifying diarrhea-causing microbes
Abscesses	Needle aspirations

Collections from normally sterile sites:

Cerebral spinal fluid	Lumbar punctures (spinal taps; **Fig. 28.16D**); testing for meningitis
Urine samples	Midstream clean catch or from catheters placed in the bladder; testing for urinary tract infections
Blood samples	Generally taken by syringe from two body sites and placed in liquid media for aerobic and anaerobic culture. The same organism isolated from blood samples taken from the two sites is considered the likely etiological agent.

THOUGHT QUESTION 28.5 Two blood cultures, one from each arm, were taken from a patient with high fever. One culture grew *Staphylococcus epidermidis*, but the other blood culture was negative (no organisms grew out). Is the patient suffering from septicemia caused by *S. epidermidis*?

THOUGHT QUESTION 28.6 A 30-year-old woman with abdominal pain went to her physician. After the examination, the physician asked the patient to collect a midstream urine sample that they would send to the lab across town for analysis. The woman complied and handed the collection cup to the nurse. The nurse placed the cup on a table at the nurse's station. Three hours later, the courier service picked up the specimen and transported it to the laboratory. The next day, the report came back "greater than 200,000 CFUs/ml; multiple colony types; sample unsuitable for analysis." Why was this determination made?

TO SUMMARIZE:

- **Special collection precautions** must be taken when collecting specimens from abscesses of suspected anaerobic etiology.
- **Common specimens** include blood, pus, urine, sputum, throat, stool, and CSF.
- **Specimens** from sites containing normal flora must be handled differently than specimens taken from normally sterile body sites.

28.4 Biosafety Containment Procedures

Case History: Fatal Meningitis

On July 15, an Alabama microbiologist was taken to the emergency room with acute onset of generalized malaise, fever, and diffuse myalgias. She was given a prescription for oral antibiotics and released. On July 16, she became tachycardic and hypotensive and returned to the hospital. She died 3 hours later. Blood cultures were positive for N. meningitidis *serogroup C. Three days before the onset of symptoms, the patient had prepared a Gram stain from the blood culture of a patient subsequently shown to have meningococcal disease; the microbiologist also handled agar plates containing cerebrospinal fluid (CSF) cultures from the same patient. Coworkers reported that in the laboratory, aspirating fluids from blood culture bottles was typically performed at the open laboratory bench. No biosafety cabinets, eye protection, or masks were used for this procedure. Testing at CDC indicated that the isolates from both patients were indistinguishable. The laboratory at the hospital infrequently processed isolates of* N. meningitidis *and had not processed another meningococcal isolate during the previous four years.*

Medical and laboratory personnel are exposed to extremely dangerous pathogens on a daily basis. The microbiologist in this case did not take appropriate measures to protect herself and ended up with a laboratory-acquired infection leading to meningitis. The CDC has published a series of regulations designed to protect workers at risk of infection by human pathogens. Infectious agents are ranked by the severity of disease and ease of transmission. Based on this ranking, four levels of containment are employed (**Table 28.4**).

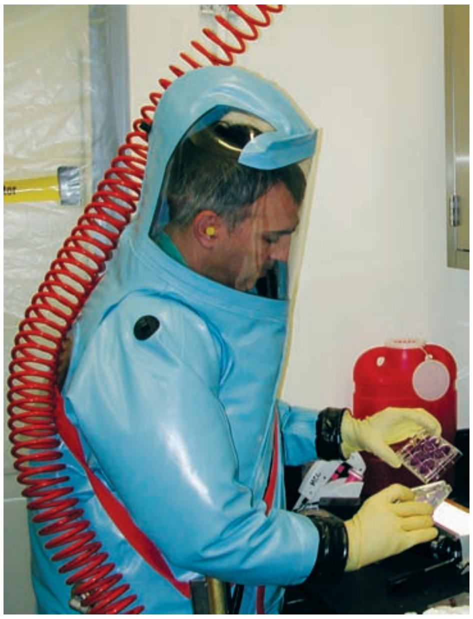
Table 28.4 Biological safety levels and select agents.

	Containment level			
	Level 1	**Level 2**	**Level 3**	**Level 4**
	Category I	**Category II**	**Category III**	**Category IV**
Class of disease agent	Agents not known to cause disease	Agents of moderate potential hazard; also required if personnel may have potential contact with human blood or tissues	Agents may cause disease by inhalation route	Dangerous and exotic pathogens with high risk of aerosol transmission; only six such labs in the United States
Recommended safety measures	Basic sterile technique; no mouth pipetting	Level 1 procedures plus limited access to lab; biohazard safety cabinets used; hepatitis vaccination recommended	Level 2 procedures plus ventilation providing directional airflow into room, exhaust air directed outdoors; restricted access to lab (no unauthorized persons)	Level 3 procedures plus one-piece positive-pressure suits; lab completely isolated from other areas present in the same building or is in a separate building
Representative organisms in class	*Bacillus subtilis* *E. coli* K12 *Saccharomyces*	*Bordetella pertussis* *Burkholderia mallei* (glanders) *Campylobacter jejuni* *Chlamydia* spp. *Clostridium* spp. *Corynebacterium diphtheriae* *Cryptococcus neoformans* *Cryptosporidium parvum* Dengue Diarrheagenic *E. coli* *Entamoeba histolytica* *Francisella tularensis* (tularemia) *Giardia lamblia* *Haemophilus influenzae* *Helicobacter pylori* Hepatitis *Legionella pneumophila* *Listeria monocytogenes* *Mycoplasma pneumoniae* *Neisseria* spp. Pathogenic *Vibrios* *Salmonella* *Shigella* spp. *Staphylococcus aureus* *Toxoplasma* *Yersinia pestis* *Yersinia enterocolitica*	*Bacillus anthracis* (anthrax) *Brucella* spp. (brucellosis) California encephalitis *Coxiella burnetii* (Q fever) EEE (Eastern equine encephalitis) Japanese encephalitis virus La Crosse encephalitis LCM (lymphocytic choriomeningitis) *Mycobacterium tuberculosis* Rabies *Rickettsia prowazekii* (typhus fever) Rift Valley fever SARS (severe acute respiratory syndrome) Variola major (smallpox) and other poxviruses VEE (Venezuelan equine encephalitis) West Nile virus Yellow fever	Ebola Guanarito virus Hantavirus Junin virus Kyasanur Forest virus Lassa fever Machupo virus Marburg virus Tick-borne encephalitis viruses

Organisms in blue are on the list of CDC select agents that are considered possible agents of bioterrorism.

Category I organisms have little to no pathogenic potential and require the lowest level of containment (biosafety level 1). Standard sterile techniques and laboratory practices are sufficient. Category II agents have greater pathogenic potential but are not generally transmitted by the respiratory route. They require more rigorous containment procedures, such as limiting laboratory access when experiments are in progress and the use of biological laminar flow cabinets if aerosolization is possible (biosafety level 2). Category III pathogens can be transmitted via the respiratory route and present a high risk of infection. To safely handle these organisms, level 2 procedures are supplemented with a lab design that ensures that ventilation air flows only *into* the room (negative pressure) and that exhaust air vents directly to the outside. Negative pressure will keep any organism that may aerosolize from escaping into hallways. In addition, access to the lab is strictly regulated and includes double-door air locks at the entrance (biosafety level 3).

By law, extremely dangerous pathogens such as the Ebola virus may only be studied at a biosafety level 4 containment facility. Practices here dictate that lab personnel wear positive-pressure lab suits connected to a separate air supply (**Fig. 28.17**). The positive pressure ensures that if the suit is penetrated, organisms will be blown away from the breach and not sucked into the suit. As reasonable as these regulations may seem, they were not always in effect. Prior to 1970, scientists had an almost cavalier approach toward handling pathogens. For instance, culture material was routinely transferred from one vessel to another by mouth pipetting (essentially using a glass or plastic pipette as a straw). This is now forbidden for obvious reasons.



Kevin Karem/CDC

Figure 28.17 Biosafety level 4 containment. Dr. Kevin Karem at the CDC performs viral plaque assays to determine the neutralization potential of serum from smallpox vaccination trials. He is protected by a positive pressure suit working in a biosafety level 4 laboratory. The airflow into his suit is so loud he must wear earplugs to protect his hearing.

TO SUMMARIZE:

- **Various levels** of protective measures are used when handling potentially infectious biological materials.
- **Category I** agents are generally not pathogenic and require the lowest level of containment.
- **Category II** agents are pathogenic but not typically transmitted via the respiratory tract. Laminar flow hoods are required.
- **Category III** agents are virulent and transmitted by respiratory route. They require laboratories with special ventilation and air-lock doors.
- **Category IV** agents are highly virulent and require the use of positive-pressure suits.

28.5 Principles of Epidemiology

Case History: Inhalation Anthrax

On October 16, a 56-year-old African-American U.S. Postal Service worker became ill with a low-grade fever, chills, sore throat, headache, and malaise. This was followed by minimal dry cough, chest heaviness, shortness of breath, night sweats, nausea, and vomiting. On October 19, he arrived at a local hospital, where he presented with a normal body temperature and normal blood pressure. He was not in acute distress but had decreased breath sounds and rhonchi (dry sounds in lungs due to congestion). No skin lesions were observed, and he did not smoke. Total WBC count was normal, but there was a left shift in the differential—that is, more polymorphonuclear lymphocytes (PMNs; see Section 26.3). A chest X-ray showed bilateral pleural effusions (accumulation of fluids in the lung) and a small right lower lobe air space opacity. Within 11 hours, blood cultures taken upon admission grew Bacillus anthracis. *Ciprofloxacin, rifampin, and clindamycin antibiotic treatments were initiated, and the patient recovered. His job at the post office was to sort mail.*

From October 4 to November 2, 2001, the Centers for Disease Control and Prevention (CDC) and various state and local public health authorities reported 10 confirmed cases of inhalational anthrax and 12 confirmed or suspected cases of cutaneous anthrax in persons who worked in the District of Columbia, Florida, New Jersey, and New York. Many of them were postal workers. It was clear that a biological attack was in progress.

The word *epidemiology* is derived from the Greek, meaning "that which befalls man." In scientific parlance, epidemiology examines the distribution and determinants of disease frequency in human populations. Put more simply, epidemiologists determine the source of a disease outbreak and the factors that influence how many individuals will succumb to the disease. Epidemiological principles are also used to determine the effectiveness of therapeutic measures and to identify new syndromes, such as SARS (severe acute respiratory syndrome) and Lyme disease. Some of the basic concepts of epidemiology were already covered in Chapter 25 when we discussed infection cycles. Now we will explore how those principles are used to track disease.

Epidemiological early-warning systems require an extensive organization that coordinates information from many sources. In the United States, that duty falls to the Centers for Disease Control and Prevention (CDC). On the world stage, it is the World Health Organization (WHO). Any disease considered highly dangerous or infectious is first reported to local public heath centers, usually within 48 hours of diagnosis. The local centers forward that information to their state agencies, which then report to the CDC in Atlanta. This is how authorities in 2001 quickly recognized that an outbreak of anthrax was under way.

The terms **endemic** and **epidemic** are often used when referring to disease outbreaks. A disease is endemic if it is always present in a population at a low frequency. For example, Lyme disease, caused by the spirochete *Borrelia burgdorferi*, is endemic to the Northeastern United States because the organism has found a **reservoir** in deer and ticks. Recall that a reservoir is an animal, bird, or insect that harbors the infectious agent and is indigenous to a geographical area. Humans become infected only when they come in contact with the reservoir. Thus, the disease incidence is low but relatively constant. An epidemic disease, on the other hand, is when large numbers of individuals in a population become infected over a short time. This is due, in part, to rapid and direct human-to-human transmission.

Figure 28.18A illustrates the difference in the frequency of cases observed between endemic and epidemic disease. An endemic disease can become epidemic if the population of the reservoir increases, which allows for more frequent human contact, or if the infectious agent evolves to spread directly from person to person, bypassing the need for a reservoir. This is the concern with the H5N1 avian flu virus, which is endemic in animals and birds in Asia (see Sections 11.4 and 25.8). A **pandemic** is an epidemic that occurs over a wide geographical area, usually the world. The bubonic plague pandemic in the fourteenth century and the AIDS pandemic in the late twentieth and early twenty-first centuries are good examples.

Finding Patient Zero

When trying to contain the spread of an epidemic, it is vital to track down the first case of the disease (known as the **index case** or **patient zero**) and then identify everyone who has had contact with the individual so that they can be treated or separated from the general population (that is, **quarantined**). When a new disease arises, the epidemiological search for the index case starts only after a number of patients have been diagnosed and a new disease syndrome declared. This is what happened with AIDS in the 1970s.

Identifying an index case within a specific community is easier if the disease syndrome is already recognized, as was the case with the 2003 SARS outbreak in Singapore. According to the World Health Organization, a suspected case of SARS is defined as an individual who

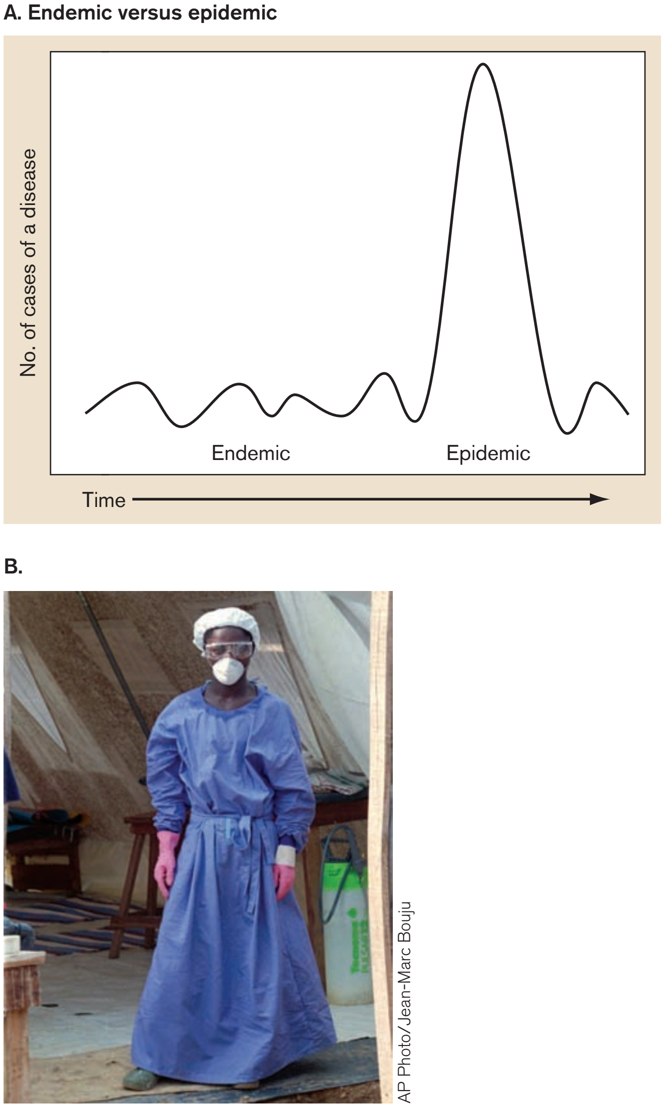


Figure 28.18 The difference between endemic and epidemic disease. A. An endemic disease is continuously present at a low frequency in a population. If the disease frequency suddenly rises, this constitutes an epidemic. **B.** A health care worker stands outside a quarantined area housing Ebola patients in the Ivory Coast. Epidemics can be minimized if infected persons are kept segregated from the general population (quarantined) to avoid spread of the infectious agent.

has a fever greater that 38°C, who exhibits lower respiratory tract symptoms, and who has traveled to an area of documented disease or has had contact with a person afflicted with SARS. The index case in Singapore was a 23-year-old woman who had stayed on the ninth floor of a hotel in Hong Kong while on vacation. A physician from southern China who stayed on the same floor of the hotel during this period is believed to have been the source of her infection, as well as that of the index patients who precipitated subsequent outbreaks in Vietnam and Canada.

During the last week of February, the woman, who had returned to Singapore, developed fever, headache, and a dry cough. She was admitted to Tan Tock Seng Hospital, Singapore, on March 1 with a low white blood cell count and patchy consolidation in the lobes of the right lung. Tests for the usual microbial suspects (*Legionella*, *Chlamydia*, *Mycoplasma*) were negative. Electron microscopy of nasopharyngeal aspirations showed virus particles with widely spaced club-like projections (**Fig. 28.19A**). At the time of her admission to the hospital, the clinical features and highly infectious nature of SARS were not known. Thus, for the first six days of hospitalization, the patient was in a general ward, without barrier infection control measures. During this period, the index patient infected at least 20 other individuals, including hospital staff, nearby patients, and visitors.

Anat Givon/AP Photo

Figure 28.19 Severe acute respiratory syndrome (SARS). **A.** The coronavirus SARS (TEM). **B.** Citizens of China, including the military, donned surgical masks in 2003 to slow the spread of SARS.

Within weeks, the WHO named the disease in China SARS and issued travel alerts (discussed further in Section 28.6). These alerts allowed Singapore health officials to rapidly identify the index patient and her contacts. As a result, they were able to limit spread of the illness. When all was said and done, SARS killed fewer than 1,000 victims worldwide, although thousands more became ill and recovered (**Fig. 28.19B**). Today, SARS remains a threat but one of lesser concern. Methicillin-resistant *Staphylococcus aureus* (MRSA) and H5N1 avian flu are considered more pressing dangers.

Identifying Disease Trends Depends on Physician Notification of Health Organizations

How do epidemiologists first recognize that an epidemic is under way, and then identify the agent and its source? Certain diseases, because of their severity and transmissibility, are called **reportable** or **notifiable diseases** (**Table 28.5**). Physicians are required to report instances of these diseases to a central health organization, such as the CDC in the United States and the WHO. As a result, the incidences of certain diseases within a population can be tracked and upsurges noted. An emerging disease not on the list of notifiable diseases can be detected as a cluster of patients with unusual symptoms or combinations of symptoms. This is possible because diseases of unknown etiology are also reported to health authorities. A new disease could manifest with common symptoms (for example, the cough and fever of SARS) that cannot be linked to a known disease agent by clinical tests. An upsurge in cases, either of a reportable disease or an emerging disease, will set off institutional "alarms" that initiate epidemiological efforts to determine the source and cause of the outbreak.

John Snow (1813–1858), the Father of Epidemiology

The first case in which the source of a disease outbreak was methodically investigated took place in the mid-nineteenth century. During a serious outbreak of cholera in London in 1854, John Snow (**Fig. 28.20A**) used a map to plot the locations of all the diarrheal cases he learned about. The source of the infection was unknown, but Snow thought that if the cases clustered geographically, he might gain a clue as to the source. Water in that part of London was pumped from separate wells located in the various neighborhoods. Snow's map revealed a close association between the density of cholera cases and a single well located on Broad Street (**Fig. 28.20B**). Simply removing the pump handle of the Broad Street well put an

Table 28.5 Notifiable infectious diseases.

Bacterial

- Anthrax
- Botulism
- Brucellosis
- *Campylobacter* infection
- *Chlamydia* infection
- Cholera
- Diphtheria
- Ehrlichiosis
- *E. coli* O157:H7 infection
- Gonorrhea
- *Haemophilus influenzae*, invasive disease
- Hansen's disease (leprosy)
- Legionellosis
- Leptospirosis
- Listeriosis
- Lyme disease
- Meningitis, infectious
- Pertussis
- Plague
- Psittacosis
- Q fever
- Rocky Mountain spotted fever
- Salmonellosis (nontyphoid fever types)
- Shigellosis
- Staphylococcal enterotoxin
- Streptococcal invasive disease
- *Streptococcus pneumoniae*, invasive disease
- Syphilis
- Tuberculosis
- Tularemia
- Typhoid fever
- Vancomycin-resistant *Staphylococcus aureus* (VRSA)

Viral

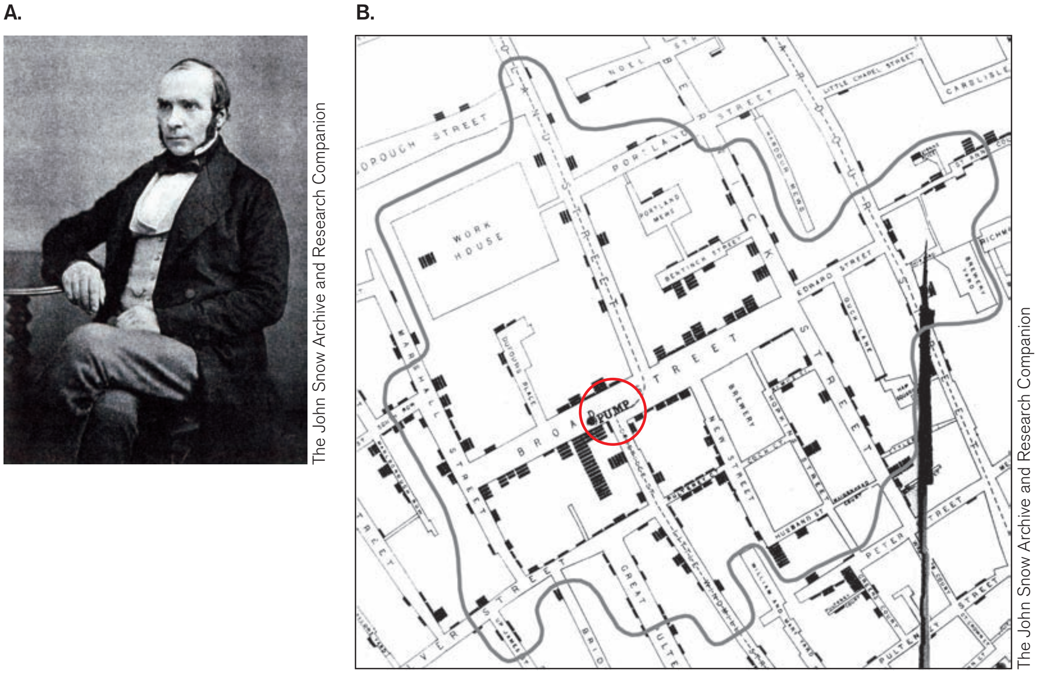
- Dengue fever
- Hantavirus infection
- Hepatitis, viral
- Human immunodeficiency virus infection
- Measles
- Mumps
- Poliomyelitis
- Rabies
- Rubella and congenital rubella syndrome
- Smallpox
- Varicella (chickenpox), fatal cases only (all types)
- Yellow fever

Fungal

- Coccidioidomycosis

Parasitic

- Amebiasis
- Cryptosporidiosis
- Cyclosporiasis
- Giardiasis
- Trichinosis
- Microsporidiosis
- Malaria



The John Snow Archive and Research Companion

The John Snow Archive and Research Companion

end to the epidemic, proving that the well water was the source of infection. This approach succeeded brilliantly despite the fact that the infectious agent that causes cholera, *Vibrio cholerae*, was not recognized until 1905, over 50 years later. Identifying clusters of patients afflicted with a given disease is still used to identify potential sources of infectious disease outbreaks.

> **THOUGHT QUESTION 28.7** Methicillin, a beta-lactam antibiotic, is very useful in treating staphylococcal infections. The development of methicillin-resistant strains of *Staphylococcus aureus* (MRSA) is a very serious development because there are few antibiotics that can kill these strains. Imagine a large metropolitan hospital in which there have been eight serious nosocomial infections with MRSA and you are responsible for determining the source of infection so it can be removed. How would you accomplish this using common bacteriological and molecular techniques?

Genomic Strategies Help Identify Nonculturable Pathogens

Microbiologists have successfully developed many strategies to identify the causes of infectious diseases. Robert Koch in the late 19th century devised a set of postulates that, when followed, can identify the agent of a new disease (discussed in Section 1.3). One important feature of Koch's postulates is that the suspected organism be grown in pure culture. However, there are bacterial diseases for which the agent could not be cultured. How might they be identified?

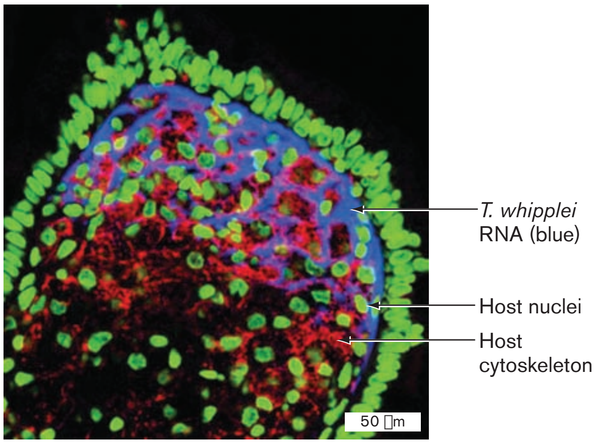
Case History: Whipple's Disease

In April, a 50-year-old man had an abrupt onset of watery diarrhea with a stool frequency of up to ten times every 24 hours. This was the latest episode in a six-year history of illness beginning with recurring fevers, flu-like symptoms, profuse night sweats, and painful joint swelling. The current bout of diarrhea was associated with gripping lower abdominal pain, especially after meals. No blood or mucus was found in the stools. Blood and stool cultures tested negative for known infectious agents. Serology was also negative for syphilis, brucellosis, toxoplasmosis, and leptospirosis. His weight fell rapidly from 83 kg to 73 kg within four weeks of onset. A flexible sigmoidoscopy showed only diffuse mild erythema in the bowel. However, the appearance of the small bowel was consistent with malabsorption, a disease in which nutrients are poorly absorbed by the intestine. A duodenal biopsy to look for the organisms of Whipple's disease showed large macrophages in the lamina propria (a layer of loose connective tissue beneath the epithelium of an organ). Bacterial rods characteristic of Whipple's disease were seen with electron microscopy. PCR analysis of tissue samples confirmed the diagnosis.

First diagnosed in 1907 by George Whipple, the symptoms of this disease are malabsorption, weight loss, arthralgia (joint pain), fevers, and abdominal pain. Any organ system can be affected, including the heart, lungs, skin, joints, and central nervous system. The cause of Whipple's disease went undiscovered for 85 years but was suspected to be of bacterial etiology even though an organism was never successfully cultured. The agent was finally identified in 1992 not by culturing, but by blindly amplifying 16S rDNA sequences from biopsy tissues.

All bacterial 16S rRNA genes have some sequence regions that are highly homologous across species and other sequences that are unique to a species. Tissues from numerous patients diagnosed with Whipple's disease were subjected to PCR analysis using the common 16S rDNA primers. If a bacterial agent were present, it was predicted that PCR should successfully amplify a DNA fragment corresponding to the agent's 16S rRNA gene. All tissues produced such a fragment, indicating that there were bacteria in the tissues. DNA sequence analysis of these fragments indicated that the organism was similar to actinomycetes but was unlike any of the known species.

The organism is actually a gram-positive soil-dwelling actinomycete that has been named *Tropheryma whipplei* in honor of the physician who first recognized the disease. Because of its bacterial etiology, Whipple's disease can be treated with antibiotics, usually trimethoprim sulfamethoxazole (Bactrim, Septra, Cotrim). **Figure 28.21** shows an in situ hybridization for *T. whipplei* RNA in a tissue biopsy.



D. N. Fredricks & D. A. Relman. 2001. *J Infect Dis* 183:1229

Figure 28.21 Whipple's disease. Fluorescent in situ hybridization of a small intestinal biopsy in a case of Whipple's disease (confocal laser scanning microscopy). In this test, a fluorescently tagged DNA probe that specifically hybridizes to *T. whipplei* RNA is added to the tissue. Other fluorescent probes are used to visualize host nuclei and cytoskeleton. *T. whipplei* rRNA is blue, nuclei of human cells are green and the intracellular cytoskeletal protein vimentin is red. Magnification approximately 200×.

This story reveals that Koch's postulates (see Figure 1.18) must sometimes be modified when identifying the cause of a new disease. In this instance, the organism could not be cultured in pure form in the laboratory but was found, via molecular techniques, in all instances of the disease. Note that more recent studies have successfully cultured *T. whipplei* in vitro. The medium used was formulated based on nutritional requirements deduced from knowing the DNA sequence of the *T. whipplei* genome (discussed in Section 25.6).

THOUGHT QUESTION 28.8 What are some reasons why some diseases spread quickly through a population while others take a long time?

Molecular Approaches Can Be Used for Disease Surveillance

A worldwide pandemic of pulmonary tuberculosis currently affects over 2 billion people. Many of the *Mycobacterium tuberculosis* infections are caused by multidrug-resistant strains that are difficult, if not impossible, to kill with existing antibiotics (see Section 26.3). This problem is especially serious among refugee populations attempting to flee war-torn countries. As a result, it is important to screen these refugees as they enter neighboring countries with low incidences of tuberculosis. Although chest X-rays are mandatory in many cases, a positive image will be obtained only if the disease is at a relatively advanced stage. Actively infected individuals who have not developed the characteristic lung tubercles seen on X-ray will not be identified.

Unfortunately, the acid-fast staining of sputum samples (discussed in Section 28.2) also fails to detect individuals at an early stage of infection. Studies have shown, however, that PCR techniques are much more sensitive for detecting these individuals. As time progresses, PCR surveillance strategies will be used more often to track the worldwide ebb and flow of microbial diseases. PCR and restriction fragment length polymorphism (RFLP) strategies are already used for epidemiological purposes to type (that is, determine relatedness of) different microbial isolates by generating a complex DNA profile that is specific for a particular strain (Section 28.2).

Bioterrorism

"A wide-scale bioterrorism attack would create mass panic and overwhelm most existing state and local systems within a few days," said Michael T. Osterholm, director of the Center for Infectious Disease Research and Policy at the University of Minnesota. "We know this from simulation exercises." These words were spoken in October 2001.

Less than a month after the September 11 attack on the World Trade Center, some unknown person(s) sent weapons-grade anthrax spores through the U.S. mail. Thankfully, only 5 persons died and a mere 25 became ill. But even though the efficiency of the attack was poor, the impact was enormous. Over 10,000 people took a two-month course of antibiotics after possible exposure, and mail deliveries throughout the country were affected. The simple act of opening an envelope suddenly became a risky endeavor.

As a result of this attack and other events, the CDC and the National Institutes of Health (NIH) have assembled a list of select agents (marked in blue in **Table 28.4**) that could potentially be used as **bioweapons**. A bioweapon is considered to be any infectious agent or toxin that has high virulence and/or mortality rate. Microorganisms considered bioweapons can be used to conduct biowarfare, in which the intent is to inflict massive casualties, or bioterrorism, in which there may be a few casualties but widespread psychological trauma.

Although the list of select agents is recent, biowarfare is not new. In the Middle Ages, victims of the Black Death (plague caused by *Yersinia pestis*) were flung over castle walls using catapults; during the French and Indian War, in the eighteenth century, Jeffery Amherst distributed smallpox-infected blankets to Native Americans; and during World War II, the Japanese Imperial Army experimented with infectious disease weapons using Chinese prisoners as guinea pigs. Even the United States has participated through the development of weapons-grade anthrax spores. It was originally thought that the strain of *B. anthracis* used in the 2001 anthrax attack was the same as the strain developed by the military. We now know that the strain used in the attack had a more ordinary pedigree.

The first documented act of bioterrorism in the United States occurred in 1984, when followers of the cult leader Bhagwan Shri Rajneesh tried to control a local election in Dalles, Oregon, by infecting salad bars with *Salmonella*. Over 900 people became ill. Rajneesh was sentenced to 20 years in prison.

How effective are bioweapons? The method by which a biological agent is dispersed plays a large role in its effectiveness as a weapon. Only a few people became ill during the 2001 anthrax attack not only because of the epidemiological surveillance, but because anthrax is inherently difficult to disperse. Thousands of spores must be inhaled to contract disease, which means that effective dispersal of the spores is critical for the use of anthrax as a weapon. Once spores hit the ground, the threat of infection is limited. Weapons-grade spores are very finely ground so that they stay airborne longer. But as we saw, the letter-borne dispersal system was not very effective in terms of generating large numbers of victims. Nevertheless, the potential threat of weapons-grade anthrax on the battlefield led the U.S. military in 2006 to resume vaccinating all soldiers serving in Iraq, Afghanistan, and South Korea.

An effective bioweapon would be one that capitalizes on person-to-person transmission. In an easily transmitted disease, one infected person could disseminate disease to scores of others within one or two days. So in terms of generating massive numbers of deaths, anthrax was a poor choice. But the goal of most terrorists is not to kill large numbers of people, but to terrorize them. In that regard, the anthrax attack succeeded.

The most effective bioweapon in terms of inflicting death (biowarfare) would have a low infectious dose, be easily transmitted between people, and be one to which a large percentage of the population is susceptible. Smallpox fits these criteria and would be the bioweapon of choice (**Fig. 28.22**). Fortunately, however, smallpox has been eradicated (almost) from the face of the Earth and is not easily obtained. Two laboratories still harbor the virus—one in the United States and one in Russia. It is believed that the virus has been destroyed in all other laboratories. Since smallpox is the perfect biowarfare agent, it is imperative that the last two smallpox repositories remain secure.

While the good news is that smallpox disease has been eradicated, the bad news is that no individual born after 1970 has been vaccinated. As a result, anyone under 35 years of age is susceptible to smallpox. Even those of us who received the smallpox vaccination over 35 years ago are at risk, since our protective antibody titers have diminished. A terrorist attack with smallpox would cause terrible numbers of deaths. The vaccine does, however, exist. Were a smallpox attack to be launched, the vaccine would be rapidly administered to limit the spread of disease. Nevertheless, the economic and psychological impact of a smallpox epidemic would be devastating.

The CDC has assembled a list of so-called "select agents" that are considered possible bioterrorist weapons (see Table 28.4). Research with organisms considered to be select agents is tightly regulated. Because *Yersinia pestis,* for instance, is a select agent, laboratory personnel working with it must now possess security clearance with the Department of Justice (even though the organism itself can be handled under biosafety level 2 conditions). The laboratory must also register with the CDC to legally possess this pathogen and access to the lab and the organism must be tightly controlled.

Much has improved since Michael Osterholm offered his dire assessment of a wide-scale bioterrorism attack. Education and surveillance procedures have been bolstered, and new detection technologies are being developed (**Special Topic 28.1**). We will probably never be fully protected from attack, biological or otherwise, but recent efforts have improved the situation.

WWW | Bioterrorism Preparedness Act

TO SUMMARIZE:

- **John Snow** founded the discipline of epidemiology.
- **Epidemiology** is a field that examines factors that determine the distribution and source of disease.
- **Endemic, epidemic, and pandemic** are terms for different frequencies of disease in different geographical areas.
- **Finding patient zero** is important for containing the spread of disease.
- **Molecular approaches using PCR and nucleic acid hybridization** are used to identify nonculturable pathogens and to track disease movements.
- **Bioweapons**, when they have been used, typically kill few people but create great fear.
- **The CDC** has assembled a list of select agents with bioweapon potential.

Special Topic 28.1 Microbial Pathogen Detection Gets Wired Up

The emergence of pathogenic infectious diseases resulting from both natural and intentional acts is a growing global concern. Acts of bioterrorism, particularly, represent a formidable challenge that dictates the need for rapid and efficient means of pathogen detection. The ideal detection system would integrate sample processing and pathogen characterization into a single automated device that would eliminate laborious, time-consuming sample processing and costly detection. One promising detection system involves a hybridization-based bioelectronic DNA detection chip that is in the testing phases.

The basic design, illustrated in **Figure 1**, requires two hybridization events to generate a detection signal. First, a DNA capture probe is affixed to a gold electrode chip. The capture probe is complementary to one part of a gene that is specific to a given pathogen. Next, a solution containing unknown DNA is injected into the chip. If the target gene is present, the capture probe will hybridize to a single-stranded part of the gene's DNA and "capture" it. The actual detection signal is then generated following a second hybridization. The second probe used is complementary to the downstream region of the same captured gene. This probe is not affixed to the gold support but contains a ferrocene label at one end. If the target DNA is captured, the second probe will anneal

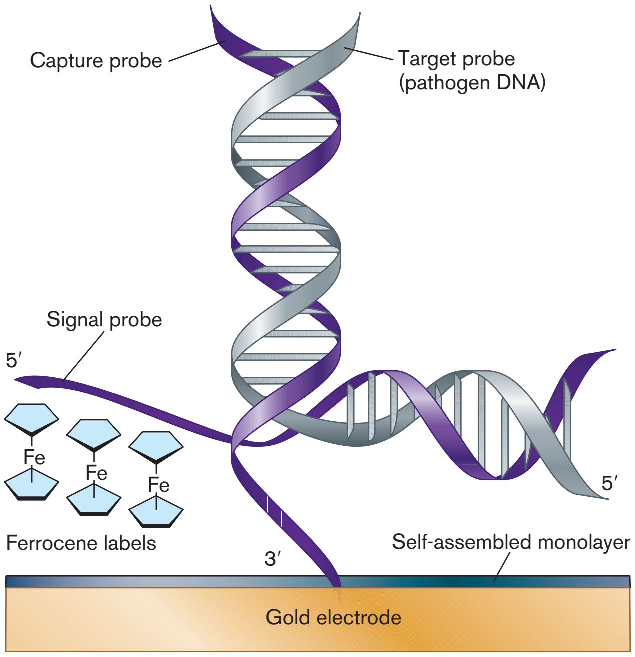

Figure 1 Electronic detection of pathogens. Schematic representation of the eSensor DNA Detection System. A self-assembled monolayer is generated on a gold electrode. For electrochemical detection to occur across the monolayer, two hybridization events must occur: the first between the capture probe (shown in purple perpendicular to the electrode) and the target (for example, HPV DNA, shown in gray), and the second between an adjacent region of the target HPV DNA and a second, ferrocene-labeled signal probe (shown in purple parallel to the monolayer).

28.6 Detecting Emerging Microbial Diseases

Case History: SARS

A 48-year-old man was hospitalized in a Dutchess County, New York, hospital with a 101°F fever, headache, and body aches. He also had difficulty breathing. He had just returned from a business trip to China.

SARS: An Epidemiological Success Story

Within seven weeks in early 2003, epidemiologists armed with global technologies and rapid DNA-sequencing techniques tracked, named, identified, completely sequenced and contained a newly emerging disease with a scary death rate: severe acute respiratory syndrome (SARS). This was a remarkable feat, especially when we consider that after the first cases of AIDS appeared in 1981, it took over three years just to identify the virus, and it took seven years to track down the Lyme disease spirochete, *Borrelia burgdorferi*, after Lyme disease was first recognized in 1975.

We now know that SARS first developed in Asia, then began to spread by jet to other countries, such as Canada. While the death rate seemed modest at about 5%, it was higher than the 4% reached during the 1918 flu epidemic that killed 25–40 million people worldwide. SARS clearly posed a formidable threat. Unprecedented cooperation between the WHO, the CDC, and numerous other health organizations around the world played a major role in tracking and containing the disease. Patient information, case histories, possible treatment regimens flooded into a secure WHO website. The most exciting posting was the 30,000-bp sequence of the SARS genome, taken from one-millionth of a gram of genetic and bring the ferrocene molecules in contact with the gold electrode, generating an electrochemical signal. These signals are then detected by a scanning AC voltammetry technique (voltammetry is an electroanalytical method whereby information about an analyte is obtained by measuring current as potential is varied). As shown in **Figure 2**, Suzanne Vernon and colleagues at the Centers for Disease Control (CDC) have used this approach to detect the presence of human papillomavirus (HPV, a cause of genital warts) in a dramatic test of the system.

Of course, an ideal system to use in the field would also include an automated DNA extraction technology, a development that is yet to come. Nevertheless, the elegance of this design promises to be invaluable for pathogen detection under a variety of circumstances.

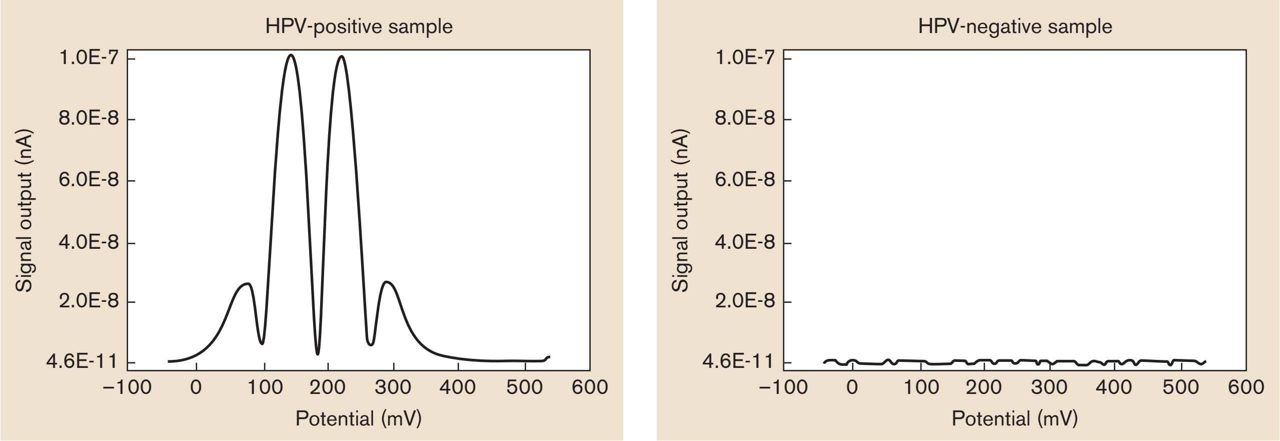

Figure 2 **Bioelectronic signal output.** The eSensor bioelectronic representative signal output. The peaks in the first panel reveal the electrochemical signal generated when the ferrocene from the DNA probe comes in contact with the gold electrode. The second panel represents a negative control sample.

material isolated from a Toronto patient. The following 2003 timeline illustrates the remarkable speed with which all this took place:

February 14—China first reports 305 cases of atypical pneumonia to WHO.
March 15—WHO issues emergency travel alert, names illness SARS.
March 17—Leading epidemiologists join WHO in conference call, agree to unprecedented cooperation.
April 4—U.S. President George Bush authorizes quarantine of SARS patients.
April 12—Canadian scientists in Vancouver post the completed genome on the Internet.
April 16—WHO announces that SARS is caused by a pathogen never before seen in humans, a new coronavirus.

Technology Helps New Infectious Agents Emerge and Spread

Despite all we know of microbes, despite the many ways we have to combat microbial diseases, our species, for all its cleverness, still lives at the mercy of the microbe. Lyme disease, MRSA, SARS, Ebola, *E. coli* O157:H7, HIV, "flesh-eating" streptococci, hantavirus—all of these and many other new diseases have emerged over the last 30 years. Worse yet, forgotten scourges, such as tuberculosis, have reappeared. Yet in the 1970s, medical science was claiming victory over infectious disease. What happened?

Part of the equation has been progress itself. Travel by jet, the use of blood banks, and suburban sprawl have all opened new avenues of infection. People unwittingly infected by a new disease in Asia or Africa can, traveling by jet, bring the pathogen to any other country in the world within hours. The person may not even show symptoms until days or weeks after the trip. This means that diseases can spread faster and farther than ever before. In addition, newly emerged blood-borne pathogens can spread by transfusion. This was a major problem with HIV before an accurate blood test was developed to screen all donated blood.

Although human encroachments into the tropical rain forests have often been blamed for the emergence of new pathogens, one need go no farther than the Connecticut woodlands to find such developments. *Borrelia burgdorferi*, the spirochete that causes Lyme disease, lives on deer and white-footed mice and is passed between these hosts by the deer tick (Fig. 26.26). This infectious cycle has been going on for years. Humans have crossed paths with these animals long before the disease erupted in our communities. Why have we suddenly become susceptible? The answer appears to be suburban development. In the wild, foxes and bobcats hunt the mice that carry the Lyme agent. These predators disappear as developers clear land and build roads and houses, leaving the infected mice and ticks to proliferate. Humans in these developed areas are more likely to be bitten by an infected tick and contract the disease than in prior decades. Luckily, many diseases that successfully leap from animals to humans find the new host to be a dead end, unable to spread the disease to others.

There are numerous examples in which technology and progress have had the unintended consequence of breeding disease. Here are just a few:

- **Mad cow disease:** Modern farming practices (North America and Europe) of feeding livestock the remains of other animals helped spread transmissible spongiform encephalopathies similar to Creutzfeldt-Jakob disease associated with prions. Because the prion is infectious, the brain matter from one case of mad cow disease could end up infecting hundreds of other cattle, which in turn increases the chance that the disease could spread to humans.
- **Lyme disease:** Suburban development in the northeastern United States destroys predators of the mice that carry *Borrelia burgdorferi*.
- **Hepatitis C:** Transfusions and transplants spread this blood-borne disease.
- **Influenza:** Live poultry markets in Asia serve as breeding grounds for avian flu viruses that can jump to humans.
- **Enterohemorrhagic *E. coli* (for example, *E. coli* O157:H7):** Modern meat-processing plants can accidentally grind trace amounts of these acid-resistant, fecal organisms into beef while making hamburgers.

Natural environmental events can also trigger upsurges in the incidence of unusual diseases. A good example of this involves the hantavirus (also known as Sin Nombre virus). An unprecedented outbreak of hantavirus pulmonary disease occurred in the Four Corners

area of Arizona, New Mexico, Colorado, and Utah in 1993 when rain lead to greater than normal increases in plant and animal numbers. The resulting tenfold increase in deer mice, which carries the virus, made it more likely that infected mice and humans would come in contact.

Detecting Emerging and Reemerging Pathogens

A world map showing the general locations of **emerging** and **reemerging diseases** is shown in **Figure 28.23.** A reemerging disease is one thought to be under control but whose incidence has risen. For example, the incidence rate of tuberculosis dropped sharply in the 1950s, but the number of recent cases has increased just as dramatically. Tuberculosis is a reemerging disease. The trigger for its reemergence was the AIDS pandemic beginning in 1980. Immunocompromised AIDS patients are highly susceptible to infection by many organisms, including *Mycobacterium tuberculosis*.

Mycobacterium tuberculosis is also reemerging among non-AIDS patients owing to the development of drug-resistant strains. Drug resistance in *M. tuberculosis* developed largely because of noncompliance on the part of patients to complete their full courses of antibiotic treatment. Treatment usually involves three or more antibiotics to reduce the risk that resistance to any one drug will develop. Many patients failed to take all three drugs simultaneously, allowing the organism to develop resistance to one drug at a time until it became resistant to all of them. These highly drug-resistant strains are almost impossible to kill. The link between noncompliance and the development of drug resistance is the primary reason why tuberculosis patients are now required to take the multiple antibiotics prescribed in the presence of the physician or a member of the medical staff.

As described in Section 28.5, highly infectious diseases are identified using aggressive epidemiological surveillance. Communications between local, national, and world health organizations are critical and helped expose the rise in tuberculosis. To see for yourself how emerging diseases are monitored, search the Internet for a website titled ProMed-mail. There you will find daily reports posted from around the world that describe new outbreaks of infectious diseases.

For example, a posting on June 21, 2006, reports that "11 students at a Franklin elementary school (Boston) have confirmed cases of salmonella, and state health officials are investigating whether owl pellets used in a class project were the source of the bacterial infection." The source was eventually confirmed to be the owl pellets. Another posting from the Congo in Africa notes reports of 100 cases of suspected pneumonic plague, including 19 deaths in the Ituri district, Oriental province. The site also posts reports of undiagnosed illnesses that *may* be the initial signs of emerging diseases. For instance, on June 23, 2006, there is a report of an undiagnosed die-off of wild birds in Zambia, which may be due to avian flu. By tracking these reports, trends of disease spread can be determined.

THOUGHT QUESTION 28.9. Using the "Maps of Outbreaks" provided on the ProMed-mail website, identify the countries considered to have anthrax epidemics.

TO SUMMARIZE:

- **Emerging diseases** can spread quickly around the world as a result of air travel.
- **Modern technology** and urban growth have provided opportunities for new diseases to emerge.

Concluding Thoughts

This chapter has examined the basic principles used to collect, detect, and track pathogenic microorganisms. As you can see, the task of controlling the spread of disease is daunting and ever changing because microorganisms continue to evolve. Known pathogens change, eluding eradication efforts by the immune system and antibiotics, while new pathogens keep emerging. The world is depending on the next generation of microbiologists to face the growing threat of these evolving microbes.

CHAPTER REVIEW

Review Questions

1. Why is it important to identify the genus and species of a pathogen?
2. What is an API strip, and what is its use in clinical microbiology?
3. Describe three examples of selective media.
4. If a colony on a nutrient agar plate is catalase-positive, does this mean it is made up of gram-positive microorganisms? Why or why not?
5. Describe the types of hemolysis visualized on blood agar.

6. What is the clinical significance of a group A, beta-hemolytic streptococcus?
7. How does one distinguish *S. aureus* from *S. epidermidis*?
8. Why are PCR identification tests preferable to biochemical approaches?
9. How is RTQ-PCR performed?
10. Describe an ELISA.
11. Name some sterile and nonsterile body sites.
12. List seven common types of clinical specimens collected for bacteriological examination.
13. Describe key features of the four levels of biological containment.
14. How is a pandemic different from an epidemic?
15. How can genomics help identify nonculturable pathogens?
16. List and provide short descriptions of four emerging diseases.
17. Name four select agents and the diseases they cause.

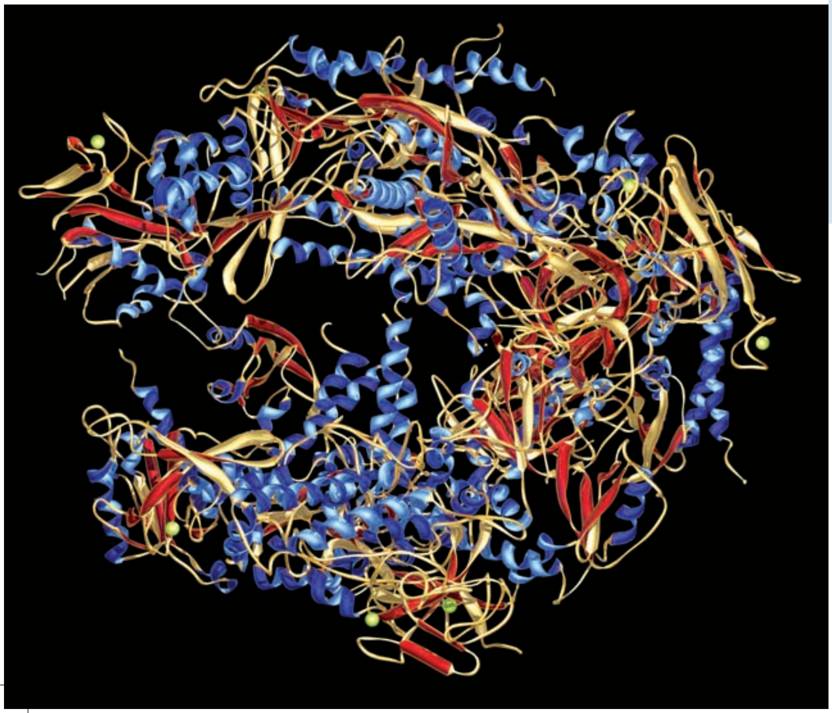
A1.7 Chemical Principles in Biological Chemistry

This appendix reviews information typically covered in an introductory biology course. We first cover the chemical bonding principles needed to understand biological molecules, with an emphasis on the special properties of water. We then discuss organic molecules, paying particular attention to four important classes of organic biomolecules—proteins, polysaccharides, nucleic acids, and lipids. Finally, we explore common chemical principles, such as concentrations, thermodynamics, equilibrium, pH, and oxidation-reduction reactions.



A computer model showing the structure of the enzyme RNA polymerase II. The molecule comprises 12 subunits. This enzyme synthesizes a complementary mRNA strand from a strand of DNA during a process called transcription. It recognizes a start sign on the DNA strand and then moves along the strand building the mRNA until it reaches a stop sign. mRNA is the intermediary between DNA and its protein product. *Source*: Mark J. Winter/Photo Researchers, Inc.

Living cells are remarkably complex machines, able to integrate and respond to multiple stimuli, to catalyze reactions, and to replicate themselves. Yet despite all the various tasks that cells perform, 98% of the mass of living organisms consists of only six elements: hydrogen (H), oxygen (O), nitrogen (N), phosphorus (P), sulfur (S), and carbon (C); and 90% of the mass is accounted for by just C, H, and O. Of the compounds formed from these elements, the most abundant in cells is water. The remainder of the cell consists, for the most part, of just four different kinds of organic (carbon-based) macromolecules: proteins, nucleic acids, carbohydrates, and lipids. In one respect, cells can be thought of as compartments that orchestrate chemical reactions between these organic molecules. It is clear that to understand life, we must understand the properties of water and organic molecules and of their building blocks, the chemical elements.

A1.1 Elements, Bonding, and Water

Cells consist mostly of water and organic molecules. These cellular components are formed from atoms of various elements. An atom consists of a positively charged nucleus that contains protons and neutrons, surrounded by negatively charged electrons. The hydrogen nucleus consists of a single proton. Protons, neutrons, and electrons differ in their mass and charge as summarized in **Table A1.1**.

The elements can be organized into a periodic table as in **Figure A1.1**, indicating each element's **atomic number** (the number of protons) and **atomic mass** (the mass in grams of 1 mole of the element). The defining characteristic of an element is the atomic number. For example, all carbon atoms have six protons in their nucleus. To maintain neutrality, atoms have negatively charged electrons equal in number to the positively charged protons.

The atomic mass is found by adding together the number of protons and neutrons. The atomic mass is an average that takes into account the relative abundance of each isotope. **Isotopes** are atoms of an element that differ in the number of neutrons. For example, the most abundant isotope of carbon is carbon-12 (with six neutrons), but there are naturally occurring isotopes of carbon-13 (seven neutrons) and carbon-14 (eight neutrons). Because carbon-13 and carbon-14 are rare, the average atomic mass is close to but not exactly 12. While some isotopes are stable, others decay at a known rate and give off radioactivity. Carbon-14 has a **half-life** (the amount of time it takes for half of the sample to decay) of 5,700 years and is used in radiocarbon dating to determine the age of organic material. Carbon-14 and shorter-lived isotopes such as tritium (hydrogen with a mass of 3—one proton and two neutrons) are used by scientists as tracers to follow specific atoms in metabolic pathways.

Table A1.1 The mass and charge of atomic particles.

Particle	Mass (atomic mass unit)	Charge (electronic charge unit)
Proton	1	+1
Neutron	1	0
Electron	0.0005	−1

Bonds Hold Elements Together to Form Molecules

Atoms combine by sharing electrons to form molecules. For example, two atoms of oxygen combine to form molecular oxygen, O_2. Molecules may also contain more than one kind of element; an example is water, H_2O. The symbols O_2 and H_2O are examples of **molecular formulas**, a shorthand notation indicating the number and type of atoms present in a molecule.

Each column (group) in the periodic table contains elements of similar reactivity as a result of the similarity in their electronic configurations, particularly of electrons in the outermost shell. The shell closest to the nucleus can hold a maximum of two electrons and the next shell a maximum of eight electrons. **Figure A1.2A** shows all the electrons for hydrogen, carbon, nitrogen, and oxygen. Each unpaired electron is capable of participating in a bond. If we examine **Figure A1.2A**, it is clear that H can form one bond, C four bonds, N three bonds, and O two bonds. For example, carbon has four unpaired electrons in its outermost shell; each can form a bond with an unpaired electron from another atom. The two atoms involved in this bond "share" the two electrons. This sharing of electrons is termed a *covalent bond*. Covalent bonds are very strong and difficult to break. In methane (CH_4), carbon forms four covalent bonds with four hydrogen atoms (**Fig. A1.2B**). Methane is stable because both carbon and hydrogen have filled their outer shells. Atoms can also share more than one pair of electrons with another atom, forming double or triple bonds. In carbon dioxide, CO_2, each oxygen shares two pairs of electrons with carbon; and in diatomic nitrogen, N_2, the nitrogen atoms each share three pairs of electrons (see **Fig. A1.2B**). The bonding in molecules can be represented in a shorthand representation by a **structural formula**, in which covalent bonds are shown as a line between two atoms (**Fig. A1.2C**).

Another way atoms can obtain full outer shells is by gaining or losing electrons. A complete transfer of electrons can occur between two atoms that have a large

Figure A1.1 **Periodic table of the elements.** The atomic number (number of protons) and atomic mass are shown for each element.

difference in **electronegativity**, a measure of the affinity of an atom for electrons. A large electronegativity indicates a strong attraction for electrons. Of the elements listed in **Table A1.2**, oxygen has the greatest attraction for electrons and sodium the weakest. If two elements with greatly different electronegativities come into close contact, one element can "steal" an electron from the other. For example, sodium (Na) and chlorine (Cl) interact to form table salt, NaCl. The electronegative Cl strips an electron away from Na, and both Cl^- and Na^+ now

Hydrogen	2.10
Sodium	0.93

have full outer shells (**Fig. A1.3A**). Both Cl^- and Na^+ are charged atoms called ions, in which the number of electrons and protons are unequal. **Anions** are negatively charged ions, and **cations** are positively charged ions. Anions and cations can form ionic crystals held together by **ionic bonds**, electrostatic attractions between anions and cations (**Fig. A1.3B**). In the absence of water, ionic crystals maintain their integrity, but they are destabilized in the presence of water. To understand why, we need to understand the structure of water.

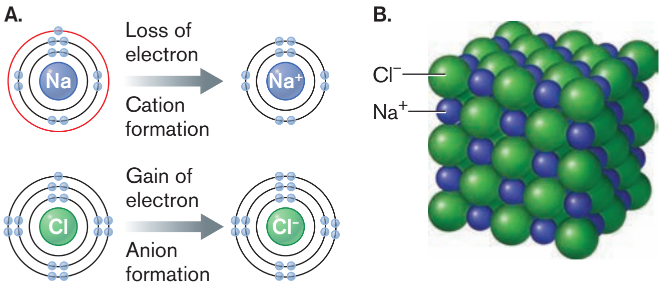

Figure A1.3 Formation of ions and ionic crystals. **A.** The loss of an electron from an atom of sodium to form the cation Na^+ and the gain of an electron by a chlorine atom to form the chloride anion Cl^-. **B.** Oppositely charged anions and cations—in this case, Cl^- and Na^+—are attracted to one another and form crystals of table salt (sodium chloride).

Water Is the Solvent of Life

Living organisms consist mostly of water, and water has many unique properties that render it particularly suitable for sustaining life. To appreciate these properties, we must understand the forces that hold water together: polar covalent bonds and hydrogen bonds. For molecules such as H_2 and O_2, there is no charge distribution within the molecule because both atoms in the molecule have the same electronegativity. Therefore, the electrons in the covalent bond are shared equally and form **nonpolar covalent bonds**. In contrast, the shared electrons in H_2O spend more of their time around the highly electronegative oxygen than in the vicinity of the less electronegative hydrogen (**Fig. A1.4A**). A bond with unequal electron sharing is a **polar covalent bond**, so called because the molecule has partial positive and negative poles. Polar covalent bonds occur in individual water

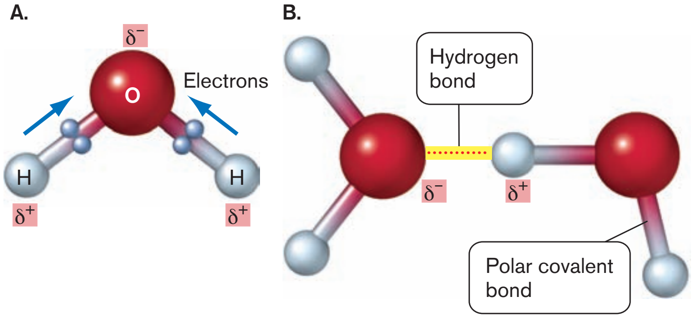

Figure A1.4 Polar covalent and hydrogen bonds in water. **A.** The polar covalent bonds in an individual water molecule. Displacement of electrons toward oxygen causes oxygen to have a partial negative charge and the hydrogen atoms to have a partial positive charge. Hence, water is polar. **B.** A hydrogen bond between two water molecules.

Table A1.3 Bond types and strengths.

Type of bond	Description	Bond strength in water (kJ/mol)[a]
Covalent	Sharing of electrons	210–418
Ionic	Electrostatic attraction between anion and cation	12.5
Hydrogen	Electrostatic attraction between a hydrogen bound to a nitrogen or oxygen and a second nitrogen or oxygen	4
van der Waals	Electrostatic attraction between temporary, shifting electron clouds	0.42 (per atom)

[a] Bond strengths are given in water, which is similar to the environment in the aqueous cytoplasm. Anhydrous bond strengths differ from those listed.

molecules, creating a partial charge separation within the molecule.

Water molecules experience a strong electrostatic attraction for one another as a result of the charge separation present in individual molecules. This electrostatic attraction, known as a **hydrogen bond**, occurs between a hydrogen bound to an oxygen or nitrogen and a second oxygen or nitrogen, either in the same or a different molecule. Hydrogen bonds are short-lived and constantly break and re-form in liquid water. **Figure A1.4B** shows the polar covalent and hydrogen bonds present in water.

The hydrogen bonds in water contribute to its unique properties that enable it to support life. Water is a liquid over a large temperature range because hydrogen bonds cause water molecules to associate, favoring the liquid state over the gas. The hydrogen bonds that keep water a liquid over a wide range of temperatures also endow water with a high specific heat, the amount of energy needed to raise the temperature of 1 gram (g) of a substance by 1°C. The high specific heat of water moderates the temperature of all aqueous environments, oceans and cells alike.

The polar nature of water is also responsible for its properties as a solvent. Compounds that are ionic or polar themselves tend to dissolve in water and are termed **hydrophilic**. For example, the ionic bonds in NaCl are very strong in the absence of water, but are easily dissolved in the presence of water. This is because the polar water can surround and interact with the sodium and chloride ions and shield them from each other (**Fig. A1.5A**). Water also dissolves polar compounds. In this case, water does not break the polar covalent bonds; rather, individual, intact polar molecules are surrounded by water owing to electrostatic interactions. In contrast, compounds that are mostly nonpolar do not dissolve in water and are termed **hydrophobic**. Nonpolar molecules have no partial charges to attract water. Because water hydrogen-bonds with other water molecules, it tends to exclude nonpolar compounds, forcing them together (**Fig. A1.5B**). The aggregated nonpolar compounds can be further stabilized by **van der Waals forces**, weak temporary electrostatic attractions between molecules caused by random movements of their electron clouds. **Table A1.3** lists the bonds we have discussed and indicates the strength of the bonds in water.

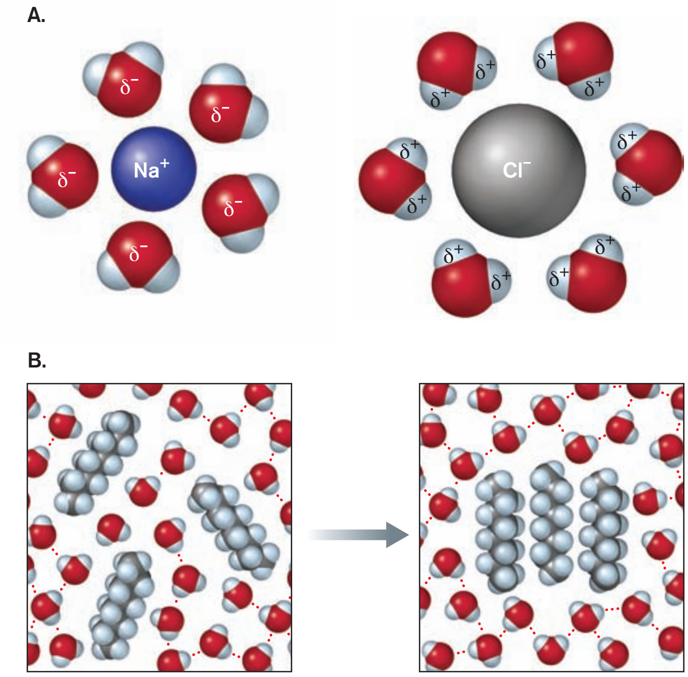

Figure A1.5 Interactions between water and solutes. **A.** Water surrounds and interacts with individual ions or polar molecules, causing them to dissolve in water. **B.** Nonpolar molecules do not dissolve in water. Instead, to minimize the disruption of hydrogen bonding among water molecules, nonpolar molecules aggregate in water.

A1.2 Common Features of Organic Molecules

Now that we have discussed water, let's take a look at some of the organic molecules found in cells. **Organic molecules** are those that contain a carbon-carbon bond.

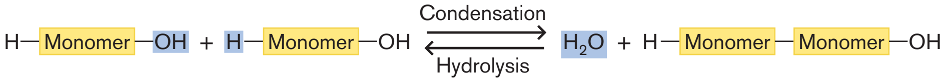

Figure A1.6 Condensation and hydrolysis reactions. Monomers can be covalently bonded to form polymers through a condensation reaction that liberates a water molecule. Polymers can be broken apart into monomers through hydrolysis (water-splitting) reactions.

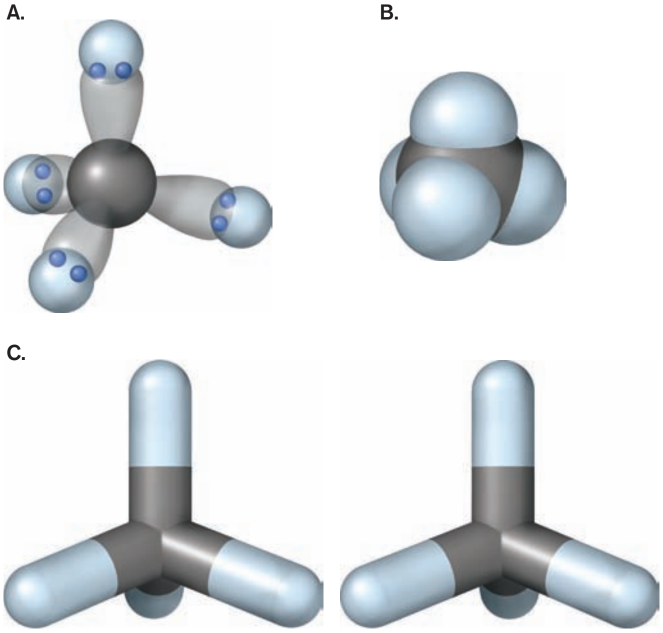

Figure A1.7 Molecular models of methane. A. A molecule of methane showing the tetrahedral arrangement of the electrons in the second (valence) shell of carbon. **B.** A space-filling model of methane. **C.** A stereo-image view of a stick model of methane. To view the stereo-image, place a piece of cardboard vertically between the two images. Position your eyes on opposite sides of the cardboard and force them to focus behind the images. The images will merge and produce a 3-D image.

The major macromolecular components of cells are proteins, polysaccharides, nucleic acids, and lipids. Although the macromolecules differ from each other in their structures and cellular functions, they all share some common features:

- As polymers, the macromolecules found in cells are composed of smaller units called monomers. The monomers are joined to one another by a common reaction, called a **condensation,** that involves splitting out a molecule of water for each monomer unit added. Conversely, the polymers can be broken apart into monomers by **hydrolysis**, the addition of a molecule of water, as depicted in **Figure A1.6**.
- The three-dimensional shape, or structure, of a molecule is critical for proper function. The structure is determined by which atoms are present and how they are bonded together. Structural formulas like those in **Figure A1.2C** represent the sequence of bonds in a molecule; however, this does not adequately convey information about the three-dimensional shape of the molecule. It is particularly important to understand the shape of carbon-containing molecules because carbon is the backbone for most cellular macromolecules. The bonding orbitals in the second shell of carbon are arranged so that they point to the vertices of a tetrahedron; methane, the simplest hydrocarbon, actually has the shape of tetrahedron, with the hydrogen atoms at the vertices (**Fig. A1.7A**). **Figure A1.7B** and **C** show two different models used to depict the three-dimensional shape of molecules. The **space-filling model** shows the volume filled by the outer shell of the atoms. The **stick model** shows the length and orientation of interatomic bonds between the nuclei of each pair of atoms.

  There are inherent difficulties in presenting three-dimensional representations, such as the models just described, on a two-dimensional page. Images on a computer screen in conjunction with special glasses can give a sense of the actual three-dimensional structures of molecules. Viewers can use the mouse to rotate the molecule to see it from any angle. Often the viewer can choose whether to view the molecule as a space-filling or stick representation.
- An important feature of any organic molecule is the number and type of functional groups present. **Functional groups** are small groups of atoms with characteristic bonding, shape, and reactivity. A few of the more common ones are shown in **Table A1.4**. Knowing which functional groups are present in a molecule allows us to infer something about the structure and reactivity of the molecule. Information about the functional groups present in a molecule is often indicated by a molecule's name; for example, amino acids contain an amino group and a carboxyl (carboxylic acid) group.

We will discuss different classes of molecules individually, but in living cells, molecules of different types are frequently found in combination. For example, sugars decorate some proteins (glycoproteins) and lipids (glycolipids), and the ribosome is a complex of proteins and ribonucleic acids. Let us now examine the structure of the fundamental biological macromolecules in detail.

A1.3 Proteins

Cells express thousands of different proteins and may contain more than 2 million protein molecules. Proteins perform many functions, such as catalyzing reactions,

Table A1.4 Common functional groups.

Functional group	General structure	Example	Comments
Aldehyde		 **Acetylaldehyde**	Can react with alcohols Alkane		 **Ethane**	Nonpolar, tends to make molecules containing it hydrophobic; nonreactive
Amino		 **Methylamine**	Acts as a base by accepting a proton; found in amino acids $R{-}NH_2 + H^+ \longrightarrow R{-}NH_3^+$
Carboxyl		 **Acetic acid**	Acts as an acid by donating a proton; the ionized form name ends in *ate* (i.e., acetate)  **Acetate** **Proton**
Ester		 **Phosphodiester**	Common linkage found in lipids
Hydroxyl	R—O—H	 **Ethanol**	Polar, makes compounds more soluble through hydrogen bonding; found in alcohols and sugars
Ketone		 **Dihydroxyacetone**	Found in many intermediates of metabolism
Phosphate		 **Glyceraldehyde-3-phosphate**	When more than one phosphate is linked together, a high-energy bond forms due to repulsion of the negative oxygens

serving as receptors and transporters, providing structure, and aiding movement. Proteins can carry out such diverse functions because they can fold into a variety of three-dimensional structures.

The Building Blocks of Proteins Are Amino Acids

Although different proteins can have vastly different structures, all proteins are composed of the same building blocks: amino acids. All 20 of the amino acids commonly occurring in nature have the same general structure. Each **amino acid** contains a central carbon atom (the alpha carbon) covalently bound to four different moieties—a hydrogen atom, an amino group, a carboxyl group, and a side chain (R, residue) that is unique for each amino acid (**Fig. A1.8A**). The alpha carbon is an example of a **chiral carbon**, a carbon with four different groups attached to it. Chiral carbons exist in two different forms called optical isomers, or enantiomers.

Asymmetrical carbon atoms

Figure A1.8 Amino acid structure and chiral carbons. **A.** All amino acids contain a central carbon (the alpha-carbon) bonded to an amino group, a carboxyl group, a hydrogen, and a variable group or side chain, designated R. At cellular pH, the amino and carboxyl groups are ionized. Because the alpha-carbon is bound to four different molecules, it is a chiral carbon. **B.** Chiral molecules exist in two different forms that are mirror images of each other. The two forms cannot be superimposed, and only the correct isomer can interact with a template (for example, an enzyme).

Optical isomers have the same molecular formula and the same order of bonds within the molecules, but a different arrangement of their atoms in space. Optical isomers are actually mirror images of each other, like your left and right hands, and the two forms cannot be superimposed (**Fig. A1.8B**). Each of the amino acid isomers is designated L or D, based on the configuration at the alpha carbon. The amino acids used to make proteins all have the L configuration at the alpha carbon, and all of these amino acids can be derived by substituting the different

R groups for one another. Some unusual D-amino acids, with the opposite configuration at the alpha carbon, are found in bacterial cell walls.

The side chains of amino acids can be grouped according to their hydrophobicity, charge, or presence of specific functional groups. **Figure A1.9** depicts the 20 common amino acids, along with their three-letter abbreviations and single-letter codes. Several amino acids have unusual features: Glycine does not contain a chiral carbon and therefore does not have optical isomers; proline has a ring structure that interrupts the regular geometry of the polypeptide chain; and the side chain of cysteine is capable of forming inter- and intramolecular disulfide (–S–S–) bonds.

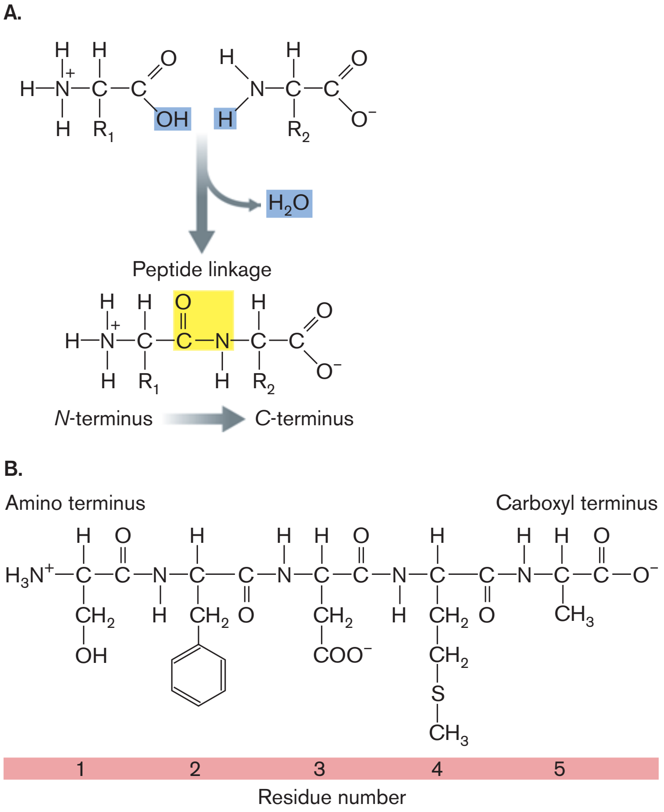

Figure A1.10 The peptide bond and primary protein structure. A. Formation of a peptide bond. Amino acids are joined by a condensation reaction between the carboxyl group of one amino acid and the amino group of another to form a covalent linkage called a peptide bond. **B.** The primary structure of a pentapeptide, a chain of five amino acids. This pentapeptide has the sequence SFDMA. A protein can be formed of hundreds or thousands of amino acids.

There Are Four Levels of Protein Organization

The first level of organization, the **primary structure**, is simply the linear sequence of amino acids. This is genetically determined; the DNA code specifies the amino acid sequence. During protein synthesis, amino acids are connected together by a condensation reaction to form a covalent **peptide bond**. The peptide bond forms between the carboxyl group of one amino acid and the amino group of a second amino acid, as shown in **Figure A1.10A**. The portion of the amino acid incorporated into the peptide after condensation is called an amino acid residue. Note that the peptide chain has an amino terminus (*N*-terminus) and a carboxyl terminus (*C*-terminus); numbering of the amino acid residues starts at the amino terminus (**Fig. A1.10B**). The bonds on either side of the alpha carbon can rotate, but there is no rotation around the peptide bond, so the backbone of a protein does not rotate freely.

The **secondary structures** of proteins are regular patterns that repeat over short regions of the polypeptide chain. **Figure A1.11A** depicts two common secondary structures, the alpha helix and the beta sheet. The alpha helices are flexible, coiled structures formed by a series of hydrogen bonds between an oxygen in a carboxyl group and a hydrogen in an amino group five amino acids down the chain. The beta-sheets are more rigid than the alpha helices. Beta sheets form as a result of extensive hydrogen bonding between regions of the protein lying next to each other. Both alpha helix and beta sheet secondary structures are stabilized by hydrogen bonding between the oxygen and hydrogen atoms of the peptide bonds in the main chain; the side chains do not directly participate. Proline, however, acts as a helix breaker because its ring structure does not allow the proper rotation around the alpha carbon that is necessary to form an alpha helix.

The **tertiary structure** of a protein is its unique three-dimensional shape. At the tertiary level of organization, regions distant in the primary structure may be brought close together. The nature and order of the side chains (the primary structure) determines how a protein folds into its final tertiary structure. The large number of amino acid side chains is responsible for the diversity of protein structures and hence functions. As proteins emerge from the ribosome, they are bound by chaperone proteins that help them fold into their functional shape, known as the **native conformation**. In soluble proteins, amino acids with hydrophobic side chains tend to cluster inside the protein to minimize reactions with water, while polar amino acids are exposed on the surface (**Fig. A1.11B**). Tertiary structure is stabilized by hydrogen bonding between side chains and between side chains and the main chain. Ionic interactions between acidic and basic side chains also contribute to tertiary structure. The one covalent interaction found stabilizing tertiary structure is disulfide bonding between two cysteine residues. The interactions that contribute to protein tertiary structure are shown in **Figure A1.11C,** and a ribbon representation of the three-dimensional structure of a protein is illustrated in **Figure A1.11D**.

Some proteins form stable, functional complexes with other proteins. These multisubunit proteins exhibit the fourth level of protein organization, **quaternary structure** (**Fig. A1.11E**). The forces that hold interacting polypeptide

chains together are the same noncovalent interactions and disulfide bonds responsible for protein tertiary structure.

It is important to note that proteins are not static structures. The individually weak hydrogen bonds, ionic interactions, and van der Waals forces that contribute to protein structure are constantly being broken and re-formed. Because these noncovalent bonds do not break all at once, the large number of such bonds present act collectively to maintain protein integrity. Some proteins are dynamic entities that may permute through a number of semistable states. Such conformational changes may be stochastic, random fluctuations due to the intrinsic thermal (kinetic) energy of the protein. Alternatively, the conformational changes may be influenced by external factors. For many proteins, alterations in conformation are critical for protein function.

A1.4 Polysaccharides

Polysaccharides are complex carbohydrates, composed of monosaccharide (simple-sugar) monomers. Carbohy-

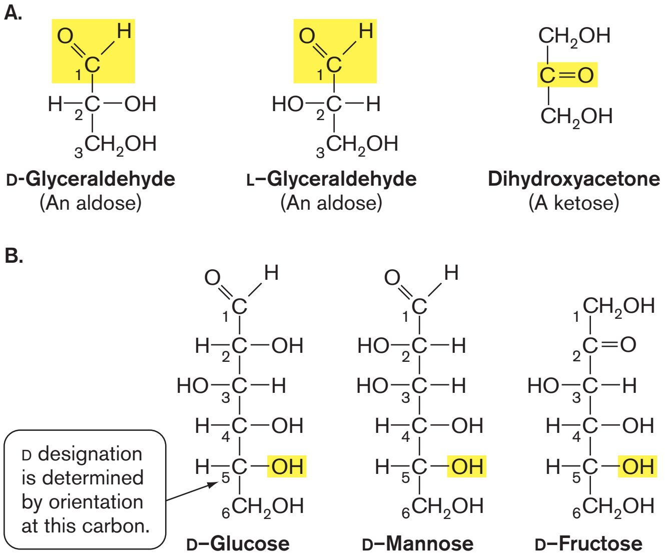

Figure A1.12 Structural formulas for some monosaccharides. A. The three-carbon sugars dihydroxyacetone and glyceraldehyde. The aldehyde and ketone functional groups are shown in yellow. Glyceraldehyde contains a chiral carbon and has two optical isomers. **B.** The hexose sugars glucose, mannose, and fructose. The numbering of the carbons starts at the carbon of the aldehyde group or at the free carbon closest to the ketone group. The D designation is determined from the orientation of the hydroxyl group on a chiral carbon farthest from the ketone or aldehyde functional group (highlighted).

drates are so named because their molecular formulas are multiples of CH_2O (hydrated carbon). Carbohydrates are a preferred energy source for many cells and also serve to store energy. They also play a structural role, as in cell walls. Moreover, when attached to proteins or lipids, they can serve an informational role.

Monosaccharides Are Aldehydes or Ketones with Multiple Hydroxyl Groups

Monosaccharides differ from each other in the number of carbons present, in whether they have an aldehyde or a ketone group, and in the orientation of the hydroxyl groups. The smallest sugars, glyceraldehyde and dihydroxyacetone, have three carbons (**Fig. A1.12A**). These two sugars have the same molecular formula, $C_3H_6O_3$, but since their atoms are arranged differently, they are **structural isomers** of each other. In addition, because glyceraldehyde contains a chiral carbon at C-2, it also has an optical isomer. In contrast to proteins, where the L-amino acids predominate, it is the D-sugars that are of biological importance.

The six-carbon sugars (hexoses) are particularly important in the cell. Hexose sugars include glucose, mannose, and fructose (**Fig. A1.12B**). Hexoses all have the molecular formula $C_6H_{12}O_6$ and are structural isomers of each other. While fructose is a keto sugar (ketose), mannose and glucose are both aldehydes (aldoses). The difference between mannose and glucose lies in the orientation of the hydroxyl group on one of the chiral carbons, C-2. The carbons in sugars are numbered starting with the carbon of the aldehyde group or the free carbon closest to the ketone group so the aldehyde group is always C-1.

In sugars of five or more carbons, one of the hydroxyl groups can react with the aldehyde or ketone group, forming a ring structure. The ring form predominates because it is more energetically favorable than the straight-chain sugar. In the formation of the cyclic form of glucose, two products can be formed (**Fig. A1.13**). Depending on how the bond between C-1 and C-2 was oriented during the formation of the ring, the cyclic form obtained will be alpha-glucose or beta-glucose. Both forms interconvert rapidly in aqueous solution, and both forms are found as components of biological structures.

The hydroxyl groups of sugars can react with other functional groups to form modified sugars. Examples include fructose 1,6-bisphosphate, an intermediate in glycolysis, and *N*-acetylglucosamine, a component of the peptidoglycan cell wall (**Fig. A1.14**).

Two Monosaccharides Condense to Form a Disaccharide

Disaccharides form when two monosaccharides undergo a condensation reaction to form a covalent glycosidic bond. The glycosidic bond often occurs between the C-1 carbon of one monosaccharide and the C-4 carbon of another

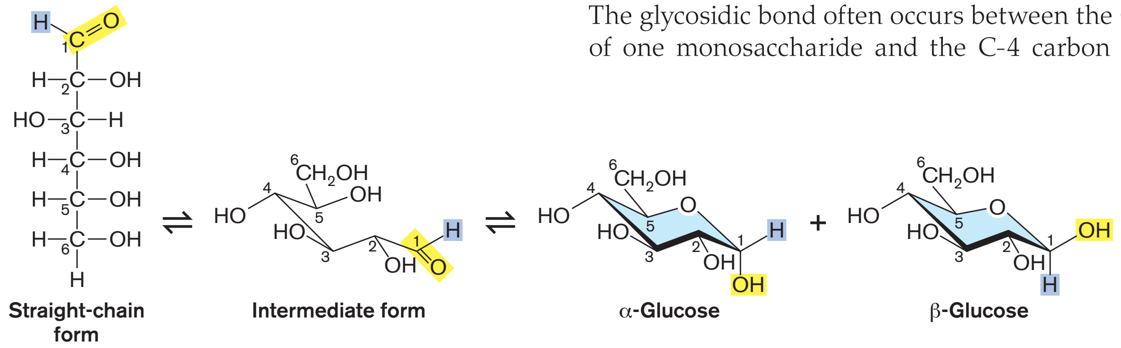

Figure A1.13 Straight-chain and cyclic forms of glucose. The straight-chain form of glucose can cyclize to form two different ring structures, alpha-glucose and beta-glucose. In this process, a new chiral carbon is formed at C-1, the anomeric carbon.

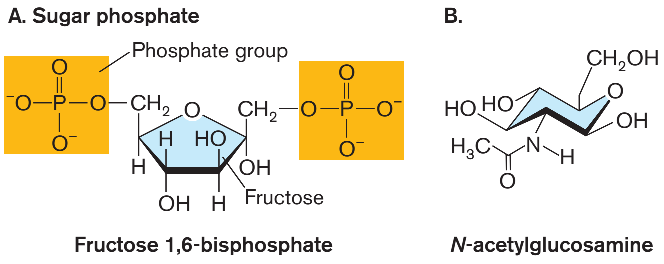

Fructose 1,6-bisphosphate

N-acetylglucosamine

monosaccharide (**Fig. A1.15**). The structure of the disaccharide varies, depending on which monosaccharides are involved and whether the C-1 carbon participating in the bond is in the alpha or beta form. Oligosaccharides consist of a few monosaccharides linked together, while polysaccharides are much longer chains of monosaccharides. Polysaccharides are unbranched if all the linkages are 1,4. In branched polysaccharides, additional sugars are attached to other hydroxyl groups (for example, at C-6).

A1.5 Nucleic Acids

Cells contain two kinds of nucleic acids: deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). DNA is the hereditary material of the cell; it encodes the information to make proteins. Three different types of RNA play key roles in protein synthesis: Messenger RNA (mRNA) is transcribed from DNA and is the template for protein synthesis; transfer RNAs (tRNAs) bind amino acids and deliver them to the ribosome; and ribosomal RNA (rRNA) is a catalytic component of the ribosome.

A Chain of Nucleotides Forms the Primary Structure of Nucleic Acids

Nucleic acids are polymers of nucleotides. **Nucleotides** have three components—a pentose sugar (ribose in RNA, 2-deoxyribose in DNA), a nitrogenous base, and a phosphate group (**Fig. A1.16A**). The nitrogenous base is attached to the C-1 of the sugar. Nitrogenous bases come in two structural classes: purines (adenine, A; and guanine, G), and pyrimidines (cytosine, C; thymine, T, found only in DNA; and uracil, U, found only in RNA). The phosphate group is esterified to the 5′-hydroxyl group of the sugar. (The prime indicates that the numbering refers to the sugar portion of the nucleotide; the base is numbered without primes.)

A nucleoside is similar to a nucleotide, except that it has only two components—a sugar and a base (that is, it lacks a phosphate group). The names of the nucleosides are listed in **Table A1.5**. *Nucleotides* are formed when a phosphate group forms a covalent ester bond to the C-5 carbon of the sugar portion of a *nucleoside*. The nomenclature for nucleotides uses the abbreviation for the nitrogenous base and adds the abbreviation MP, DP, or TP to designate the phosphate group as a monophosphate, diphosphate, or triphosphate, respectively (**Fig. A1.16B**). A small "d" in front of the nucleotide indicates that the sugar is 2-deoxyribose. For example, adenosine diphosphate is ADP, and deoxycytosine triphosphate is dCTP. In addition to being the precursors for nucleic acid synthesis, the ribose nucleotides have cellular functions of their own. For example, ATP is an energy carrier in the cell, and GTP and cyclic adenosine monophosphate (cAMP) are signaling molecules.

Table A1.5 Bases and nucleosides.

Base (abbreviation)[a]	Nucleoside (base plus ribose or deoxyribose)
Adenine (A)	Adenosine
Guanine (G)	Guanosine
Cytosine (C)	Cytidine
Thymine (T)	Thymidine
Uracil (U)	Uridine

[a] A,T,G, C, and U are abbreviations for the nucleotide bases; however, they are also used when referring to the nucleotides in a DNA or RNA strand to indicate which base is present in the primary structure.

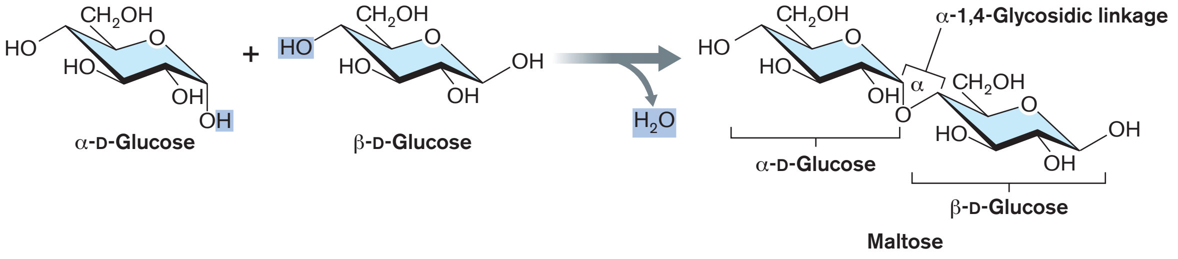

Figure A1.15 Formation of the disaccharide maltose. Maltose forms by a condensation reaction between two molecules of D-glucose, so that the C-1 of one molecule of glucose is linked by an oxygen atom to the C-4 of a second molecule of glucose. The hydroxyl groups of the second glucose can be either alpha or beta (the beta form is shown). The covalent glycosidic bond is called an α-1,4-glycosidic linkage because the oxygen on the C-1 carbon of the glycosidic bond is in the α position.

Figure A1.16 **Nucleotide and DNA structure.** **A.** A nucleotide consists of a five-carbon sugar (ribose or deoxyribose), a phosphate group, and a nitrogenous base. **B.** A nucleotide may be a monophosphate, diphosphate, or triphosphate. The phosphate attached to the sugar is designated alpha, the beta phosphate is in the middle, and the gamma phosphate is distal to sugar. **C.** The primary structure of DNA. The orientation of the strand is determined by the presence of a free phosphate on the 5′ end and a free hydroxyl on the 3′ end. The sequence of a nucleic acid is read from the 5′ end to the 3′ end, so for this portion of the DNA strand, the primary structure is GCTA. **D, E, F.** The secondary structure of DNA. **D.** A ribbon structure of the DNA double helix showing the purine-pyrimidine base pairs. **E.** A space-filling model of DNA. Note that the base pairs stack on top of each other like the rungs of a ladder. **F.** Hydrogen bonding between the base pairs. Two hydrogen bonds form between A and T, three hydrogen bonds between G and C. Note the antiparallel orientation of the two strands.

The nucleotide triphosphate monomers (collectively designated NTPs or dNTPs) form nucleic acids through reactions catalyzed by nucleic acid polymerase enzymes. The phosphate at the C-5 position forms a diester linkage with the hydroxyl group at C-3, releasing pyrophosphate. At one end of the nucleic acid is a free phosphate group; at the other end is a free C-3 hydroxyl group. The terminus with a free phosphate is called the 5′ end, and the terminus with the free C-3 hydroxyl is called the 3′ end (**Fig. A1.16C**). Repeating sugar-phosphate linkages form the "backbone" of the molecule, while the information content of nucleic acids resides in the sequence of bases attached to the backbone. This linear sequence of nucleotides, from the 5′ end to the 3′ end, is the primary structure of the nucleic acid.

The Secondary Structure of DNA Is the Famous Double Helix

Two strands of DNA, held together by hydrogen bonding between a purine and a pyrimidine on opposite strands, twist around each other to form a helix (**Figs. A1.16 D** and **E**). Two hydrogen bonds form between adenine and thymine, and three hydrogen bonds form between cytosine and guanine (**Fig. A1.16F**). The sugar-phosphate backbone of DNA is on the outside of the helix. The base pairs are inside the helix, but portions of them are accessible to proteins such as transcription factors at two grooves in the helix—a wide major groove and a narrower minor groove. The double-stranded structure of DNA is critical to its function as the hereditary material. Each strand of DNA encodes the information to make a new double helix based on strict base-pairing rules.

The Secondary Structure of RNA Is Diverse

In contrast to the invariant double-helix structure of DNA, RNA molecules have a variety of secondary structures that allow RNA molecules to perform a number of different functions in the cell. Secondary structures are possible because RNA is single-stranded and capable of complementary base pairing. Base pairing in RNA is similar to the base pairing exhibited by DNA, except that in RNA, uracil replaces thymine. Base pairing is used in making mRNA from a DNA template and also in protein synthesis, where a tRNA charged with an amino acid matches its anticodon with the codon on the mRNA (**Fig. A1.17**). Because RNAs are single-stranded, they can undergo *intramolecular* as well as *intermolecular* base pairing. Base pairing within a single RNA molecule can lead to interesting three-dimensional shapes that may allow the RNA to function as a catalyst. The activity of catalytic RNAs (ribozymes) may be enhanced by the reactive hydroxyl group at the C-2 of the ribose sugar, which is lacking in DNA.

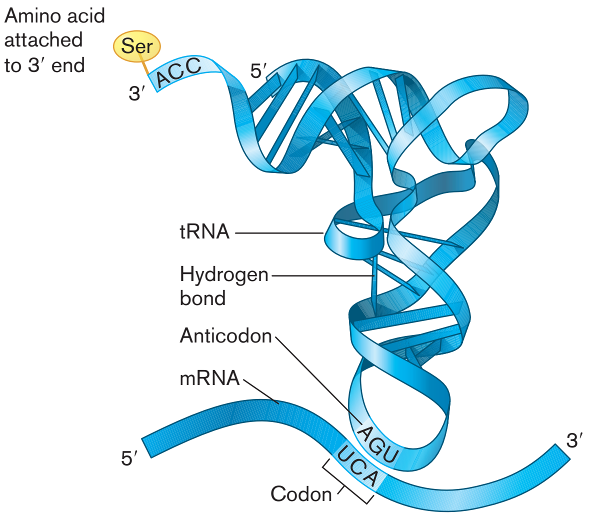

Figure A1.17 RNA secondary structure. A tRNA folds up into a secondary structure stabilized by the hydrogen bonds shown in the figure. The tRNA forms complementary base pairs with an mRNA.

A1.6 Lipids

Lipids are a structurally diverse class of molecules that have diverse functions. They are major structural components of cell membranes, they store energy, and they act as cellular signals. The common structural feature of lipid molecules is that they contain a substantial number of nonpolar C–H and C–C covalent bonds. Because lipids are nonpolar they are hydrophobic and do not dissolve in water.

Lipids Can Be Hydrophobic or Amphipathic

An example of a hydrophobic lipid is isoprene (**Fig. A1.18**), which functions as a building block for more complex cellular lipids such as squalene. Other lipid

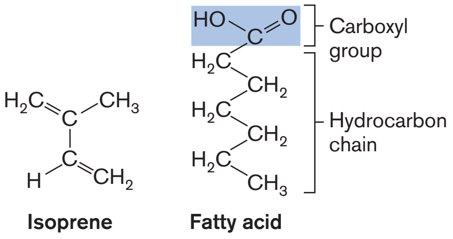

Figure A1.18 Lipid building blocks. Isoprene is used to make squalene and cholesterol. Fatty acids are components of triglycerides and phospholipids.

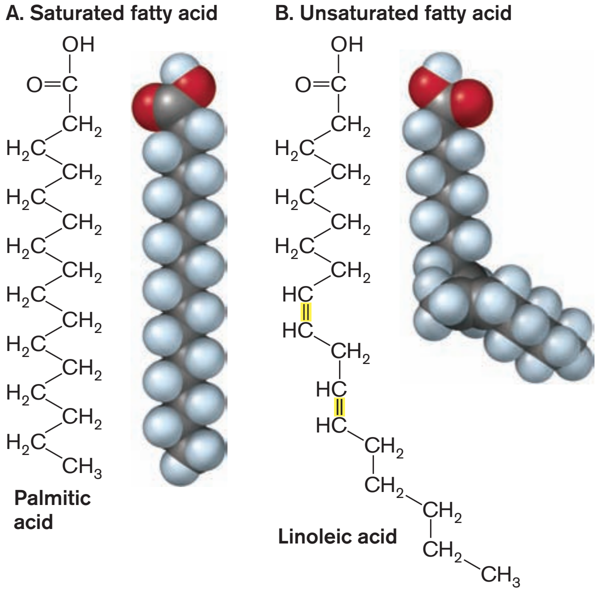
building blocks include the fatty acids (**Fig. A1.18**). In contrast to isoprene, the fatty acids have both a hydrophobic portion (the hydrocarbon tail) and a hydrophilic component (the carboxylic acid). Molecules with both hydrophobic and hydrophilic portions are described as **amphipathic**.

Fatty Acids May Be Saturated or Unsaturated

The cell contains many different fatty acids, which differ in the number of carbons (usually even) and their saturation (**Fig. A1.19**). In saturated fatty acids, the carbon-carbon bonds are all single bonds, and the carbons are bonded to the maximum number of hydrogen atoms. Unsaturated fatty acids contain one or more double bonds between adjacent carbons in the hydrocarbon tail. Monounsaturated fatty acids have one double bond; polyunsaturated fatty acids have multiple double bonds. Saturated fatty acids can pack together in an arrangement where they can be stabilized by van der Waals forces between adjacent hydrocarbon chains. Thus, saturated fatty acids (including animal fats such as lard) tend to be solids at room temperature. In unsaturated fatty acids, the double bond causes a kink in the chain that prevents tight packing, so unsaturated fatty acids, such as vegetable oils, tend to remain fluid at room temperatures.



A. Saturated fatty acid **B. Unsaturated fatty acid**

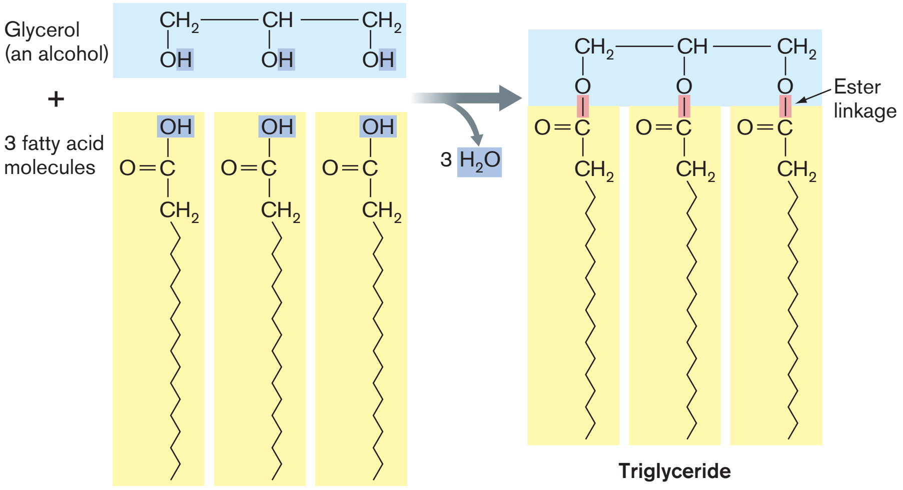
Figure A1.19 Saturated and unsaturated fatty acids. **A.** Palmitic acid is a saturated fatty acid; there are no double bonds between the carbon atoms. **B.** Linoleic acid is an example of a polyunsaturated fatty acid (it has more than one double bond). Note that the double bonds create kinks in the hydrocarbon tail.

Glycerol Is an Important Building Block of Many Lipids

The three hydroxyl groups on glycerol can undergo a condensation reaction with the carboxylic acid portion of fatty acids to form triesters, known as triglycerides.

Triglycerides are a compact energy source for cells (**Fig. A1.20**). Phospholipids, key components of the cell membrane, contain fatty acids attached to two of the hydroxyl groups of glycerol and a phosphate covalently attached to the third hydroxyl. The structure of phospholipids and how they function in cell membranes is fully explored in Appendix A2.1.

Figure A1.20 Formation of a triglyceride. Condensation reactions form covalent ester linkages between the carboxyl groups of three fatty acids and the three hydroxyl groups of glycerol.



A1.7 Chemical Principles in Biological Chemistry

To Express Very Large or Very Small Quantities, We Use Scientific Notation

Scientists often express very large numbers (such as the number of microorganisms in a liter of seawater) or very small numbers (such as the diameter of a bacterium) with the help of exponents. For example, a million, or 1,000,000, is often written as 1×10^6. The positive exponent 6 indicates how many decimal places to the right of the number 1 our number is. One-millionth, or 0.000001, is written as 1×10^{-6} to indicate six decimal places to the left of the number 1. Special prefixes can be used to modify the magnitude of units. These are listed in **Table A1.6**. For example, 1×10^{-6} is designated by the symbol μ (which stands for "micro"), so a length of 0.2 micrometer (μm) is equivalent to 2×10^{-7} meter (m).

When scientists work with a set of numbers that range over many orders of magnitude, they often use a logarithmic scale. For example, the pH scale is based on base 10 logarithms. Base 10, or common, logarithms are abbreviated log, as opposed to natural logarithms, abbreviated ln. Base 10 logarithms are defined as $\log 10^x = x$. For example the log of $1 \times 10^{-4} = -4$. The log of 10 = 1, and the log of 1 = 0.

Molarity Is a Unit Commonly Used to Measure Concentration

Scientists often measure concentrations. Concentration refers to how much of something is present in a given volume. A frequent way to report concentration is in units of molarity. **Molarity** is defined as the number of moles of substance per liter of solution (usually water). One mole is Avogadro's number (6.02×10^{23}) of molecules. If you wanted to make a 1-molar solution of NaCl, it would be impossible to know when you had added 6.02×10^{23} molecules to a liter of water. It's more convenient to weigh out a mole of NaCl on a balance. The weight of a mole of a substance is Avogadro's number times the weight of a molecule. For example, NaCl has a mass of 58.5 atomic mass units (amu), 23 from sodium and 35.5 from chlorine (see **Fig. A1.1**). Each amu is equal to 1.66×10^{-24} grams (g), so one molecule of NaCl weighs 9.71×10^{-23} g. A mole of NaCl then weighs 9.7×10^{-23} g times 6.021×10^{23} (Avogadro's number) = 58.5 g. (Note that this weight is the same as just adding together the atomic masses of Na and Cl and expressing it in grams.) So to make a 1-molar solution of NaCl, you would take 58.5 g of NaCl and add water up to a liter.

The Change in Free Energy Determines Whether a Reaction Proceeds Spontaneously

Reactions in organisms, such as the synthesis of proteins from amino acids by condensation, can occur only if they are energetically favorable. The study of energy and matter changes is called thermodynamics. All systems (including living systems, such as cells) must obey the laws of thermodynamics. The first law of thermodynamics states that energy is neither created nor destroyed. In a closed system (a system that is not exchanging energy with its environment), the total amount of energy remains constant. Although the amount of energy remains constant, energy can be converted from one form to another. The second law of thermodynamics states that in energy transformations, some energy becomes unavailable to do work and is lost as disorder, or entropy. In other words, entropy tends to increase. The laws of thermodynamics are summarized in **Figure A1.21.**

The total energy in a system, called enthalpy, can be expressed in the following equation, where *H* stands for

Table A1.6 Common numerical prefixes.

Prefix	Symbol	Factor
kilo	k	10^3
deci	d	10^{-1}
centi	c	10^{-2}
milli	m	10^{-3}

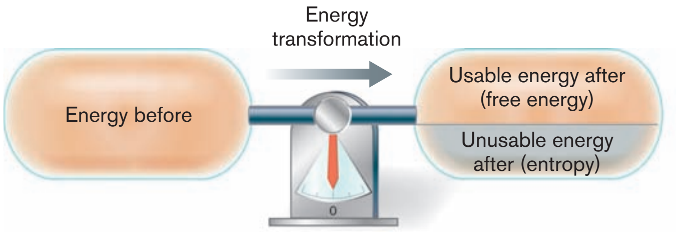
femto	f	10^{-15}



Energy transformation
Energy before
Usable energy after (free energy)
Unusable energy after (entropy)
0

Figure A1.21 The first and second laws of thermodynamics. The first law states that in an energy transformation, the total amount of energy remains constant. Both sides have the same amount of energy (the balance reads zero). The second law states that in an energy transformation, the amount of usable energy, or free energy, decreases and the amount of unusable energy, or entropy, increases.

enthalpy, G stands for free energy, S stands for entropy, and T stands for temperature:

$$H = G + T\,\Delta S$$

Because scientists are interested in the amount of free energy—that is, the amount of energy available, or free, to do work—the energy equation is usually written in terms of G:

$$\Delta G = \Delta H - T\,\Delta S$$

The triangle is the Greek letter delta, which signifies "change in." Here, a change in energy is defined as the energy of the products minus the energy of the reactants. Thus, ΔG means $G_{\text{products}} - G_{\text{reactants}}$, and ΔS indicates $S_{\text{products}} - S_{\text{reactants}}$.

Systems Tend Toward the Most Stable, Lowest Free Energy State

Reactions are favored when the free energy of the products is less than the free energy of the reactants, that is, when ΔG is negative. Reactions with a negative ΔG are termed spontaneous, or **exergonic**, because they are energetically favorable and can occur without an input of energy. Reactions with a positive ΔG are **endergonic**. They are not energetically favorable, and energy needs to be added for them to proceed. Reactions with a ΔG of zero are at equilibrium, and neither products nor reactants are favored.

The sign of ΔG is determined by changes in both enthalpy and entropy. For example, the following reaction, the oxidation, or "burning," of methane to release carbon dioxide and water, is spontaneous and has a negative change in free energy:

$$CH_4 + O_2 \rightleftharpoons CO_2 + H_2O + \text{energy}$$

The bonds in methane and oxygen have more energy than the bonds in CO_2 and H_2O. Because the products CO_2 and H_2O have less energy than the reactants, the change in enthalpy for this reaction, ΔH ($H_{\text{products}} - H_{\text{reactants}}$), is negative and the reaction is said to be exothermic.

A reaction does not need to be exothermic to be spontaneous. Consider an ice cube placed at room temperature. The ice cube will spontaneously melt even though this reaction is endothermic, absorbing heat from the environment. Ice melting is spontaneous because of the increase in entropy in going from a solid to a liquid. Remember that entropy, S, is a measure of the disorder of a system. Gases are more disordered than liquids, and liquids are more disordered than solids. Thus, the change in entropy, ΔS ($S_{\text{products}} - S_{\text{reactants}}$), from solid water (ice) to liquid water is positive because the product, liquid water, has more entropy than ice. Positive changes in entropy may result in a negative change in free energy, especially at high temperatures.

There is a Relationship between the Standard Free Energy Change and Chemical Equilibrium

To compare changes in free energy among different reactions, a standard change in free energy, $\Delta G°$ (the circle is pronounced naught), is defined as the change in free energy when the concentrations of all reactants and products are at 1 molar. $\Delta G°$ is a constant and depends on the nature of the products and reactants. Another constant, $\Delta G°'$ refers to the standard change in free energy at pH 7. A standard free energy change can be related to an equilibrium constant, K_{eq}, that indicates whether products or reactants will be favored at equilibrium. Reactions between biomolecules can be written as chemical equations. For example, in the following reaction, reactants A and B form products C and D:

$$A + B \underset{k_r}{\overset{k_f}{\rightleftharpoons}} C + D$$

The double arrow indicates that the reaction is reversible; A and B can be forming C and D at the same time that C and D are reverting to A and B. What determines whether the forward or reverse reaction will predominate? The forward and reverse rates depend on rate constants k_f and k_r, respectively. The rate constants depend on the nature of the interacting molecules and are an indication of how easily they will react. The forward and reverse rates also depend on concentrations of reactants and products:

$$\text{Rate forward} = [A][B]k_f$$

$$\text{Rate reverse} = [C][D]k_r$$

If the forward and reverse reactions are allowed to proceed, eventually equilibrium will be reached. All chemical reactions have a preferred state called **equilibrium**, where there is no *net* change in the reaction. Equilibrium is not static; rather, at equilibrium, the rate of the forward reaction equals the rate of the reverse reaction:

$$[A][B]k_f = [C][D]k_r$$

For every reaction, there is an equilibrium constant, K_{eq}, that indicates the relative ratios of products and reactants at equilibrium:

$$K_{eq} = k_f/k_r = [C][D]/[A][B]$$

A K_{eq} of 1 means that neither products nor reactants are favored; a K_{eq} greater than 1 indicates that products are favored at equilibrium; and a K_{eq} less than 1 means that reactants predominate. K_{eq} and $\Delta G°$ are related as follows where R is the gas constant (8.3×10^{-3} kJoule/mole × degree) and T is the temperature in kelvins:

$$\Delta G° = -RT \ln K_{eq}$$

A value of 298 K is often used (this is roughly 25°C). The relationship between K_{eq} and $\Delta G°$ is usually shown with the base 10 logarithm instead of the natural log:

$$\Delta G° = -2.303\ RT \log K_{eq}$$

This equation defines a relationship between $\Delta G°$ and K_{eq} that is discussed in Chapter 13. When K_{eq} is 1 (neither products nor reactants favored), $\Delta G°$ (defined as the change in free energy when concentrations of all substances are at 1 molar) is zero because the reaction is at equilibrium at that point. A K_{eq} of less than 1 (reactants favored) corresponds to a positive $\Delta G°$ because at 1-molar concentrations of reactants and products, the reaction will move to the left. A K_{eq} of more than 1 (products favored) corresponds to a negative $\Delta G°$ because at 1-molar concentrations, the reaction will move to the right.

Free Energy in Cells and the Law of Mass Action

Although the standard changes in free energy are useful for comparing the energetics and equilibria of different reactions, they do not reflect what is happening in the cell where concentrations of substances are probably not 1 molar. While K_{eq} and $\Delta G°$ are constants and unique for a particular reaction, ΔG depends on the actual concentrations of products and reactants as shown in the equation relating ΔG to $\Delta G°$:

$$\Delta G = \Delta G° + 2.303\ RT \log ([C][D]/[A][B])$$

In this equation, the concentrations of products and reactants are not their equilibrium concentrations, but the actual concentrations present at a given point in time. Because the concentrations of products and reactants will change as a reaction proceeds, the value of ΔG will change over time.

At equilibrium, where the total energy on each side of the reaction is equivalent, ΔG is zero. For an exergonic reaction at equilibrium, the total energy of reactants and products is equivalent because the amount of products is greater than the amount of reactants. If, at equilibrium, reactants (A, B) are added or products (C, D) are removed, ΔG will become negative. A negative ΔG causes the reaction to move to the right to reestablish equilibrium. As A and B convert to C and D, ΔG becomes less and less negative until it reaches zero again at equilibrium. If, at equilibrium, products are added or reactants are removed, ΔG will become positive and the reaction will proceed to the left to reestablish equal energy on both sides. This **law of mass action** is the tendency of a reaction to reestablish equilibrium after perturbations in the concentrations of products or reactants.

The law of mass action means that a reaction with a positive $\Delta G°$ can be made spontaneous and driven to the right by keeping the concentration of reactants high or the concentration of products low. The cell employs this strategy in metabolic pathways, where the product of one reaction is constantly removed by a subsequent reaction.

The Rate at Which a Reaction Proceeds Depends on the Activation Energy

It is important to realize that although a reaction with a large positive K_{eq} and negative $\Delta G°$ is spontaneous, it may be slow. The value of $\Delta G°$ says nothing about the rate of a reaction. Everyday examples of spontaneous but slow reactions are the aging process in humans and the rusting of metal. A reaction will be slow, even though it is spontaneous, if it must pass through an unstable, high-energy transition state on the way to forming products. The **activation energy** (E_a) is the energy needed to reach this transition state (**Fig. A1.22**). For reactions with low activation energies, random collisions between reactants may provide enough energy to boost them up and over the E_a. For reactions with high activation energies, collisions between molecules may not provide enough energy for them to reach the transition state.

Enzymes are biological catalysts that can speed up reaction rates by stabilizing transition states and lowering the activation energy. Most enzymes are proteins that specifically bind reactants and provide an environment

that facilitates product formation. Although enzymes increase reaction rates, they do not change the $\Delta G°$ or K_{eq} of a reaction. **Figure A1.22** illustrates how the difference in free energy between products and reactants is unchanged even in the presence of an enzyme that lowers the activation energy.

Many Biological Processes Are Sensitive to Changes in pH

Many biological processes occur only within a narrow range of hydrogen ion concentrations. Hydrogen ions (H^+) are also referred to as protons because they have lost their single electron and consist of only a proton. Hydrogen ion concentration is reported using a pH (power of hydrogen) scale, where pH is the negative logarithm of the hydrogen ion concentration: $pH = -\log [H^+]$. In pure water, which is considered neutral, $[H^+]$ is 1×10^{-7} molar (M), a pH of 7. Because the pH scale is logarithmic, every pH unit corresponds to a tenfold change in hydrogen ion concentration. A solution with a pH of 6 has a hydrogen ion concentration of 1×10^{-6} M, ten times the hydrogen ion concentration at pH 7. Hydrogen ion concentration $[H^+]$ multiplied by hydroxide ion concentration $[OH^-]$ always equals 1×10^{-14}. Hence, the concentrations of H^+ and OH^- are reciprocally related (if one goes up, the other goes down). If the pH is less than 7, a solution is acidic (more H^+, less OH^-). If the pH is greater than 7, the solution is basic, or alkaline (less H^+, more OH^-).

Acids (for example, carboxyl groups) donate protons, and bases (for example, amino groups) accept protons (**Fig. A1.23**). At intracellular pH (near 7), the carboxylic acid and amino group of amino acids are both ionized (charged), the carboxyl group carrying a negative charge and the amino group a positive charge. The ionization of these groups can change if the pH changes. At lower pH (more acidic solution) protons move back onto the ionized carboxylic acid. For example, the side chain of an acidic amino acid such as glutamate (see **Fig. A1.9**) is ionized at normal cell pH but may regain a proton and become glutamic acid at a lower pH. At higher pH values (lower proton concentrations), amino groups lose protons to become uncharged. Disturbances in the ionization state of carboxyl or amino groups on the side chains of amino acid residues can disrupt ionic bonds between these groups and lead to protein denaturation. This effect of pH on protein tertiary structure is one reason why cells can tolerate only a narrow range of intracellular pH.

Oxidation-reduction (Redox) Reactions Are an Important Way of Transferring Energy in Biological Systems

Biomolecules may undergo an important class of chemical reactions termed redox reactions. Redox reactions involve the transfer of electrons from one molecule to another or from one atom to another. The molecule that gains electrons becomes reduced, and the molecule that loses electrons becomes oxidized (**Fig. A1.24).** (A useful mnemonic device to remember this is “LEO the lion says GER.” LEO: lose electrons oxidation; GER: gain electrons reduction.)

Redox reactions are always coupled. If one atom loses electrons, another atom must gain electrons.

Figure A1.25 **The oxidation of methane.** Bonding electrons were shared equally by carbon and hydrogen in methane, but are closer to oxygen in carbon dioxide and water. Carbon and hydrogen have been oxidized; oxygen has been reduced.

Oxygen, with its large electronegativity, usually gains electrons and becomes reduced in redox reactions. Molecules that become reduced are called oxidizing agents because they cause something else to become oxidized. In contrast, reducing agents can donate electrons, reduce other molecules, and become oxidized themselves in the process. Molecules with reduced carbons contain more energy than their oxidized counterparts. Common reducing agents in the cell are NADH, NADPH, and $FADH_2$. These are all high-energy molecules that can donate electrons.

In addition to achieving a complete transfer of electrons, redox reactions can also occur if electrons are shifted toward or away from an atom. For example, in the burning (oxidation) of methane, electrons have moved away from the carbon and toward the oxygen (**Fig. A1.25**). Oxygen usually acts as an oxidizing agent; thus, we expect it to get reduced (gain electrons). By default, then, methane is oxidized; indeed, while the bonding electrons were shared fairly equally between C and H in methane, they are now close to the O in both carbon dioxide and water and farther away from the C and H. Thus, methane has been oxidized and oxygen has been reduced. This reaction releases energy because CO_2 and H_2O are the most stable lowest-energy forms available when carbon, hydrogen, and oxygen are combined.

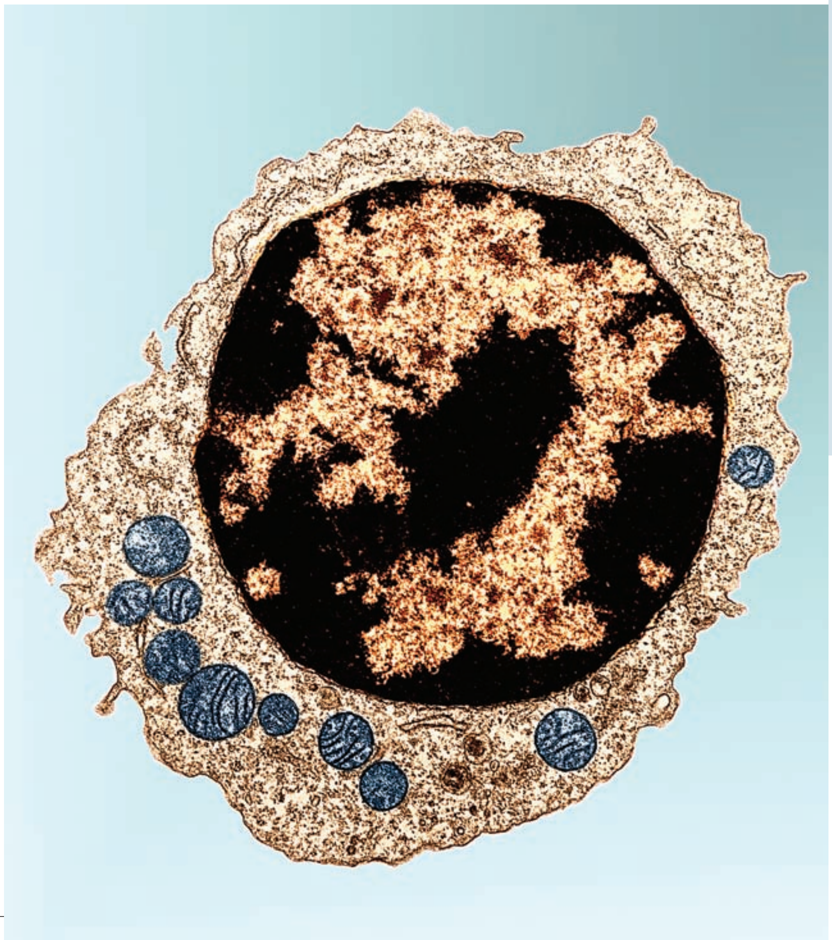
Appendix 2

Introductory Cell Biology: Eukaryotic Cells

A2.1 The Cell Membrane
A2.2 The Nucleus and Mitosis
A2.3 Problems Faced by Large Cells
A2.4 The Endomembrane System
A2.5 The Cytoskeleton
A2.6 Mitochondria and Chloroplasts

This appendix presents a review of cell biology principles generally covered in an introductory-level biology class. Cell biology encompasses fundamental principles of cell structure and function. Because all cells are enclosed by a cell membrane and need to regulate the transport of materials across the membrane, we cover this topic first. We then go on to discuss structures unique to eukaryotic cells.

All eukaryotic cells contain a nucleus, an organelle that houses the DNA. We describe the structure of the nucleus and the process of mitosis—a process that ensures the accurate separation of replicated chromosomes during cell division. We then explore the challenges encountered by eukaryotic cells owing to their large size compared to most prokaryotic cells. The endomembrane system, a network of internal membranes is discussed next, followed by a discussion of the cytoskeleton, a collection of proteins that form the basis of cell architecture and are responsible for cell movement. Finally, we discuss mitochondria and chloroplasts, the energy-producing organelles of eukaryotic cells.



This eukaryotic cell (lymphocyte white blood cell) shows numerous major organelles such as a large nucleus (orange) and multiple mitochondria (blue). (TEM ×20,550) *Source*: ©Gopal Murti/Visuals Unlimited

The cell is the basic unit of life. All organisms consist of either a single cell or a collection of cells. All cells can potentially perform a common set of tasks, including replication, catalysis, and regulation. The structures that enable these functions are found in all cells and include the cell membrane, DNA, and ribosomes (**Fig. A2.1**). Although the detailed organization of these structures differs in cells from the three domains (**Bacteria**, **Archaea**, and **Eukarya**; see **Table A2.1**), the fundamental structure and function of the cell membrane, DNA, and ribosomes are the same in all cells. This appendix describes the cell structures that are found across all three domains of life, then focuses on those that are unique to the eukaryotic domain, specifically organelles and the cytoskeleton.

A2.1 The Cell Membrane

All cells are enclosed by a **cell membrane** (sometimes called the **plasma membrane** or **cytoplasmic membrane**) that creates an internal environment distinct from the external environment. The aqueous fluid inside the membrane is called **cytoplasm** (or **cytosol**). Major functions of the cell membrane include the regulated transport of substances into and out of the cell and the reception of signals from the external environment. Membranes are also critical for energy production.

As shown in **Figure A2.2**, membranes consist mainly of lipids and proteins, but also contain some carbohydrates found in hybrid structures such as glycolipids and glycoproteins (sugars joined to lipids or to proteins, respectively). Although the membrane contains more lipid molecules than protein molecules, proteins may contribute most of the mass. The number and nature of proteins within a membrane depend on the membrane under consideration. For example, the inner membrane of the mitochondrion contains a rich array of proteins involved in energy production

Membrane proteins can be classified based on how they interact with membranes (**Fig. A2.2A**). **Transmembrane proteins** (integral proteins) span the bilayer. Transmembrane proteins are **amphipathic** meaning they have both hydrophobic and hydrophilic portions; the hydrophilic portions face the cytoplasm and the extracellular environment, and the hydrophobic components span the membrane. The transmembrane domains are often alpha-helices containing 15–20 amino acid residues (**Fig. A2.2B**). The portions of the protein that are intracellular, in the membrane, and extracellular depend on the protein and can be quite different for different proteins.

Peripheral membrane proteins are associated with the cell membrane but are not directly inserted into the bilayer. Some peripheral membrane proteins are retained at membranes through noncovalent interactions with transmembrane proteins, others by noncovalent interactions with the lipids of the membrane.

Lipids Are Responsible for Forming Membranes

The predominant lipids in membranes are phospholipids. **Phospholipids** consist of a core of glycerol, to which two fatty acids and a modified phosphate group are attached

Table A2.1 Comparison of cell structures in the three domains.

Feature	*Bacteria*	*Archaea*	*Eukarya*
Genome	Usually circular DNA Usually one chromosome May have plasmids Usually lacks introns	Usually circular DNA Usually one chromosome May have plasmids	Linear DNA Multiple chromosomes, in pairs Plasmids rare May have introns
Location of DNA	Nucleoid region in cytoplasm	Nucleoid region in cytoplasm	Contained within membrane-bound nucleus
Cell membrane	Glycerol bonded to straight-chain fatty acids via ester linkages	Glycerol bonded to branched fatty acids via ether linkages	Glycerol bonded to straight-chain fatty acids via ester linkages
Cell wall	Usually present, composed of peptidoglycan	Usually present, composed of pseudopeptidoglycan	If present composed of cellulose (algae) or chitin (fungi)
Internal membranes	Uncommon May have mesosomes or energy-transducing lamellae	Uncommon	Extensive membranous organelles
Ribosomes	Sensitive to chloramphenicol and streptomycin	Not sensitive to chloramphenicol and streptomycin	Not sensitive to chloramphenicol and streptomycin

via ester linkages (**Fig. A2.3A**). Unlike eukaryotes and bacteria, archaea have phospholipids with ether linkages. Phospholipids are amphipathic; the fatty acid hydrocarbon tails are hydrophobic, and the phosphate head group is hydrophilic. Amphipathic lipids are most stable in water when the hydrophilic portions interact with water and the hydrophobic portions cluster together away from water. One way phospholipids can achieve stability is by forming a bilayer. Indeed, the cell membrane is a **phospholipid bilayer**, two layers of phospholipids whose hydrocarbon fatty acid tails face the interior of the bilayer and whose charged phospholipid head groups face the aqueous cytoplasm and extracellular environment (**Fig. A2.3B**). The phospholipid layer in contact with the cytoplasm is called the **inner leaflet**, and the layer in contact with the environment is called the **outer leaflet**. Cells contain a number of different phospholipids that differ in how the phosphate head group is modified (**Fig. A2.3C**). Phospholipids can also differ in the length and saturation of the fatty acids chains (see Section A1.6 for fatty acid structures), and, as we shall see, these structural variations have functional consequences.

In addition to phospholipids, eukaryotic membranes contain a variable amount of the steroid cholesterol (**Fig. A2.3D**). Like phospholipids, cholesterol is amphipathic, with a hydrophilic hydroxyl group and hydrophobic hydrocarbon rings and tail. In membranes, cholesterol is oriented so that the hydrophilic hydroxyl group interacts with the phosphate head groups of phospholipids, while the hydrophobic rings and tail of cholesterol interact with the phospholipid hydrocarbon tails. The amount of cholesterol present in membranes varies among cells and also among organelles within a cell. Cholesterol contributes to membrane integrity by providing mechanical stability to the phospholipid bilayer. Bacterial membranes do not contain cholesterol but do contain hopanoids that serve similar roles.

Movement of Membrane Lipids and Proteins

Membranes are not static structures; rather, many membrane components (a mosaic of various lipids and proteins) can undergo rapid movement. The **fluid mosaic model** of membranes states that membrane components are free to diffuse in the plane of the membrane. Recent evidence indicates that certain membrane proteins may be restricted to specific regions of the membrane by interactions with cytoskeletal proteins and that these membrane regions may be enriched with specific lipids (for discussion of cytoskeletal proteins, see Section A2.5).

Although many phospholipids and membrane proteins can move laterally within a leaflet, they do not “flip-flop” from one leaflet of the bilayer to the other (**Fig. A2.3E**). Flip-flop of phospholipids is rare owing to the highly unfavorable interactions of charged head groups moving through the hydrophobic interior of the membrane. Thus, the inner and outer leaflets of the membrane may be made up of different phospholipids. It is thought that such phospholipid asymmetry may be important for the correct functioning of membrane proteins—that is, that proteins may work best when surrounded by particular phospholipids.

Glycolipids and glycoproteins also contribute to membrane asymmetry because the carbohydrate moieties always face the extracellular environment.

Membrane fluidity refers to the movement of membrane phospholipids within the plane of the membrane, and this fluidity is important for proper membrane function. For example, transport across the membrane is affected by membrane fluidity. Decreased fluidity is associated with decreased transport rates. Because a drop in temperature decreases fluidity, cold temperatures may slow transport processes across the membrane.

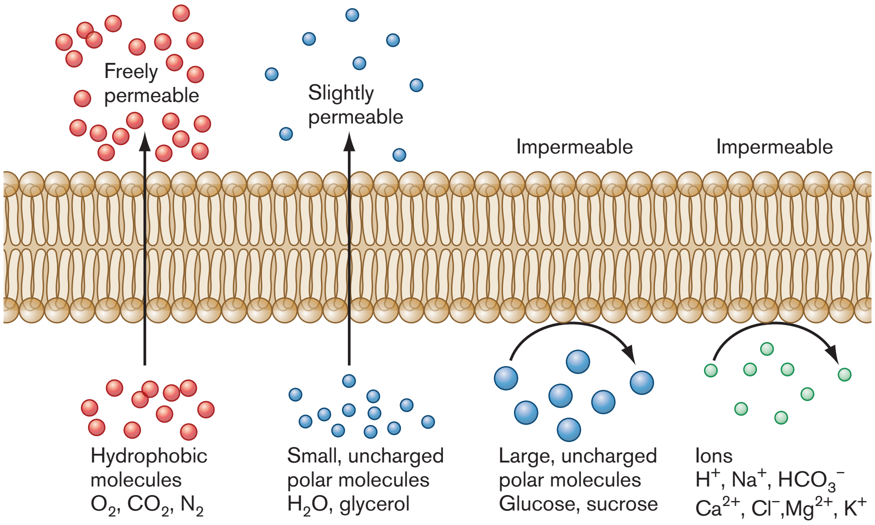
The composition of the membrane, especially the types of phospholipids present, can have a dramatic effect on membrane fluidity. For example, saturated fatty acids decrease membrane fluidity because the linear hydrocarbon tails pack together well. In contrast, unsaturated fatty acids have kinks in the hydrocarbon chains that limit packing and increase fluidity (**Fig. A2.3F**). The length of the fatty acid chains also affects fluidity. Phospholipids with longer hydrocarbon chains have increased hydrophobic interactions with neighboring lipids and thus decreased membrane fluidity. Organisms can alter membrane fluidity in response to temperature stress by changing the length and degree of saturation of fatty acids present in membrane phospholipids. For example, as environmental temperatures drop, both eukaryotes and prokaryotes maintain membrane fluidity by replacing long-chain fatty acids with shorter chains and increasing the percentage of unsaturated fatty acids in their membranes.

Cholesterol also influences membrane fluidity. The effects of cholesterol on membrane fluidity are complicated and depend on factors such as the ratio of saturated to unsaturated fatty acids in the membrane. Cholesterol may prevent packing of saturated fatty acids, thus increasing fluidity. In membranes with unsaturated fatty acids, cholesterol may fill in the spaces between adjacent phospholipids, stabilizing them and decreasing fluidity. In this case, cholesterol can decrease the permeability of the membrane to hydrophobic substances by packing in between the hydrocarbon chains and preventing substances from slipping through.

Membranes Are Semipermeable: Some Substances Pass through Them Easily; Others Do Not

The major functions of membranes (such as containing cytoplasmic components, regulating what substances enter and leave cells and organelles, and producing energy) depend on the semipermeable nature of membranes. **Semipermeable** (also called **selectively permeable**) **membranes** are permeable to some substances but not to others. In general, the cell membrane is permeable to hydrophobic molecules and impermeable to charged molecules (**Fig. A2.4**). Diffusion across the membrane also depends on the size of the molecule. The membrane is freely permeable to small nonpolar molecules such as O_2. Larger nonpolar molecules can also diffuse across the membrane, albeit more slowly. Molecules that are polar but small (such as ethanol and water) can also diffuse across the membrane. The membrane is impermeable to large polar molecule such as glucose and to charged molecules, regardless of their size. The impermeability of the membrane to charged substances such as ions is important for energy production at membranes because the proton motive force depends on the ability of the membrane to separate compartments of different ion concentrations.

Figure A2.4 **Selective permeability of cell membranes.**



Transport Proteins Move Many Substances across Cell Membranes

Although ions and large polar molecules such as glucose cannot diffuse directly across the cell membrane, they do need to enter cells. In both eukaryotes and prokaryotes, movement of molecules across the cell membrane is accomplished through specific transmembrane proteins such as channels and transporters. Channels can also increase the diffusion of molecules that move across the membrane too slowly on their own to supply the cell's needs. For example, aquaporins can increase the rate of water movement across the membrane. There are many different types of transporters, each differing in its energy requirements and in the types of molecules that it transfers across the membrane.

Diffusion Moves Substances across Cell Membranes and within Cells

Diffusion is the net movement of molecules from an area of high concentration to one of low concentration. It is a spontaneous process because it is accompanied by an increase in entropy (positive □S) that results in a negative free energy change (□G). The process requires no energy input and is brought about by the random, thermal movement of molecules.

Many factors can influence the *rate* of diffusion of a molecule across a membrane. Diffusion rates can be determined with an artificial membrane system as depicted in **Figure A2.5.** Molecules are added to the left side of the beaker, and samples from the right side are analyzed at various time points for the presence of the test molecule.

Factors that influence diffusion of molecules across a membrane include:

- **Temperature.** Increased temperatures mean faster motion. The faster the molecules are moving, the faster they will arrive at the membrane and cross it.
- **Solubility of the molecules in the membrane.** To cross the membrane, the molecules must penetrate it. Hydrophobic molecules will dissolve in the membrane and cross it; charged molecules will not.
- **Surface area of the membrane.** To cross the membrane, molecules must first encounter it. The chances of this happening are increased with an increase in membrane surface area.
- **Concentration gradient of the dissolved molecules.** A larger concentration gradient speeds up diffusion because the more molecules there are, the more will encounter the membrane and cross.
- **Thickness of the membrane.** Diffusion rates are inversely proportional to the square of the distance the solute must travel across the membrane. The thinner the membrane, the faster the molecules can get across.
- **Mass of the molecule.** Friction between a molecule and its medium is a source of resistance that slows down motion. Larger molecules with more mass experience more resistance and cross the membrane more slowly.

These factors can be expressed as follows:

$$\text{Diffusion rate } \square \; \frac{\text{temperature } \square \text{ surface area } \square \text{ concentration gradient}}{\text{mass } \square \text{ distance}^2}$$

Conditions for the diffusion of gases and other substances across the cell membrane will be most favorable when the surface area of the membrane is large, the concentration gradient across the membrane is high, and the membrane is thin.

Transport of Water Across the Cell Membrane Must Be Tightly Controlled

(high solute) (**Fig. A2.6A**). Cells must maintain osmotic balance with the surrounding environment. The direction of water movement depends on the concentration of dissolved solutes in the cell relative to the cell's environment. When a cell is in an **isotonic** environment (equal concentrations of dissolved solutes inside the cell and out), there is osmotic balance, and water will enter and exit the cell at equal rates (that is, there is no net movement of water). In a **hypertonic** environment (higher concentration of solutes outside the cell), there is a net loss of water from a cell. The cell shrinks, and the concentration of cell contents increases. In a **hypotonic** environment (lower concentration of solutes outside the cell), there is a net uptake of water by the cell; the cell swells, and the cell components are diluted (**Fig. A2.6B**). If enough water enters, the cell is destroyed by **lysis**—a rupturing of the cell membrane and dispersal of cell contents. Both hypertonic and hypotonic environments can cause other problems for cells. Proteins have specific salt requirements, and intracellular environments that have salt concentrations that are either higher or lower than normal for a cell can cause denaturation of proteins, with potentially fatal results for the cell. Thus, transport of water across the cell membrane must be tightly controlled, and cells need mechanisms that allow them to live in environments that are not isotonic.

Most cells live in environments that are hypotonic. To deal with this challenge, most prokaryotes and many eukaryotes have a cell wall external to the cell membrane. As water enters by osmosis and pushes against the cell wall (turgor pressure), the wall resists the tension and pushes back with an equal but opposite force known as wall pressure. The wall pressure is an inward pressure exerted by the cell wall against the cell membrane (**Fig. A2.7**). When turgor pressure and wall pressure are equal in magnitude, the cell is at equilibrium with respect to

water movement. Organisms that lack a cell wall employ other strategies to deal with hypotonic environments. For example, some freshwater protists that lack a cell wall expel excess water through a contractile vacuole.

In contrast to freshwater microbes, ocean-dwelling organisms face the problem of water loss. Many of these organisms accumulate solutes known as osmolytes to ensure that they are isotonic to the external environment, thus preventing water loss.

Eukaryotes Can Move Substances across the Cell Membrane by Endocytosis and Exocytosis

All cells use diffusion and transport proteins to move molecules into or out of the cell, but some eukaryotes can, in addition, use endocytosis and exocytosis to achieve this end. In **endocytosis**, parts of the cell membrane bud into the cytoplasm and eventually separate from it to form **endosomes** (**Fig. A2.8**). Endosomes are a type of **vesicle**, a small membranous sphere found within a cell. The interior of these endosomes contains extracellular material. **Phagocytosis** (cell eating) is a form of endocytosis in which large extracellular particles are brought into the cell. **Pinocytosis** (cell drinking) is endocytosis of the extracellular fluid. Endocytosis is a controlled, energy-requiring process that relies on many proteins, including cytoskeletal proteins. **Exocytosis** is the reverse of endocytosis. In exocytosis, intracellular vesicles fuse with the cell membrane, and the contents of the vesicles are released to the extracellular environment. Cells can use exocytosis to release wastes.

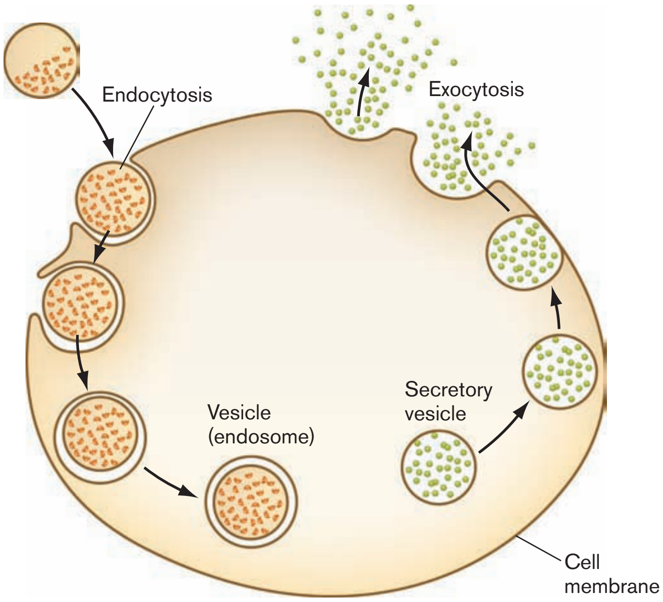

Figure A2.8 Endocytosis and exocytosis.

A2.2 The Nucleus and Mitosis

All cells need to synthesize proteins, and all cells contain DNA, the genetic material that encodes the information needed to specify protein primary structure. The central dogma of molecular biology holds that DNA is transcribed into messenger RNA (mRNA), and mRNA is translated into protein on ribosomes. Although this central dogma of molecular biology holds for all cells, details in the structure of DNA and ribosomes vary among the three domains of life (see **Table A2.1**). For example, ribosomes always function in protein synthesis, but ribosomes from organisms in different domains differ in their sedimentation rates and their sensitivity to various antibiotics. DNA always encodes the information needed for protein synthesis, but whereas bacterial chromosomes are usually circular, eukaryotic chromosomes are typically linear. Another difference between DNA in prokaryotes and DNA in eukaryotes is the location of DNA within the cell. Prokaryotic DNA is found in an area of the cytoplasm known as the nucleoid, while eukaryotic DNA is enclosed by a membrane-bound nucleus.

Eukaryotic DNA Is Housed in the Membrane-bound Nucleus

Eukaryotes derive their name (*eukaryote* means “true kernel”) from the fact that they possess a **nucleus**, and, indeed, the nucleus is often the most prominent feature of eukaryotic cells viewed under a microscope (**Fig. A2.9A**). The nucleus is an **organelle**, an intracellular membrane-bound compartment with a specific function. The nucleus contains **chromatin,** a complex of DNA and proteins. The nuclear membrane (envelope) consists of two concentric phospholipid membranes. The outer nuclear membrane is continuous with the membrane of the endoplasmic reticulum (ER), and the space between the two nuclear membranes is continuous with the lumen (inside) of the ER (**Fig. A2.9B**). Nuclei contain a region called the **nucleolus**, where ribosome assembly begins. At the nucleolus, multiple rRNA (ribosomal RNA) genes are transcribed, and the resulting rRNA combines with ribosomal proteins imported into the nucleus from the cytoplasm to form the ribosomal subunits. The ribosomal subunits then need to exit the nucleus.

The nuclear membrane contains nuclear pore complexes (NPCs) that allow for transport of material into and out of the nucleus. Metabolites and small proteins can diffuse through the NPCs, but larger proteins and organelles cannot enter by diffusion. Large proteins that need to enter the nucleus are actively transported in through the NPCs. These selectively imported proteins contain a nuclear localization signal, a sequence of amino acids that acts like a zip code to direct them into the nucleus. In addition to their role in protein import, NPCs also function in exporting mRNAs out of the nucleus.

Eukaryotic Cells Replicate by Mitosis

Cells need to ensure an accurate replication and division of their DNA. Prokaryotes replicate by fission, as described in Chapter 3. Eukaryotic cells replicate their nuclear DNA and divide by mitosis. **Mitosis** is a series of steps that segregates duplicated chromosomes and ensures that each daughter cell receives a copy of the genetic material. When the cell is not undergoing mitosis, it is in interphase (**Fig. A2.10A**). During interphase, the individual chromosomes are long and thin and not visible by a light microscope. Interphase can be divided into three phases: G_1, S, and G_2. Cells that are not committed to dividing are in G_1, the first gap phase. If cell division is to occur, then the chromosomes are replicated during S phase (S for "synthesis"). The duplicated chromosomes, called sister chromatids, remain attached to each other at the centromere (**Fig. A2.10B**). After chromosome replication, a second gap phase, G_2, occurs, after which mitosis can proceed.

Mitosis is divided into a number of steps: prophase, metaphase, anaphase, and telophase (**Fig. A2.10C**). During *prophase*, the chromosomes condense and become visible by light microscopy. The nuclear membrane may break down. The mitotic spindle, responsible for separating the sister chromatids to opposite poles of the cell, begins to form. The mitotic spindle is a network of microtubules (see Section A2.5) that originate from centrosomes. There are two centrosomes, and these migrate to opposite sides of the cell. Each centrosome contains two centrioles, and each centriole contains nine sets of microtubules in a radial formation (see Section A2.5). The free ends of the microtubules establish connections with the sister chromatids at a structure called the kinetochore.

At *metaphase*, the spindle apparatus is complete and each sister chromatid is connected to a microtubule. The chromosomes are arranged along an imaginary plane in the middle of the cell. In the next phase of mitosis, *anaphase,* the microtubules shorten and pull the sister chromatids apart, separating the replicated chromosomes. At the end of anaphase, each set of chromosomes is located on opposite sides of the cell. During, *telophase*, the final step in mitosis, the nuclear membrane re-forms around the chromosomes and the chromosomes become long and thin again. Cytokinesis also occurs during telophase and partitions the original cell into two daughter cells by the formation of a cell membrane between them.

The preceding description of mitosis forms a synopsis of this process as it occurs in eukaryotic cells from multicellular organisms, where it has been particularly well studied. However, some unicellular eukaryotes exhibit differences from the canonical mitotic phases. In yeast, for example, the nuclear envelope does not break down. Despite these differences, the end result, the separation of duplicated chromosomes into two daughter cells, is the same.

A2.3 Problems Faced by Large Cells

Most eukaryotic cells range in size from 10 to 100 micrometers (μm) in diameter, about ten times as large as the typical prokaryotic cell (1–10 μm diameter). Cells face two major challenges as a result of increased cell size. The first problem is that as cells increase in size, their volume (the cytoplasm) increases faster than their surface area (the cell

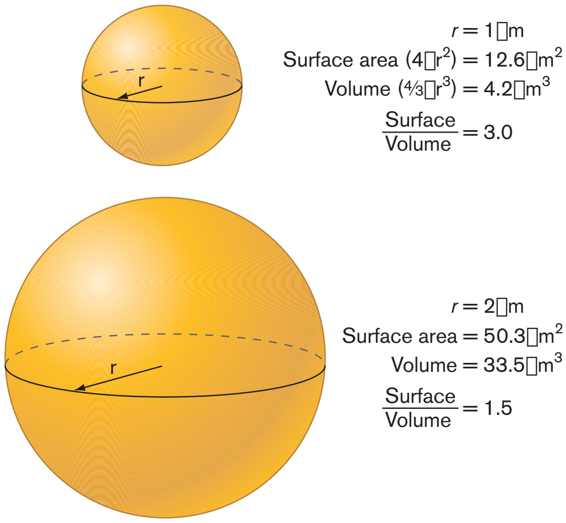
membrane) (**Fig. A2.11**). Cells are filled with metabolically active cytoplasm that requires nutrients and energy and produces wastes. Energy production, nutrient import, and waste disposal are events that take place at the cell membrane. As cells increase in size, the cell membrane area may not be able to keep up with the demands placed on it by a proportionally larger cytoplasm. The eukaryotic cell's answer to this problem is the endomembrane system, an extensive network of internal membranes that effectively increases the membrane surface area without an increase in cell volume.

The second problem associated with an increase in size is related to diffusion. The amount of time it takes a molecule to diffuse a given distance is proportional to the distance squared. For example, if it takes a particular molecule 1 second to diffuse 1 μm, then it takes that same molecule 100 seconds to diffuse 10 μm. Many biochemical reactions depend on the partners in the reaction finding each other by diffusion (that is, their rate is diffusion controlled), so longer diffusion times result in slower reactions. Furthermore, signals received at the cell membrane



r
$r = 1\ \mu m$

Volume $(\frac{4}{3}\pi r^3) = 4.2\ \mu m^3$
$\frac{\text{Surface}}{\text{Volume}} = 3.0$
r
$r = 2\ \mu m$
Surface area $= 50.3\ \mu m^2$
Volume $= 33.5\ \mu m^3$
$\frac{\text{Surface}}{\text{Volume}} = 1.5$

Figure A2.11 Cell volume increases faster than surface area. Because the surface area increases by the radius squared and the volume increases by the radius cubed, the volume increases faster than the surface area.

need to be communicated throughout the cell. In a large cell, the amount of time it takes for a molecule to traverse the cell by diffusion may be too slow for the cell to rapidly adjust to signals it receives from the environment or from other sites within the cell. To deal with this problem, eukaryotic cells possess a cytoskeleton, a group of proteins that, among other things, maintains cell shape and moves molecules around the cell, relieving the cell from the need to rely on diffusion for transport.

As we shall see in the next two sections, the endomembrane system and the cytoskeleton have other advantages for the eukaryotic cell.

A2.4 The Endomembrane System

The endomembrane system is a series of compartments found inside eukaryotic cells and bounded by membranes that are separate from the cell membrane. Organelles of the endomembrane system include the endoplasmic reticulum (ER), the Golgi complex (also called the Golgi apparatus), lysosomes, and peroxisomes. Different organelles contain unique subsets of proteins that contribute to their function. To a large extent, the function of the ER and the Golgi complex is to direct to their proper cellular location proteins destined for lysosomes, for the cell membrane, or for secretion from the cell.

Organelles Provide Many Advantages to the Eukaryotic Cell

- Endomembranes increase the membrane surface area without increasing the cell volume.
- Separating cellular contents in small, enclosed compartments increases the concentrations of enzymes and their substrates, allowing reactions to proceed faster (**Fig. A2.12**).
- Organelles can provide different environments that allow disparate reactions to occur simultaneously. For example, proteins are being synthesized by ribosomes in the neutral pH cytoplasm, while at the same time proteins are being hydrolyzed within the acidic organelles known as lysosomes.
- Compartmentalization protects cytoplasmic components from harmful substances. For example, hydrogen peroxide (H_2O_2), a product of cellular oxidation reactions, is produced and converted to water within **peroxisomes**. Localizing the reaction within the peroxisome keeps the toxic peroxide away from other cell components, such as proteins and DNA, that are sensitive to oxidative stress.

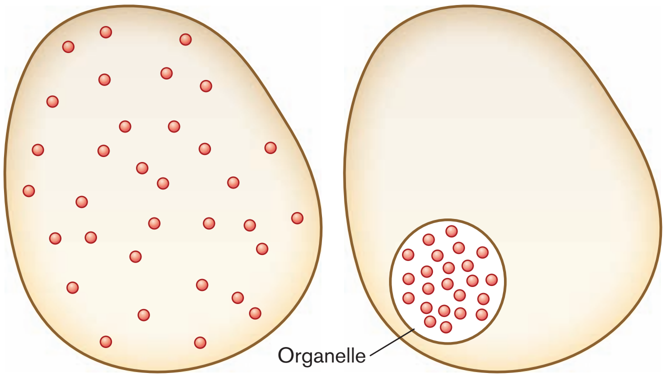

Figure A2.12 Advantages of organelles. Solutes (red dots) are concentrated in organelles, reactive molecules are separated from the cytoplasm, and membrane surface area is increased without an increase in cell volume.

Some Eukaryotic Cells Use Lysosomes to Digest Organic Matter

Lysosomes are membrane-bound organelles that help eukaryotic cells obtain nourishment from macromolecular nutrients. Lysosomes contain many hydrolytic enzymes (for example, proteases, nucleases, and lipases) and have an acidic pH of around 5. Lysosomes are formed when vesicles containing hydrolytic enzymes and proton pumps bud off from the Golgi complex (**Fig. A2.13A**). Lysosomes then fuse with vesicles containing the material to be digested. Often this material comes from outside the cell via phagocytosis (**Figs. A2.13A** and **B**). Phagocytosis and lysosomal digestion help the eukaryotic cell because they effectively increase the membrane surface area over which nutrients can be absorbed. Bacteria lack these processes; to obtain nutrition from large molecules in their environment, bacteria must secrete digestive enzymes. The extracellularly digested materials are subsequently transported across the bacterial cell membrane through specific transporters (see Section 4.2). In contrast, lysosomes allow for intracellular digestion, and digested material crosses the lysosomal membrane into the cytoplasm. Any waste products left in the lysosome can leave the cell via exocytosis.

The Area Inside the Endoplasmic Reticulum Is Separate from the Cytoplasm

The endoplasmic reticulum is continuous with the outer nuclear membrane, and the lumen (interior) of the ER is continuous with the space between the two nuclear membranes (**Fig. A2.14A**). As well as being continuous with the space between the nuclear membranes, the lumen of the ER is spatially equivalent to the interior spaces of other endomembrane components and to the outside of the cell. This means that material in the ER does not need to cross a membrane to enter these other spaces, and

mixing can occur via vesicle fusion. For example, material contained within the lumen of the ER can mix with the contents of the Golgi complex or with the extracellular milieu by fusion of vesicles from the ER with Golgi membrane or the plasma membrane. These topologically equivalent areas, indicated by a common color in **Figure A2.14A**, are completely separated from the cytoplasm by endomembranes, so that the ER can be used to sequester substances that must be held at low concentrations in the cytoplasm, for example, calcium ions.

Smooth ER and Rough ER Have Different Structures and Functions

There are two morphologically and functionally distinct types of endoplasmic reticulum—smooth ER and rough ER, as shown in the micrograph of **Figure A2.14C**. The smooth ER is the site of lipid synthesis and some detoxification of noxious compounds. The rough ER is the site where transmembrane proteins, secreted proteins, and resident proteins of the ER, Golgi, or lysosomes are

translated. The rough ER appears rough because its cytoplasmic surface is studded with ribosomes. These ribosomes are located on the rough ER because the protein being synthesized by the ribosome has a signal sequence on its amino terminus (the first part of the protein translated from the mRNA). A **signal sequence** is a specific sequence of amino acids that directs proteins to a specific cellular location. The signal sequence that directs proteins to the ER recognizes a receptor (the **signal recognition particle**) on the rough ER membranes (**Fig. A2.15A**), so the protein-ribosome complex is directed to the surface of the ER membrane. Note that the ribosomes attached to the rough ER are identical to cytoplasmic ribosomes and only attach to the ER transiently because of the type of protein they are translating, proteins that contain the correct signal sequence.

The Translation of Proteins across Rough Endoplasmic Reticulum

After the ribosome docks with the signal recognition particle, the protein is threaded through the ER membrane as it is translated. Secreted proteins and proteins destined for the lumen of an organelle are threaded completely through the ER membrane and end up in the lumen of the ER (see **Fig. A2.15A**). In contrast, transmembrane proteins are not threaded completely through, and part of the protein spans the membrane (**Fig. A2.15B**). The membrane-spanning regions of transmembrane proteins usually contain a continuous stretch of about 20 hydrophobic amino acids that form an alpha helix with the hydrophobic side chains facing out toward the hydrophobic hydrocarbons of the membrane.

As the nascent polypeptide chains are threaded across the ER membrane, the unfolded proteins are bound by chaperonins. Chaperonins (also known as heat-shock proteins) prevent partially folded proteins from clumping together and help proteins attain their correct tertiary structure. In the ER, proteins may be modified. The signal sequence that directed the proteins to the ER is usually cleaved off. The environment inside the ER allows disulfide bonds to form between cysteine residues of some proteins. Other ER proteins have oligosaccharide groups covalently attached, a posttranslational modification known as glycosylation. The enzymes that attach the sugars are found only in the ER lumen. In transmembrane proteins of the cell membrane, sugars always face the extracellular environment because the extracellular environment is topologically equivalent to the lumen of the ER (see **Fig. A2.14A**).

Resident ER proteins, those that will stay and function in the ER, are retained inside the ER because they contain a sequence of amino acids that acts as an ER retention signal.

Secreted proteins and proteins destined for the lumen of an organelle end up in the lumen of the ER. **B.** Transmembrane proteins are not completely inserted through the ER membrane, and a portion of the protein remains within the membrane.

The Golgi Complex Directs the Transport of Proteins

Proteins not retained in the ER pass on to the Golgi complex by way of vesicles. The **Golgi complex** consists of separate membrane stacks (cisternae) that each contain unique enzymes. The *cis* face of the Golgi complex is nearest to the ER, and the *trans* face is farthest from the ER, closest to the cell membrane (see **Figs. A2.14A** and **B**). As proteins pass through the cisternae, the carbohydrates on them may be trimmed and modified. These modified carbohydrates can serve as address tags to target proteins to particular organelles. For example, proteins tagged with mannose-6-phosphate (mannose phosphorylated on its number 6 carbon) are selectively sent to lysosomes; that is, vesicles enriched in proteins containing mannose-6-phosphate bud off from the Golgi and are directed to lysosomes. Proteins not targeted to lysosomes or marked for retention in the Golgi complex, may be sent to the cell membrane. Vesicles leaving the Golgi complex may fuse with the cell membrane, releasing their contents to the extracellular environment (see **Fig. A2.14A**). Transmembrane proteins in these vesicles can then become part of the cell membrane. Regions of transmembrane proteins that were inside vesicles will face the extracellular environment, and cytoplasmic portions will remain cytoplasmic.

A2.5 The Cytoskeleton

Eukaryotic cells contain proteins called intermediate filaments, microfilaments, and microtubules that are collectively termed the **cytoskeleton**. As their name implies, these proteins serve as a cell skeleton and impart specific shapes to eukaryotic cells. However, cytoskeletal proteins are multifunctional and are also involved in whole-cell movements and movements of substances within the cell.

Intermediate Filaments Are Formed of Various Proteins

Intermediate filaments (**Fig. A2.16A**) consist of various fibrous proteins that have a diameter of about 10 nm. Intermediate filaments often form a meshwork under the cell membrane and, in cells that lack a cell wall, help impart and maintain cell shape. Intermediate filaments also strengthen the cell by resisting tension placed on the cell membrane. The proteins that make up intermediate filaments vary with cell type. Intermediate filaments are fairly stable and are not thought to undergo acute changes in length the way microfilaments and microtubules do.

Microfilaments Are Polymers of the Protein Actin

Microfilaments, also known as actin filaments, have a diameter of 7 nm (**Fig. A2.16B**). They are formed when individual actin monomers (globular actin, or G-actin) polymerize, in a process fueled by ATP hydrolysis, to form chains of filamentous actin (F-actin). Two F-actin chains twist around each other to form microfilaments that have a plus end and a minus end. Microfilaments are dynamic structures, growing and shrinking in a controlled manner. New monomer units add to the plus end and dissociate from the minus end. Whether actin will polymerize

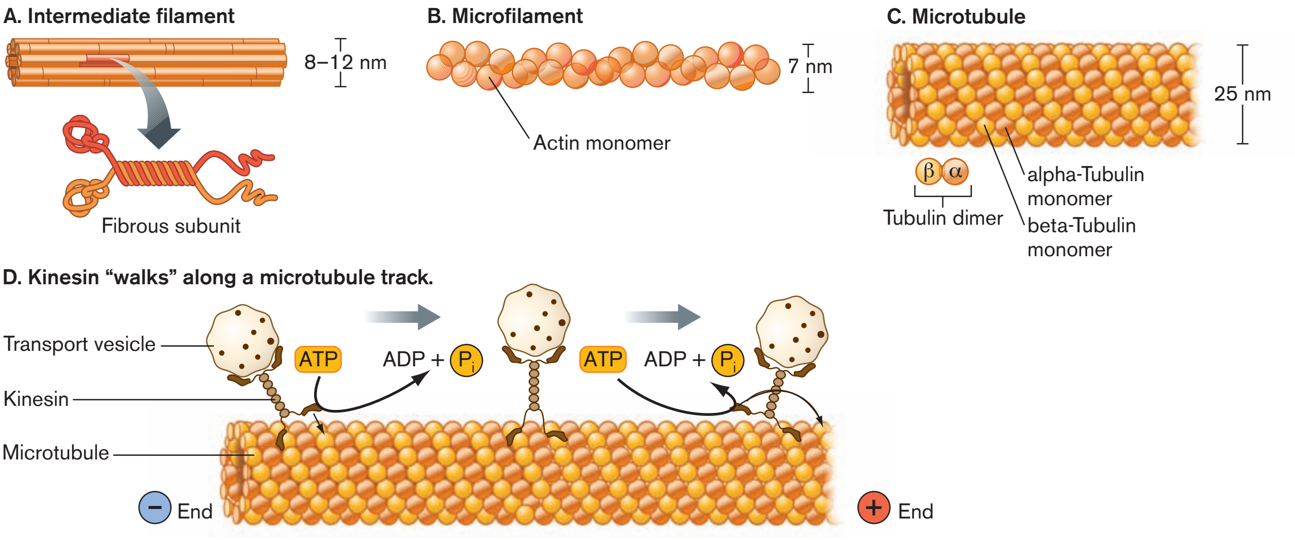

Figure A2.16 Cytoskeletal proteins. **A.** Intermediate filaments are ropelike assemblages of various proteins. **B.** Microfilaments consist of two strands of actin polymers twisted together. **C.** Microtubules are polymers of tubulin dimers. **D.** Fueled by the hydrolysis of ATP, the motor protein kinesin can move vesicles or organelles toward the plus end of microtubules.

or depolymerize depends on a number of factors, including the concentration of G-actin. The critical concentration is a measure of the ability of actin to polymerize. At G-actin concentrations below the critical concentration, F-actin will depolymerize, and at concentrations greater than the critical concentration, G-actin will polymerize. The plus end of microfilaments has a critical concentration less than that of the minus end, so actin is preferentially added on to the plus end and removed from the minus end.

Some microfilaments play a structural role in the cell and work in conjunction with intermediate filaments to maintain cell shape. These structural microfilaments have protein caps at both ends to prevent changes in microfilament length. Other microfilaments have functions that require dynamic changes in length. For example, the pseudopod movement of an ameba depends on the polymerization of actin at the leading edge of growth. The plus end of the microfilament is located underneath the cell membrane of the extending pseudopod, and polymerization is enhanced by the actin-binding protein profilin. Microfilaments are also responsible for cytoplasmic streaming, a mixing of the cytoplasm that aids diffusion. The protein myosin works with microfilaments to generate the forces needed for cell streaming, pseudopod formation, and cytokinesis, the separation of daughter cells after nuclear division.

Microtubules Are Polymers of Tubulin

Microtubules have a larger diameter (25 nm) than microfilaments and intermediate filaments (**Fig. A2.16C**). The hollow microtubule structure consists of 13 tubulin dimers; one alpha-tubulin protein plus one beta-tubulin protein forms one tubulin dimer. Like microfilaments, microtubules have plus (faster-growing) and minus (slower-growing) ends and are dynamic structures that can polymerize and depolymerize. Polymerization is an energy-requiring process, and the necessary energy is obtained by coupling polymerization to GTP hydrolysis. Microtubules aid movement of substances within the cell and are also involved in powering whole-cell movement by cilia and flagella.

Traffic of proteins through the endomembrane system (see Section A2.4) relies on the controlled movement of vesicles from one cellular compartment to the next. Microtubules provide tracks that can move vesicles from one organelle to the next in an efficient, directed fashion. Working with microtubules to accomplish this are motor proteins. Motor proteins such as kinesin and dynein can capture cargo (for example, vesicles or organelles) and walk them along microtubule tracks in an ATP-dependent process (**Fig. A2.16D**). Kinesin moves cargo toward the plus end of microtubules, while dynein moves cargo toward the minus end. In addition to moving vesicles, microtubules are responsible for the segregation of duplicated chromosomes during mitosis.

Eukaryotic Cilia and Flagella

Cilia and flagella are thin extensions of the cell membrane that can move in a whiplike fashion, driven by interactions between microtubules and the motor protein dynein. Flagella (singular, flagellum) are relatively long, and cells usually have only one or two of them; cilia (singular, cilium) are shorter and more numerous. Both flagella and cilia can move cells through space. Cilia may also aid in food capture—for example, by sweeping extracellular fluid into the gullet of a paramecium. Eukaryotic cilia and flagella differ from bacterial cilia and flagella; bacterial flagella depend on the proton motive force to rotate a motor that causes flagellar movement, whereas eukaryotic flagella rely on ATP hydrolysis by dynein to move the flagella in a whiplike fashion.

The study of protists has played a key role in determining the structure and function of flagella and cilia. Much information about flagella structure has come from studies of a *Chlamydomonas* species, a unicellular alga that has two long flagella (**Fig. A2.17A**). Dynein was first discovered in the cilia of the unicellular eukaryote *Tetrahymena* (**Fig. A2.17B**). Flagella and cilia have the same structure and mechanism of action, so for convenience we will restrict the following discussion to flagella.

A cross section through a flagellum reveals a central bundle of microtubules called the axoneme (**Fig. A2.17C**). The axoneme originates at a microtubule-organizing center called the basal body, which is similar to the centriole (see Section A2.2). The minus ends of the microtubules are at the basal body; the plus ends at the tip of the flagellum are capped to prevent changes in length.

As shown in the electron micrograph in **Figure A2.17D,** the axoneme has a characteristic arrangement of two central microtubules and nine microtubule doublets around the periphery. The microtubule doublets are connected to each other and to the central microtubules through protein cross-links called bridges and spokes. (**Fig. A2.17E**). The motor protein dynein connects adjacent microtubule doublets. If the cell membrane is removed from the surface of a flagellum and the protein cross-links (but not dynein) are dissolved, the microtubule doublets are observed to lengthen in the presence of ATP. This is due to the action of dynein, which slides the microtubule doublets past each other (**Fig. A2.17F**). In intact flagella, the tension imparted as dynein tries to slide microtubules past each other is translated into a bending motion. Controlled cycles of dynein activation and inactivation on opposite sides of the axoneme lead to the whiplike motion of flagella.

The force generated by dynein propels the adjacent microtubule doublet in the direction of its minus end. In intact flagella, this force is translated into a whiplike motion.

A2.6 Mitochondria and Chloroplasts

Mitochondria and **chloroplasts** are organelles involved in cellular energy production. Mitochondria perform oxidative respiration and are found in nearly all eukaryotes. Chloroplasts perform photosynthesis and are found only in photosynthetic eukaryotes, such as green algae. Both organelles are thought to have become part of eukaryotic cells through a process of endosymbiosis. The **endosymbiosis theory** states that mitochondria and chloroplasts were once free-living prokaryotes that became ingested, but not digested, by a larger (possibly eukaryotic) cell (**Fig. A2.18A**). A symbiotic relationship developed, with the larger eukaryotic cell providing protection to the prokaryote and the prokaryote providing energy to the eukaryote. As we shall see, the structure of mitochondria and chloroplasts strongly supports the endosymbiosis theory.

Mitochondria Produce ATP by Oxidative Respiration

Mitochondria are the powerhouses of the eukaryotic cell. A cell may contain tens or hundreds of mitochondria, depending on its energy needs. Mitochondria have two membranes, an outer membrane and an inner membrane (**Fig. A2.18B**). The inner membrane has numerous infoldings called cristae that increase its surface area. It is thought that as a result of the endocytosis of the prokaryote, the inner mitochondrial membrane is derived from the prokaryote and the outer membrane is derived from the larger eukaryote. Supporting this idea is the fact that the inner membrane has structural characteristics of a prokaryotic cell membrane, while the outer membrane is similar to the host eukaryotic membrane. For example, 20% of the phospholipids in the inner membrane are cardiolipin, a phospholipid largely absent from eukaryotic membranes.

Mitochondria contain two distinct compartments: the intermembrane space between the two membranes and the matrix inside the inner membrane. Different stages of oxidative respiration occur in specific compartments. As predicted by the endosymbiosis theory, the topology of these processes is similar in prokaryotes and mitochondria (**Table A2.2**). For example, in prokaryotes, the citric acid cycle occurs in the cytoplasm; in mitochondria, the citric acid cycle takes place inside the matrix, the metabolic equivalent of the prokaryotic cytoplasm.

The fact that mitochondria contain their own DNA and ribosomes lends further support to the endosymbiosis theory, since these cell features would be a necessary part of any free-living organism. Both the DNA and ribosomes of mitochondria show similarities with the DNA and ribosomes of prokaryotes. For example, like prokaryotic DNA, mitochondrial DNA is circular, and mitochondrial ribosomes are sensitive to antibiotics that disrupt

Table A2.2 **Location of oxidative respiration components in prokaryotes and mitochondria.**

Feature	Prokaryotes	Mitochondria
Electron transport chain (ETC)	Cell membrane	Inner membrane
ATP synthase	Cell membrane	Inner membrane
Citric acid cycle	Cytoplasm	Matrix
Proton motive force	Protons diffuse from lower-pH extracellular environment into the cytoplasm across the cell membrane.	Protons diffuse from the lower-pH intermembrane space into the matrix across the inner membrane.

prokaryotic ribosomes. Although nuclear DNA encodes some mitochrondrial proteins, phylogenetic analysis has shown that these nuclear genes are related to prokaryotic genes. Furthermore, the generation of new mitochondria is not tied to the replication of the cell, and the division of mitochondria within the cell is similar to the fission seen in prokaryotic cells.

Chloroplasts Allow Eukaryotes to Perform Photosynthesis

Chloroplasts are organelles found only in photosynthetic eukaryotes. In the light reactions of photosynthesis, chloroplasts convert light energy from the sun to ATP and reduced NADPH. In the subsequent light-independent reactions, the ATP and NADPH are used to reduce CO_2 to sugar.

Like mitochondria, chloroplasts are probably the result of endosymbiosis. Bacteria related to cyanobacteria are thought to be the prokaryotic partners that gave rise to chloroplasts. Like eukaryotic chloroplasts, cyanobacteria contain chlorophylls *a* and *b* and perform aerobic photosynthesis. In addition, cyanobacteria contain extensive internal membranes called thylakoids that contain chlorophyll and participate in the light reactions of photosynthesis.

Chloroplasts have three membranes whose topology can be understood in light of the endosymbiosis theory (**Fig. A2.18C**). The outer membrane appears to be derived from the host eukaryotic cell; the inner membrane is equivalent to the bacterial cell membrane; and the thylakoid membrane is derived from the prokaryotic thylakoid membranes. The region inside the inner membrane is called the stroma and is equivalent to the bacterial cytoplasm. The thylakoid membrane is packed with the chlorophyll pigments that give chloroplasts their green color. ATP and NADPH are produced in the stroma and used there in the light-independent reactions. As would be expected as a result of endosymbiosis, chloroplasts, like mitochondria, contain their own circular DNA and their own ribosomes.

Answers to Thought Questions

Chapter 1

1.1 The minimum size of known microbial cells is about 0.2 μm. Could even smaller cells be discovered? What factors may determine the minimum size of a cell?

ANSWER: The smallest cells known, about 0.2 μm in length, are cell wall-less bacteria called mycoplasmas; for example, *Mycoplasma pneumoniae*, a causative agent of pneumonia. Bacteria might be discovered that are smaller than 0.2 μm, but it is hard to see how their cell components such as ribosomes (about a tenth this size) could fit inside such a small cell. The volume required for DNA and the apparatus of transcription and translation probably sets the lower limit on cell size.

1.2 If viruses are not functional cells, are they truly "alive"?

ANSWER: A traditional definition of a life form includes an entity with the capability for metabolism and homeostasis (maintaining internal conditions of its cytoplasm) as well as reproduction and response to its environment. Viruses reproduce themselves indefinitely, and respond to the environment of the host cell, but lack metabolism or homeostasis outside their host cell. Nevertheless, viruses such as herpesviruses contain numerous metabolic enzymes that participate in the metabolism of their host. Certain large viruses such as the mimivirus appear to have evolved from cells. Some microbiologists argue that viruses should be considered "alive" if reproduction is the main criterion, and if the viral "environment" is considered the inside of the host cell.

1.3 Why do you think it took so long for humans to connect microbes with infectious disease?

ANSWER: For most of human history we were unaware of the existence of microbes. Even after microscopy had revealed their existence, the incredible diversity of the microbial world and the difficulties in isolating and characterizing microbial organisms made it difficult to discern the specific effects of microbes. All healthy people contain microbes; and most disease-causing microbes are indistinguishable from normal flora by light microscopy. Not all microbial diseases are directly transmittable from human to human; they may require complex cycles with intermediate hosts, such as the fleas and rats that carry bubonic plague.

1.4 How could you use Koch's postulates to demonstrate the causative agent of influenza? What problems would you need to overcome that were not encountered with anthrax?

ANSWER: In order to use Koch's postulates to demonstrate the causative agent of influenza, an animal model host would be needed. Secretions from diseased patients could be applied to different animal species, such as monkeys and mice, in order to find an animal that shows signs of the disease. To determine the causative agent of disease, the patient's secretions could be filtered in order to separate bacteria and viruses. Only the filtrate would cause disease, as it contains viruses (relevant to Koch's postulates 1 and 3). Viruses, however, are more difficult to isolate in pure culture than bacteria (postulate 2), a problem Koch did not address. Furthermore, some viruses, such as HIV (human immunodeficiency virus) have no animal model; they grow only in human cells. Today, viruses are usually isolated in a tissue culture. Once isolated, the virus could be used to inoculate a new host animal (if an animal model exists) or a tissue culture, and determine whether infection results (postulates 3 and 4). Another problem Koch did not address was the detection of infectious agents too small to be observed under a microscope. Today, antibody reactions are used to determine whether an individual has been exposed to a putative pathogen. An antibody test could be used to determine whether healthy and diseased individuals had been exposed to the isolated virus.

1.5 Why do you think some pathogens generate immunity readily, whereas others evade the immune system?

ANSWER: Some pathogens (microbes that cause disease) have external coat proteins that strongly stimulate the immune system and induce production of strong antibodies. Other pathogens have evolved to avoid the immune system by changing the identity of their external proteins. Immunity also varies greatly with the host's status. The very young and very old generally have weaker immune systems than people in the prime of their lives. Some pathogens, such as HIV, will directly attack the immune system, limiting the immune response to the pathogen.

1.6 How do you think microbes protect themselves from the antibiotics they produce?

ANSWER: Microbes protect themselves from the antibiotics they produce by producing their own resistance factors. As discussed in later chapters, microbes may synthesize pumps to pump the antibiotics out; or they make altered versions of the target macromolecule, such as the ribosome subunit; or they make enzymes to cleave the antimicrobial substance.

1.7 Why don't all living organisms fix their own nitrogen?

ANSWER: Nitrogen fixation requires a tremendous amount of energy, about thirty molecules of ATP per dinitrogen molecule converted to ammonia (discussed in Chapter 15). In a community containing adequate nitrogen sources, organisms that lose the nitrogen fixation pathway would make more efficient use of their energy reserves than those that spend energy to fix nitrogen from the atmosphere. Another consideration is that nitrogenase is an oxygen-sensitive enzyme, whereas plants, animals, and fungi are aerobes. In order to fix nitrogen, aerobic organisms need to develop complex mechanisms to exclude oxygen from nitrogenase.

1.8 What arguments support the classification of Archaea as a third domain of life? What arguments support the classification of archaea and bacteria together, as prokaryotes, distinct from eukaryotes?

ANSWER: The sequence of 16S rRNA (small-subunit rRNA) and other fundamental genes differs as much between archaea and bacteria as it does between archaea and eukaryotes. The composition of archaeal cell walls and phospholipids is completely distinct from those of bacteria and eukaryotes. Some aspects of gene expression, such as the RNA polymerase complex, are more similar between archaea and eukaryotes than between archaea and bacteria. On the other hand, archaeal and bacterial cells are prokaryotic; they both lack nuclei and complex membranous organelles. Archaeal metabolism and lifestyles are more similar to those of bacteria than eukaryotes. Some archaea and bacteria sharing the same environment, such as high-temperature springs, have undergone horizontal transfer of genes encoding traits such as heat-stable membrane lipids.

1.9 Do you think engineered strains of bacteria should be patentable? What about sequenced genes or genomes?

ANSWER: Microbes—as well as multicellular organisms, such as transgenic mice—have been patented, and the patents have stood up in court. DNA sequence per se is not patentable, but specific plans for use of DNA sequence can include the sequence as part of the patent. The reason for granting these patents is to encourage medical research by companies that need to earn a profit. The disadvantage of patents is that they restrict information flow and undercut competition. Furthermore, religious and philosophical arguments have been made that patenting live organisms cheapens life. Current laws attempt to reach a balance among these concerns.

Chapter 2

2.1 You have discovered a new kind of microbe, never observed before. What kind of questions about this microbe might be answered by light microscopy? What questions would be better addressed by electron microscopy?

ANSWER: Light microscopy could answer questions such as: What is the overall shape of this cell? Does it form individual cells or chains? Is the organism motile? Only light microscopy can visualize an organism alive. Electron microscopy can answer questions about internal and external subcellular structures. For example, does a bacterial cell possess external filamentous structures such as flagella or pili? If the dimensions of the unknown microbe are smaller than the lower limits of a light microscope's resolution, EM may be the only way to observe the organism. Viruses are often characterized by shape, and this shape is observed by electron microscopy.

2.2 Explain what happens to the refracted light wave as it emerges from a piece of glass of even thickness. How does its new speed and direction compare with its original (incident) speed and direction?

ANSWER: The part of the wave front that emerges first travels faster than the portion still in the glass, resulting in the wave front bending toward the surface of the glass. Ultimately, the wave travels in the same direction and with the same speed as before it entered the glass. The path of the emerging light ray is parallel to the path of the light ray entering the glass and is shifted over by an amount dependent on the thickness of the glass. This refraction will alter the path of the beam of light and decrease the amount reaching the lens of the microscope. Immersion oil has the same refractive index as glass and will limit the amount of light lost in this way.

2.3 Parabolic lenses are generally "biconvex," that is, curving outward on both sides. What would happen to parallel light rays that pass through a lens that is concave on both sides? Or a lens that is convex on one side and concave with equal curvature on the other?

ANSWER: When light passes through a lens that is concave (curving inward) on both sides, the light rays diverge within the lens material, then diverge again more steeply on their way out. If the lens is concave on one side and convex with equal curvature on the opposite side, then the light rays will diverge within the lens but will emerge parallel, although slightly farther apart than when they entered.

2.4 In theory, what angle θ would produce the highest resolution? What practical problem would you have in designing a lens to generate this light cone?

ANSWER: In theory, an angle theta (θ) of 90 degrees would produce the highest resolution. However, a 90-degree angle of theta generates a cone of 180 degrees, which would require the object to sit in the same position as the objective lens; in other words, to have a focal distance of zero. In practice, the cone of light needs to be somewhat less than 180 degrees, in order to allow room for the object and to avoid substantial aberrations (light-distorting properties) in the lens material.

2.5 Under starvation conditions, bacteria such as *Bacillus thuringiensis,* the biological insecticide, repackage their cytoplasm into spores, leaving behind an empty cell wall. Suppose, under a microscope, you observe what appears to be a hollow cell. How can you tell if the cell is indeed hollow or if it is simply out of focus?

ANSWER: You could tell whether the cell is out of focus or actually hollow by rotating the fine-focus knob to move the objective up and down while observing the specimen carefully. If the hollow shape appears to be the sharpest image possible, it is probably a hollow cell. If the hollow shape turns momentarily into a sharp, dark cell, it was probably out of focus before. You could also use a confocal microscope to visualize the center of the hollow cell.

2.6 Some early observers claimed that the rotary motions observed in bacterial flagella could not be distinguished from whiplike patterns, comparable to the motion of eukaryotic flagella. Can you imagine an experiment to distinguish the two and prove that the flagella rotate? *Hint:* Bacterial flagella can get "stuck" to the microscope slide or coverslip.

ANSWER: To prove that flagella rotate, you can "tether" the bacteria to the microscope slide by getting one of its flagella stuck to the slide. A simple way to tether bacteria is by using a slide coated with anti-flagellin antibody. When the flagellum is stuck to the slide, its motor continues to rotate; thus, the entire cell now rotates. The rotation of the cell body can easily be seen by video microscopy. If the flagella moved in a whiplike fashion, the tethered cell would move back and forth, not rotate.

2.7 What experiment could you devise to determine the actual order of events in DNA movement toward the pole during formation of an endospore?

ANSWER: One way to track the movement of DNA during sporulation would be to stain the DNA with a dye such as propidium iodide at various stages of sporulation. Another way to determine the order of events in sporulation could be to observe mutant strains of bacteria that contain defects at different points in the sporulation process. (Sporulation is discussed further in Chapter 4.)

2.8 Compare and contrast fluorescence microscopy with dark-field microscopy. What similar advantage do they provide, and how do they differ?

ANSWER: Both dark-field and fluorescence enable detection (but not resolution) of objects whose dimensions are below the wavelength of light. Dark-field technique is based on light scattering, which detects all small objects without discrimination. Fluorescence, however, provides a means to label specific parts of cells, such as cell membrane or DNA, or particular species of microbes, using fluorescent antibody tags.

2.9 An electron microscope can be focused at successive powers of magnification, as in a light microscope. At each level, the image rotates at an angle of several degrees. Based on the geometry of the electron beam, as shown in Figure 2.34, why do you think this rotation occurs?

ANSWER: The image rotates because the electron beam is not straight, as for photons, but travels in a spiral through the magnetic field lines. As magnification increases, the spiral expands, and it reaches the image plane at a slightly different angle than before.

2.10 What kind of research questions could you investigate using SEM? What questions would be answered using TEM?

ANSWER: SEM could be used to examine the surface of cells: Do the cells possess a smooth surface, or does their surface contain protein complexes or bulges that serve special functions? How do pathogens attach to the surface of cells? TEM can be used to determine the intracellular structure of attachment sites as well as of internal organelles. TEM can also visualize the shape of macromolecular complexes such as flagellar motors or ribosomes.

2.11 What kind of experiments could prove or disprove the interpretations of the images of "nanobacteria" in blood plasma?

ANSWER: Attempt to observe the proposed "nanobacteria" in the presence of a general antibacterial agent such as sodium azide. If the particles still appear despite the sodium azide, they cannot be alive and are probably inorganic in nature. Another approach is to use PCR amplification of 16S ribosomal RNA sequences to establish the existence of a novel isolate. So far, the PCR sequences obtained from "nanobacteria" in blood plasma have been identified as those of an environmental microbe that commonly contaminates PCR samples.

Chapter 3

3.1 Which molecules occur in the greatest number in a prokaryotic cell? The smallest number? Why does a cell contain 100 times as many lipid molecules as strands of RNA?

ANSWER: Inorganic ions occur in the largest number in a prokaryotic cell (250 million/cell). They are also the smallest in size. DNA molecules are found in the smallest number (one large molecule, branched during replication). A prokaryotic cell contains a hundred times as many lipid molecules as strands of RNA because lipids are small structural molecules, highly packed. RNA molecules are long macromolecules that are either packed into complexes (such as ribosomal RNA), or are temporary information carriers (messenger RNA), present only as needed to make proteins.

3.2 Why does the Svedberg coefficient of the intact ribosome (70S) differ from the sum of the individual subunits of the ribosome (30S and 50S)?

ANSWER: The Svedberg coefficient is a nonlinear function. A particle's mass, density, and shape will determine its S value. It depends on the frictional forces retarding the particle's movement, which in turn are based on the average cross-sectional area of the particle. The sum of the cross-sectional areas of the two separate subunits is greater than the cross-sectional area of the complex; thus, the sum of their S units (30S + 50S) is greater than that of the intact complex (70S).

3.3 What are the advantages and limitations of biochemical and genetic approaches to cell structure and function?

ANSWER: Biochemistry is useful to separate particles and identify their functions in isolation. In some cases, particles can also be combined together to study the function of a complex such as the cell-free translation system. On the other hand, biochemistry may miss aspects of function that are observed only in the intact cell. Genetics reveals the functions of specific genes in the phenotype of a living cell. On its own, however, genetics reveals little about the spatial relationships of gene products working together. Together, genetics and biochemistry reveal a more complete view of how cellular structures function.

3.4 Amino acids have acidic and basic groups that can dissociate. Why are they *not* membrane-permeant weak acids or weak bases? Why do they fail to cross the phospholipid bilayer?

ANSWER: At neutral pH, amino acids each have both a positively charged amine and a negatively charged carboxylate, that is, they can act as either a weak acid or a weak base. Charged ions, no matter what their size, will not freely pass a plasma membrane. If either charged group becomes neutralized by acid or base, the other group remains charged, so the molecule as a whole will never cross the membrane.

3.5 The actual thickness of the cell wall is difficult to determine based solely on electron microscopic observation of the envelope layers. Devise a biochemical experiment that can show the number of layers of peptidoglycan in cells of a given species.

ANSWER: To demonstrate the number of layers of peptidoglycan in a cell wall, determine the percentage by weight of peptidoglycan in the cell sample. Estimate the surface area of cells based on scanning EM. Given the known thickness of a layer of peptidoglycan, calculate how many layers would be needed to yield the amount of peptidoglycan present in the cell.

3.6 Why would laboratory culture conditions select for evolution of cells lacking an S-layer?

ANSWER: Degeneration of protective traits is a common problem when conducting research on microbes that can produce thirty generations overnight. Their rapid reproductive rate gives ample opportunity for spontaneous mutations to accumulate over an experimental time scale. In the case of the S-layer, in a laboratory test tube free of predators or viruses, mutant bacteria that fail to produce the thick protein layer would save energy compared to S-layer synthesizers, and would therefore grow faster. Such mutants would quickly take over a rapidly growing population.

3.7 Suppose that one cell out of a million has a mutant gene blocking S-layer synthesis, and suppose that the mutant strain can grow twice as fast as the S-layered parent. How many generations would it take for the mutant strain to constitute 90% of the population?

ANSWER: After each generation, the parent strain increases two-fold, whereas the mutant numbers increase by a factor of four. The mutant fraction is equal to $(4^N)/[4^N + (10^6 \ \square\ 2^N)]$, where N is the number of mutant cells after a given generation. Plotting this out on an Excel spreadsheet shows that by the twenty-third generation, the mutant fraction approximates 90%.

3.8 Why would the proteins listed in **Table 3.2** be confined to specific cell fractions? Why could a protein not function throughout the cell?

ANSWER: Each protein has evolved a specific function optimized for a specific part of the cell. For example, water-conducting porins are found solely in the inner membrane (cell membrane), which is otherwise impermeable to water. The outer membrane, which is water-permeable, is the sole location for specific porins transporting small peptides and sugars. The sugars then need to be taken across the inner membrane by transport proteins that evolved to function best in this location. Similarly, different chaperones (proteins that aid peptide folding) have evolved to function best in the cytoplasmic environment or in the periplasmic environment, membrane-enclosed regions that differ substantially in pH and ion concentrations. In a different chemical environment of the cell, the protein denatures and loses its functional structure.

3.9 What do you think are the advantages and disadvantages of a contractile vacuole, compared with a cell wall?

ANSWER: The disadvantage of a contractile vacuole is that it requires continual input of energy to bail out the water. On the other hand, the contractile vacuole permits the existence of a cell that is flexible enough to engulf other cells as prey. A cell wall does not require energy (other than the initial energy to synthesize it). A cell wall is inflexible and does not allow another cell to be engulfed as prey.

3.10 How would a magnetotactic species have to behave if it were in the Southern Hemisphere instead of in the Northern Hemisphere?

ANSWER: In the Northern Hemisphere, the field lines for magnetic north point downward; in the Southern Hemisphere, the opposite is true. Thus, if downward direction is the aim of magnetotaxis, bacteria existing in the two hemispheres would have to respond oppositely to the magnetic field; in the Southern Hemisphere, anaerobic magnetobacteria swim toward magnetic south. Near the equator, the proportions of north-seeking and south-seeking bacteria are roughly equal.

3.11 Most strains of *E. coli* and *Salmonella* commonly used for genetic research actually lack flagella entirely. Why do you think this is the case? How can a researcher maintain a motile strain?

ANSWER: The motility apparatus requires fifty different genes generating different protein components. Cells that acquire mutations eliminating expression of the motility apparatus gain an energy advantage over cells that continue to invest energy in motors. In a natural environment, the nonmotile cells lose out in competition for nutrients despite their energetic advantage; but in the laboratory, cells are cultured in isotropic environments such as a shaking test tube, where motility confers no advantage. These culture conditions lead to evolutionary degeneration of motility, as they do for the S-layer (see Thought Question 3.7). In order to maintain a motile strain, bacteria are cultured on a soft agar medium containing an attractant nutrient. As cells consume the attractant, they generate a gradient and chemotaxis leads them to swim outward. By subculturing only bacteria from the leading edge of swimming cells, one can maintain a motile strain.

Chapter 4

4.1 In a mixed ecosystem of autotrophs and heterotrophs, what happens when a heterotroph allows the autotroph to grow and begin to make excess organic carbon?

ANSWER: At first the growth of the heterotroph might outpace the growth of the autotroph, using the carbon sources faster than the autotroph can make them. As the organic carbon sources diminish through consumption, growth of the heterotroph decreases, but the CO_2 formed by the heterotroph will allow the autotroph to grow and make more organic carbon. Ultimately, the ecosystem comes into balance.

4.2 In what situation would antiport and symport be passive rather than active transport?

ANSWER: Antiport and symport would be passive when both molecules are moving down their concentration gradients. A symport or an antiport system can do work to move a molecule from a low concentration to a high (against a concentration gradient) as long as the co-transported molecule is moving from high to low concentration. When this happens, it is a form of active transport. If a symport or antiport moves both molecules with the concentration gradient (from high concentration to low), it is passive transport, assuming the molecules are moving no faster than the rate of diffusion.

4.3 What kind of transporter, other than an antiporter, could produce electroneutral coupled transport?

ANSWER: Electroneutral coupled transport can occur by symport if molecules of opposite charge are symported; for example Na^+ flux together with Cl^-.

4.4 What would be the phenotype (growth characteristic) of a cell that lacks the *trp* genes (genes required for the synthesis of tryptophan)? What would be the phenotype of a cell missing the *lac* genes (genes whose products catabolize the carbohydrate lactose)?

ANSWER: The difference lies in the function of the two pathways. The *trp* operon is a biosynthetic operon. Errors in the biosynthetic pathway will lead to a failure to produce tryptophan. Therefore, a *trp* auxotrophic mutant will *only* grow on defined medium if tryptophan is added. The lactose operon involves the catabolism of a carbon source, lactose. If any of these genes are damaged, the cells are no longer able to use lactose as a carbon source. A *lac* mutant will *not* grow on defined medium with lactose as the sole carbon source.

4.5 The addition of sheep blood to agar produces a very rich medium called blood agar. Do you think blood agar can be considered a selective medium? A differential medium? *Hint:* Some bacteria can lyse red blood cells.

ANSWER: Blood agar can be considered differential, because different species growing on blood have different abilities to lyse the red blood cells in the agar. Some do not lyse, others completely lyse red blood cells (secreted hemolysin produces complete clearing around a colony), while still others only partially lyse the blood (the secreted hemolysin produces a greening around the colony). It will therefore differentiate between hemolytic and non-hemolytic bacteria. The medium is very rich and does not prevent the growth of any organism so is not considered selective.

4.6 A virus such as influenza virus might produce 800 progeny virus particles from one infected host cell. How would you mathematically represent the exponential growth of the virus? What practical factors might limit such growth?

ANSWER: In theory, the growth rate of the virus would be proportional to 800^n. In practice, however, all the virus particles would never find 800 different host cells to infect. Furthermore, it turns out that only a small proportion of the influenza virus progeny are viable (see Chapter 11).

4.7 Suppose 1,000 bacteria are inoculated in a tube of minimal salts medium, where they double once an hour; and 10 bacteria are inoculated into rich medium, where they double in 20 minutes. Which tube will have more bacteria after 2 hours? After 4 hours?

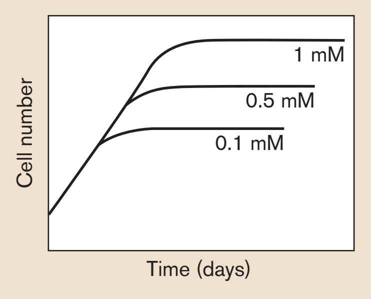
ANSWER: After 2 hours, the minimal medium will contain $1{,}000 \times 2^2 = 4{,}000$ bacteria, whereas the rich medium will contain only $10 \times 2^{(2\text{ h})(3/\text{h})} = 640$ bacteria. After 4 hours, the minimal medium will contain 1.6×10^5 bacteria, whereas the rich medium will have surpassed this count, reaching nearly 4.1×10^5.

4.8 An exponentially growing culture has an optical density at 600 nm (OD_{600}) of 0.2 after 30 minutes and an OD_{600} of 0.8 after 80 minutes. What is the doubling time?

ANSWER: Because the OD_{600} has increased from 0.2 to 0.8, there are four times as many cells after 80 minutes as after 30 minutes, and the culture has doubled twice. Two doublings occurred in 50 minutes; therefore the doubling time is 25 minutes.

4.9 **Figure 4.20C** shows growth curves for different population densities of *Thiobacillus thiooxidans* when the concentration of sulfur in the medium is constant. Draw the growth curves you would expect to see if the initial population density was constant but the concentration of sulfur varied.

ANSWER:



4.10 It takes 40 minutes for a typical *E. coli* cell to completely replicate its chromosome and about 20 minutes to prepare for another round of replication. Yet the organism enjoys a 20-minute generation time growing at 37°C in complex medium. How is this possible?

ANSWER: After the DNA is replicated about halfway around the chromosome, each daughter half-chromosome initiates a second round of replication, so the time needed to divide from one cell to two is effectively halved. Most cells in a log-phase culture in rich medium actually have four copies of the DNA origin of replication, each with a separate attachment site on the cell envelope, the future midpoint of a cell two generations ahead (see Chapter 3).

4.11 What can happen to the growth curve when a culture medium contains two carbon sources, one a preferred carbon source of growth-limiting concentration and a second, nonpreferred source? (see Section 10.3)

ANSWER: There are two possibilities. If the enzyme systems needed to utilize both carbon sources are always made, the growth curve will look normal because both will be used simultaneously. Usually the enzyme system for the nonpreferred carbon source is not produced until the preferred source is used up. In this case, a second lag phase will interrupt the exponential phase. This is called a diauxic growth curve and is commonly seen when cells are grown on both glucose and lactose. Lactose is the nonpreferred carbon source and is used second. The second lag phase marks the exhaustion of one nutrient and the gearing up by the cell to use the other (see Chapter 10).

4.12 How would you modify the equations describing microbial growth rate to describe the rate of death?

ANSWER: The death rate applies to a period of declining cell numbers. Therefore, the logarithm of the cell number ratio of N_1 to N_0 will be a negative number, and this factor will need to be preceded by a negative sign to convert it to a positive "halving time," or half-life of the culture.

4.13 Why are cells in log phase larger than cells in stationary phase?

ANSWER: Cells strive to maintain a certain DNA/mass ratio. In so doing, they balance the amount of biochemical processes needed to sustain viability. If the cell mass becomes large relative to the number of copies of a given, critical gene, the amount of enzyme produced may not be sufficient to keep the cell alive and growing. In addition, the DNA/mass ratio serves as a signal to trigger cell division. Thus, when a cell divides faster than it replicates its chromosome, it must start a second round of replication before it finishes the first. This type of replication ensures that at least one chromosome duplication will be complete at the time of division. Because fast-growing cells contain more than one chromosome, they will increase in size to maintain the desired DNA/mass ratio. If the ratio were not maintained, cell division would not occur when needed.

4.14 How might *Streptomyces* and *Actinomyces* species avoid committing suicide when they make their antibiotics?

ANSWER: Bacteria that produce antibiotics need to make defenses against the antibiotic within their own cytoplasm.

For example, their genes can express an altered form of the target molecule, such as a ribosomal subunit; or they can make pumps to pump the antibiotic out of the cell.

Chapter 5

5.1 Why haven't cells evolved so that all their enzymes have the same temperature optimum? If they did, wouldn't they grow even faster?

ANSWER: An enzyme's function is not determined by temperature alone. There are other physicochemical constraints based on the variety and complexity of functions different enzymes must carry out. The thousands of different enzyme molecules must work in a coordinated fashion to support the basic functions of life. By having some enzymes work below or above their optimum temperatures, the rate of the reactions they catalyze will be altered. A population will evolve based on the entire organism's ability to reproduce, not the speed at which each individual chemical reaction is carried out. The primary goal of a microbe is not just to grow fast but also to survive. Growing too fast could deplete food sources and produce toxic by-products too quickly.

5.2 If microbes lack a nervous system, how can they sense a temperature change?

ANSWER: Most bacteria respond to outside stimuli, such as heat, by altering their gene expression. They sense heat by monitoring the level of misfolded proteins, a consequence of too high a temperature. The mechanism does not perceive heat per se, but recognizes the deleterious effects of moving outside the optimum growth temperature range so that the cell can launch an emergency response. The same mechanisms can sense other environmental stresses that misfold proteins, such as acid stress. See Chapter 10.

5.3 What could be a relatively simple way to grow barophiles in the laboratory?

ANSWER: High pressures can be maintained using a syringe. Scientists would place medium in a stainless steel syringe and maintain pressure with a calibrated vise.

5.4 How might the concept of water availability be used by the food industry to control spoilage?

ANSWER: Food preservation traditionally includes water exclusion by salt, as seen in hams, back bacon, salted fish, etc., or by high concentration of sugar, as in canned fruit or jellies. The lower a_w prevents microbial growth. Dehydrating foods will also prevent microbial growth.

5.5 In Chapter 4, we stated that an antiporter couples movement of one ion down its concentration gradient with movement of another molecule uphill, against its gradient. If this is true, how could a Na^+/H^+ antiporter work to bring protons into a haloalkaliphile growing in high salt at pH 10? Since the Na^+ concentration is lower inside the cell than outside and H^+ concentration is higher inside than outside (see **Fig. 5.16**), both ions are moving against their gradients.

ANSWER: In this situation the cell has to expend some energy to make the antiporter work. The energy involved is rooted in the charge difference between the inside of the cell (negative charge) and the outside of the cell (positive charge, called delta psi, □□. See Chapter 13). The antiporter in this case must also exchange a different number of NA^+ and H^+ ions, maintaining an electrical charge difference across the membrane. For example, export $2NA^+$ and import $1H^+$.

5.6 If anaerobes cannot live in oxygen, how do they incorporate oxygen into their cellular components?

ANSWER: They incorporate oxygen from their carbon sources (e.g., CO_2 and carbohydrates such as glucose), all of which contain oxygen. This form of oxygen will not damage the cells.

5.7 How can anaerobes grow in the human mouth when there is so much oxygen there?

ANSWER: A synergistic relationship occurs between facultatives and anaerobes within a tooth biofilm. The facultatives consume oxygen within the biofilm microenvironment, which allows the anaerobes to grow underneath them.

5.8 What evidence led people to think about looking for anaerobes? *Hint:* Look up Spallanzani, Pasteur, and spontaneous generation on the web.

ANSWER: The priest Lazzaro Spallanzani (1729–1799), during his quest to disprove spontaneous generation, said, "Every beast on Earth needs air to live, and I am going to show just how animal these little animals are by putting them in a vacuum and watching them die." He dipped a glass tube into a culture, sealed one end and attached the other to a vacuum. He was astonished to find that the microbes lived for weeks. He then wrote: "How wonderful this is. For we have always believed there is no living being that can live without the advantages air offers it." Fifty years later, Pasteur observed that air could kill some organisms. After looking at a drop of liquid from a fermentation culture, he wrote, "There is something new here—in the middle of the drop they are lively, going every which way, but on the edge they were stiff as pokers."

5.9 How would you test the killing efficacy of an autoclave?

ANSWER: Construct a death curve by measuring survival of a known quantity of spores (e.g., *Bacillus stearothermophilus*) after autoclaving for various lengths of time. Spores should be used because they are more resistant to heat than any vegetative cell. Typically, autoclaves are regularly checked with spore strips that change color once the endosopores are no longer viable.

Chapter 6

6.1 Which viruses do you know that have a narrow host range, and which have a broad host range?

ANSWER: Examples of viruses with a narrow host range include poliovirus (poliomyelitis), which infects only humans and chimpanzees; smallpox, which infects only humans; and feline T-cell leukemia virus, which infects only cats. Examples of viruses with a broad host range include rabies, which infects numerous species of mammals, and influenza strains, which show preference for particular species but can jump between various mammals and birds.

6.2 What would happen if a virus particle remained intact within a host cell instead of releasing its genome?

ANSWER: The virus would be unable to reproduce, because DNA polymerases could not reach its genome for reproduction and RNA polymerase could not transcribe its genes to make gene products.

6.3 Why do viral capsids take the form of an icosahedron instead of some other polyhedron?

ANSWER: The icosahedron is a polyhedron of 20 triangular faces, the largest number possible. Thus, the icosahedron turns out to be the largest and most economical form to enclose space based on a small repeating unit. Natural selection probably favored viruses that could build the largest capsid based on the smallest amount of genetic information.

6.4 How can viruses with different kinds of genomes (RNA versus DNA) combine and exchange genetic information?

ANSWER: DNA viruses require messenger RNA intermediates to express their proteins. It is possible that a DNA virus could acquire the ability to package its RNA transcript in a capsid, rather than its DNA. Alternatively, RNA retroviruses form DNA intermediates within their host cell; these DNA intermediates might recombine with the DNA genome of another virus.

6.5 What are the relative advantages and disadvantages (to a virus) of the slow-release strategy, compared with the strategy of a temperate phage, which alternates between lysis and lysogeny?

ANSWER: A disadvantage of slow release is that the phages can never reproduce progeny phage as rapidly as in a lytic burst. The drain on resources of the host cell infected by a slow-release virus causes it to grow more slowly compared with uninfected cells; in contrast, a lysogenized cell suffers little or no reproductive deficit compared with uninfected cells. An advantage of reproduction by slow release is the continual release of phage, while avoiding the possibility of releasing all particles into an environment where no other host cell exists.

6.6 How could humans evolve to resist rhinovirus infection? Is such evolution likely? Why or why not?

ANSWER: Resistance to all rhinovirus infections might evolve through a mutation in the host gene encoding ICAM-1. The mutation would have to prevent rhinovirus binding without impairing the protein's ability to bind integrin. Such evolution is unlikely because of the importance of integrin binding and because rhinovirus infection is rarely fatal; thus, there is little selection pressure to evolve inherited resistance. Note, however, that the immune system rapidly generates immunity to particular strains of rhinovirus. Over a lifetime, most individuals acquire immunity to many rhinovirus strains but remain susceptible to others.

6.7 What are the advantages and disadvantages to the virus of replication by the host polymerase, compared with using a polymerase encoded by its own genome?

ANSWER: An advantage of using the host polymerase is energetic; the virus avoids the energetic cost of manufacturing a polymerase to package with each virion. This is an advantage to the virus, since its reproductive potential is limited by the energy resources of its host cell. Furthermore, because DNA and RNA polymerases are so central to cell function, the host species is unlikely to evolve a mutant form of the polymerase that resists the virus. On the other hand, the advantage of the virus making its own polymerase is that the viral polymerase can evolve to better meet the needs of its own replication, such as high speed and low accuracy to generate frequent variants.

6.8 Why does bacteriophage reproduction give a step curve, whereas cellular reproduction generates an exponential growth curve? Could you design an experiment in which viruses generate an exponential curve? Under what conditions does the growth of cellular microbes give rise to a step curve?

ANSWER: Lytic viruses appear to make a step curve because the number of progeny per infected cell is 100 or more, released simultaneously. After two or three generations the cell cycles would fall out of synchrony, and the curve would smooth out, but the later cell cycles are rarely observed in practice because by then the supply of host cells is exhausted. If, however, an extremely low ratio of viruses to host cells is provided, the growth of virus particles will eventually generate an exponential curve. By contrast, the growth of cellular microbes is rarely observed during the first few doublings. By the time we measure the population, the cells are all undergoing different stages of division, and the population growth overall generates a smooth exponential curve. If, however, we observe the growth of a synchronized population of cells, we see a step curve of cell division two.

Chapter 7

7.1 What do you think happens to two single-stranded DNA molecules isolated from *different* genes when they are mixed together at very high concentrations of salt?

ANSWER: In high salt conditions, the stacking of hydrophobic bases is so strongly favored that two single strands of DNA will form a duplex no matter what the sequence of base pairs.

7.2 Do you think the kinetics of denaturation and renaturation are dependent on DNA concentration?

ANSWER: The speed of denaturation does not depend on DNA concentration, but the speed of renaturation does. The higher the concentration of ssDNA, the more likely it is that complementary sequences will find each other and the faster the duplex can re-form.

7.3 DNA gyrase is essential to cell viability. Why, then, are nalidixic acid-resistant cells that contain mutations in *gyrA* still viable?

ANSWER: The *gyrA* mutations alter only the nalidixic acid binding site on GyrA, not its gyrase activity. In other words, active DNA gyrase is still made, but the drug cannot bind to it.

7.4 Bacterial cells contain many enzymes that can degrade DNA. How, then, do linear chromosomes in organisms like *Borrelia burgdorferi* (the causative agent of Lyme disease) avoid degradation?

ANSWER: DNA-digesting exonucleases act on free 5′ or 3′ ends. The *Borrelia* linear chromosomes possess covalently closed hairpin ends called telomeres and do not possess free 5′ or 3′ groups.

7.5 Suppose you have the following capabilities: You can label DNA in a bacterium by growing cells in medium containing either nitrogen ^{14}N or the heavier isotope ^{15}N; you can isolate pure DNA from the organism; you can subject DNA to centrifugation in a cesium chloride solution, a solution that forms a density gradient when subjected to centrifugal force, thereby separating the light (^{14}N) and heavy (^{15}N) forms of DNA to different locations in the test tube. Given these capabilities, how might you prove that DNA replication is semiconservative?

ANSWER: Grow bacteria in medium containing heavy ^{15}N, so that all the DNA made by the cells will be in the heavy form. Transfer the cells to medium containing only ^{14}N and allow the cells to divide for one generation. Extract the DNA and centrifuge the preparation in cesium chloride. If replication is semiconservative, a hybrid DNA band will be seen at a position located between and equidistant from where heavy DNA and light DNA would be located. The hybrid band will be composed of one heavy strand and one light strand, which makes it of intermediate weight (density). This, in fact, was how Meseleson and Stahl proved semiconservative replication in 1958, five years after the discovery that DNA was double-stranded.

7.6 How fast does *E. coli* DNA polymerase synthesize DNA (in nucleotides per second), given that the genome is 4.6 million base pairs, replication is bidirectional, and the chromosome completes a round of replication in 40 minutes?

ANSWER: It takes *E. coli* 40 minutes (2,400 seconds) to complete the replication of its 4,639,221-bp chromosome. Since Pol III works as a dimer to synthesize both strands simultaneously, we will only consider one strand in the calculation. The rate is 4,639,221 nt per 2,400 seconds = 1,933 nt per second. But there are two replication forks, so each polymerase dimer only synthesizes one-half of the chromosome, which means that each polymerase still synthesizes a remarkable 800–1000 nt per second.

7.7 Individual cells in a population of *E. coli* typically initiate replication at different times (asynchronous replication). However, depriving the population of a required amino acid can synchronize reproduction of the population. What happens is that ongoing rounds of DNA synthesis finish, but new rounds do not begin. Replication stops until the amino acid is once again added to the medium, an action that triggers simultaneous initiation in all cells; that is, reproduction of the population becomes synchronized. Why?

ANSWER: Initiation requires synthesis of the initiator protein DnaA. Consequently, depriving the population of an amino acid prevents protein synthesis, which precludes synthesis of DnaA. Because DnaA is not required to complete already initiated rounds of replication, all rounds already started are completed, but reinitiation cannot occur. Adding the amino acid once again will allow all cells to simultaneously make DnaA so that initiation is triggered in all cells at the same time.

7.8 The antibiotic rifampin inhibits transcription by RNA polymerase, but not by primase (DnaG). What happens to DNA synthesis if rifampin is added to a synchronous culture?

ANSWER: Initiation of DNA synthesis requires primer transcription at the origin by RNA polymerase, an enzyme sensitive to rifampin. Primase (DnaG), which synthesizes RNA primers in the lagging strand throughout DNA synthesis, is resistant to rifampin. So adding rifampin to a synchronized culture will prevent new rounds of DNA replication but will not affect already initiated rounds.

7.9 Knowing that *E. coli* possesses restriction enzymes that cleave DNA from other species, how is it possible to clone a gene from one organism to another without the cloned gene sequence being degraded?

ANSWER: The best way to overcome the restriction barrier is to use a mutant strain of *E. coli* in which its restriction system has been inactivated. DNA entering the cell will not be degraded and, if the modification system is still in place, will be modified. Once modified, that DNA can be safely transferred to other *E. coli* strains that still have their restriction enzymes.

7.10 PCR is a powerful technique, but one can easily contaminate a sample and amplify the wrong DNA—perhaps sending an innocent person to jail. What might you do to minimize this possibility?

ANSWER: Use sterile, filtered micropipet tips. The filters prevent contamination of the micropipet and subsequent reactions. Also, perform a control PCR reaction without adding a DNA sample. If the water, buffers, or tubes are contaminated with a given DNA, a PCR product will appear even when DNA template has not been added deliberately to the reaction.

Chapter 8

8.1 If each sigma factor recognizes a different promoter, how does the cell manage to transcribe genes that respond to multiple stresses, each involving a different sigma factor?

ANSWER: In these situations, a given gene will have multiple promoters. Each promoter will be recognized by a different sigma factor and will begin transcription at different distances from the ORF start codon.

8.2 With respect to two different sigma factors with different promoter recognition sequences, predict what would happen to the overall gene expression profile in the cell if one sigma factor were artificially overexpressed. Could there be a detrimental effect on growth?

ANSWER: Since sigma factors compete for the same site on core polymerase, overexpressing one sigma factor could displace the other sigma factor from the RNA polymerase population and compromise expression of those target genes. If those genes were important to survival, the cell could die.

8.3 Why might some genes contain multiple promoters, each one specific for a different sigma factor?

ANSWER: The gene might need to be expressed under multiple conditions at different levels. If a given condition increases expression of an alternate sigma factor, the target gene will need a promoter that the new sigma can recognize. As the need disappears and the sigma factor diminishes in concentration, a promoter that uses the housekeeping sigma will be needed. For example, the gene for DnaK heat shock protein has promoters for RpoH (sigma-32) and sigma-70, the housekeeping sigma factor. The level of protein needed during normal growth is supplied by sigma-70. Upon encountering heat stress, the RpoH sigma factor level increases and mediates an increase in DnaK production.

8.4 How might the redundancy of the genetic code be used to establish evolutionary relationships?

ANSWER: The codon preferences of different microorganisms are based in part on their GC content. Thus, an organism with an AT-rich genome will preferentially use codons for a given amino acid that have As and Ts over those with Gs and Cs. Evolutionarity, finding a long AT-rich region encoding mRNA with AT bias within a chromosome that is otherwise GC-rich, suggests that the AT-rich region was horizontally inherited from some illicit DNA exchange with another species. (See Chapter 9.)

8.5 Synthesis of ribosomal RNAs and ribosomal proteins cause a major energy drain on the cell. How might the cell regulate synthesis of these molecules when growth rate slows as a result of amino acid limitation?

ANSWER: As energy levels fall, fewer amino acids are made, which means that fewer charged tRNA molecules are assembled. This will cause ribosomes to pause during translation until finding the right charged tRNA. This pause causes synthesis of a signal molecule called guanosine tetraphosphate (ppGpp), which interacts with RNA polymerase and selectively stops transcription of the rRNA genes. This also stops new ribosome synthesis. As cells divide, the ribosomes will dilute to a lower steady-state level. Since less rRNA is made, fewer partners for ribosomal proteins are available and unassembled ribosomal proteins accumulate. These proteins bind sequences in their own mRNA molecules that are similar to the target sequences on rRNA. By binding to their mRNA, these ribosomal proteins can prevent their own translation. (See Chapter 10.)

8.6 While working as a member of a pharmaceutical company's drug discovery team, you have found that a soil microbe snatched from the jungles of South America produces an antibiotic that will kill even the most deadly, drug-resistant form of *Enterococcus faecalis,* which is an important cause of heart valve vegetations in bacterial endocarditis. Your experiments indicate that the compound stops protein synthesis. How could you more precisely determine the antibiotic's mode of action?

ANSWER: One way is to take a culture of sensitive bacteria and isolate resistant mutants (bacteria that are not killed by the antibiotic), purify their ribosomes, and separate the 30S and 50S ribosomal subunits. Cross-mix subunits from sensitive and resistant cells (for example, mix 30S subunits from sensitive cells with 50S subunits from resistant cells). Then measure protein synthesis by the hybrid ribosomes with and without the drug. If resistance is due to an altered ribosomal protein or RNA, then the subunit mix containing the altered component will make protein regardless of whether the drug is present. Once identified, the responsible ribosomal subunits from resistant and sensitive cells can be broken down further into their component parts, reconstituted in hybrid form, and again tested for an ability to make protein in the presence of drug. This reductive approach will likely, but not always, uncover the target ribosomal protein or rRNA.

8.7 How might one gene code for two proteins with different amino acid sequences?

ANSWER: By having two different translation start sites in different reading frames. While this is not a common occurrence, it happens.

8.8 Why involve RNA in protein synthesis? Why not translate directly from DNA?

ANSWER: Because transcription enables the cell to amplify the gene sequence information into multiple copies of RNA. Amplification means that more ribosomes can be engaged in translating the same protein, causing the concentration of the protein to rise more quickly than if only a single gene were used. The transcriptional process also presents an opportunity to regulate production of a protein.

8.9 Codon 45 of a 90-codon gene was changed into a translation stop codon. This produced a shortened, truncated protein. What kind of mutant cell could produce a full-length protein from the gene *without* removing the stop codon?

ANSWER: A mutant in which a tRNA gene has been altered by mutation so that the anticondon of the tRNA"sees"the stop codon as an amino acid codon. This mutated tRNA molecule will transfer its amino acid to the peptide chain. The attached amino acid can be used to bridge the gap caused by the stop condon, and a full-length protein is made. These modified tRNAs are called suppressor tRNAs because they suppress the mutant phenotype.

8.10 An ORF 1,200 bp in length could encode a protein of what size and molecular weight?

ANSWER: There are three bases per codon, so the ORF can encode 400 amino acids. The average molecular weight of an amino acid is 110 Da. Therefore, the hypothetical protein will be approximately 44,000 Da (44 kDa).

Chapter 9

9.1 Transfer of an F factor from an F^+ cell to an F^- cell converts the recipient to F^+. Why does transfer of an Hfr not do the same?

ANSWER: The last piece of an Hfr to transfer is the F factor and *oriT.* It is a rare event that an entire chromosome will transfer from one cell to another, so most Hfr transfers do not result in transfer of *oriT* and so cannot initiate conjugation.

9.2 Would it be easier to demonstrate generalized transduction using a temperate phage (which generates a lysogen) or a virulent phage?

ANSWER: Both can be used, but more care must be taken with a virulent phage. The reason is that a lytic phage can kill a potential recipient through superinfection. Superinfection occurs when a normal phage particle and a transducing particle infect the same cell. The normal lytic phage will lyse the cell before a recombinant can be formed. Generalized transduction usually occurs more easily with a temperate phage (like P22 or P1) because a superinfecting temperate phage will usually just lysogenize the cell and not kill it. Therefore, the host DNA delivered by the transducing particle has time to recombine into the recipient genome. Lytic phage, like the variant of the lysogenic P1 phage called P1 vir, commonly used for *E. coli* transduction, can be used in the lab if care is taken to avoid superinfection. (The vir designation stands for *virulent* because the mutant P1 phage lost the ability to lysogenize.) If citrate is added moments after mixing P1 vir transducing lysate with a recipient, the ions needed for phage absorption are chelated, thereby limiting superinfection. In nature, where dilution of phage may be very great, there is less chance of superinfection and death. In this situation, transduction can easily be performed by lytic phage.

9.3 How do you think phage DNA containing restriction sites evade the restriction-modification screening systems of its host?

ANSWER: Phage DNA will survive because sometimes the modification enzyme gets to the foreign DNA before the restriction enzyme. Once methylated, the phage DNA will be shielded from restriction and the methylated molecule will replicate unchallenged. If, on the other hand, a foreign DNA fragment (not necessarily a phage) has been modified and the conditions are right, it might recombine into the host chromosome and convey a new character to the strain.

9.4 Type I restriction-modification system genes are often designated *hsdR, hsdM,* and *hsdS,* which code, respectively, for the restriction (HsdR), modification (HsdM), and sequence recognition (HsdS) proteins. Can a plasmid grown in a wild-type strain be used to transform a strain defective in *hsdR*? An *hsdS* mutant? Can a plasmid grown in an *hsdM* mutant strain be transformed into an *hsdR* defective strain?

ANSWER: A plasmid grown in a wild-type strain will be methylated, but methylated or not, it can survive in a restrictionless *hsdR* mutant or an *hsdS* mutant that lacks the recognition protein needed by both the restriction and modification subunits. Since an *hsdM* mutant lacks the modification protein, it cannot protect its genes from restriction enzymes and would commit suicide, so this last experiment cannot be done.

9.5 In a transductional cross between an $A^+B^+C^+$ genotype donor and an A^- B^- C^- genotype recipient, 100 A^+ recombinants were selected. Of those 100, 15% were also B^+, while 75% were C^+. Is gene *B* or *C* closer to gene *A*?

ANSWER: Gene *C,* because it was cotransduced with *A* at the highest frequency.

9.6 Calculate the mutation rate for a gene in which the number of mutations increases from 0 to 50 as cell number increases from 10^1 to 10^8.

ANSWER: One calculation that quickly estimates mutation rate is $m\,[\ln 2/N_t]$ where m = number of mutation in the culture and N_t = the number of cells in the culture. Because bacterial cultures grow logarithmically, $\ln 2/N_t$ estimates the number of generations that went into making the culture. Thus:

$50[\ln 2/(10^8 - 10^1)] =$

$50[0.69/(10^8 - 10^1)] =$

$50[0.69/\text{approx. } 10^8] =$

$50/1.44(10^8)$ = mutation rate

mutation rate approx. equals 3.47 ▯ 10^{-7}

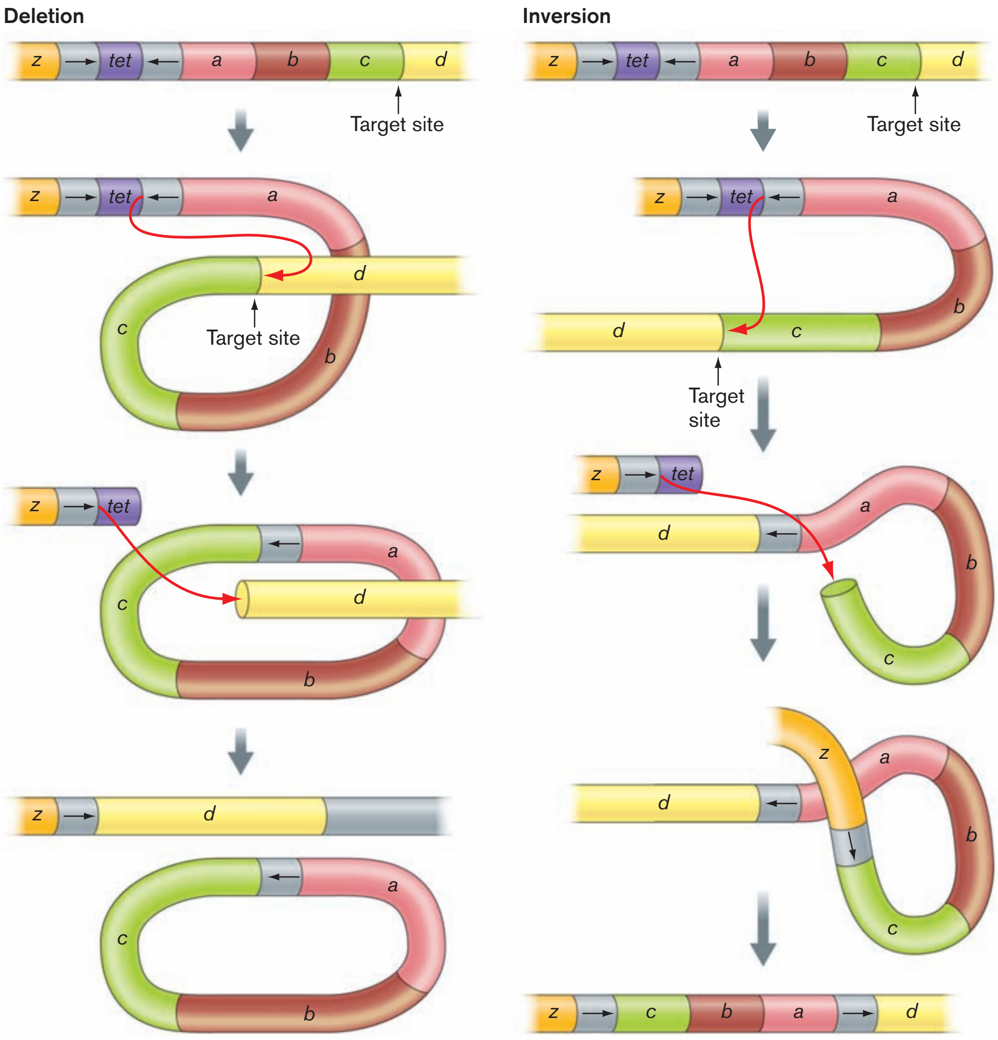
9.7 It has been reported that hypermutable bacterial strains are overrepresented in clinical isolates. Out of 500 isolates of *Haemophilus influenzae,* for example, 2–3% were mutator strains having mutation rates 100–1,000 times higher than lab reference strains. Why might mutator strains be beneficial to pathogens?

ANSWER: The mutator strains may speed microbial evolution, which could help the microbe outwit the immune system or escape the effects of administered antibiotics.

9.8 Diagram how a composite transposon like Tn*10* can generate inversions or deletions in target DNA during transposition. *Hint*: This occurs when the transposon tries to jump from one site to another in the same chromosome using the ends of the inverted repeats closest to the tetracycline resistance gene (see **Fig. 9.35**). If you draw it right, you will see that in the end, the tetracycline gene is lost.

ANSWER: From the diagram below you can see that inversions or deletions occur when the inner rather than outer ends of the inverted repeats are the targets of the transposase. The tetracycline resistance gene is lost, and the chromosome will contain a deletion or inversion depending on the orientation of the chromosome (looped or unlooped) at the time of transposase action.

DIAGRAM FOR ANSWER TO THOUGHT QUESTION 9.8



9.9 The heat-shock gene *dnaK* in *E. coli* encodes a chaperone (Hsp70), homologs of which are found in all three domains of life. However, there is no other phylogenetic evidence that a *dnaK*-like gene was present in the most recent common ancestor of all organisms. For instance, some species of archaea do not encode a *dnaK* homolog, while other archaeal species do. In fact, molecular phylogenies indicate that the archaeal homologs are quite closely related to those of bacteria. It seems that the most recent common ancestor of all *dnaK* (or *hsp70*) genes existed more recently than the common ancestor of all organisms. That being the case how do you suppose *hsp70* genes arose in archaea?

ANSWER: The gene is thought to have been moved by some type of horizontal gene transfer mechanism from domain Bacteria to some members of domain Archaea.

Chapter 10

10.1 If the gene *lacZ* has a nonsense mutation in its open reading frame, will *lacY* be translated?

ANSWER: *LacY* mRNA will still be translated because each gene in this polycistronic mRNA (*lacZYA*) has its own ribosome binding site and the *lacY* ribosome binding site is functional. A transitional stop codon in an upstream gene does not usually affect transcription of the downstream RNA.

10.2 Null mutations completely eliminate the function of a mutated gene. Predict the effect of the following null mutations on the induction of β-galactosidase by lactose and predict whether the *lacZ* gene is expressed at high or low levels: *lacI, lacO, lacP, crp, cya* (the gene encoding adenylate cyclase). Also, what effect will those mutations have on catabolite repression?

ANSWER: Loss of LacI repressor will lead to constitutive expression of *lacZ* but will not affect catabolite repression. A *lacO* mutant will not bind LacI repressor, so the phenotype will mimic that of a *lacI* mutation. A *lacP* mutation will prevent expression of *lacZYA* because RNA polymerase will not bind. Mutations in *crp* or *cya* will prevent catabolite repression, but *lacZYA* induction by lactose will be normal. However, without the cAMP-CRP complex, expression can never achieve maximal levels.

10.3 Predict what will happen to the expression of *lacZ* under the following partial diploid conditions (see Section 9.1). The genotypes of these strains are presented as follows: chromosomal genes/plasmid gene. (a) $lacI\ lacO^+P^+Z^+Y^+A^+$/plasmid $lacI^+$; (b) $lacO\ lacI^+P^+Z^+Y^+A^+$/plasmid $lacO^+$; (c) $crp\ lac\ I^+O^+P^+\ Z^+Y^+A^+$/plasmid crp^+.

ANSWER: (a) The $lacI^+$ gene on the plasmid will produce LacI repressor protein that can diffuse through the cytoplasm, bind chromosomal *lacO,* and repress the *lacZYA* operon. Because the complementing gene is on a different DNA molecule than the mutation, the gene is said to work in *trans.* (b) Because the *lacO* gene does not produce a diffusible product (e.g., protein or RNA), the plasmid $lacO^+$ cannot complement a *lacO* mutation in trans, the strain will not make β-galactosidase. Thus, the *lacO* gene only functions in *cis,* that is, when it resides next to the gene it regulates. (c) The *crp* gene produces a diffusible protein product, so it can function in *trans* and complement a *crp* mutation. The strain will make β-galactosidase to the highest level, in the presence of inducer lactose.

10.4 Researchers often use isopropyl-β-D-thiogalactopyranoside (IPTG) rather than lactose to induce the *lacZYA* operon. IPTG structure resembles lactose, which is why it can interact with the LacI repressor, but it is not degraded by β-galactosidase. Why do you think the use of IPTG is preferred in these studies?

ANSWER: There are at least two reasons. First, the level of IPTG inducer will not change, but the level of lactose inducer will continually decrease as it is consumed. This can affect the kinetics of induction. Second, the act of degrading lactose produces glucose and galactose. Glucose, as the preferred carbon source, will catabolite repress the *lacZYA* operon, once again affecting the kinetics of induction.

10.5 Predict the phenotype of a *spoIIAA* mutant that completely lacks this anti-anti-sigma factor (see **Fig. 10.16**).

ANSWER: The *spoIIAA* mutant will have no way to efficiently remove anti-sigma F factor from sigma F. As a result, sigma F will almost never be active, even in the forespore. The cell can get as far as asymmetrical cell division to make what would be the forespore but since sigma F and anti-sigma F equally distribute in both compartments, sigma F will not be activated.

10.6 What is the phenotype of a *fljA* mutant? A *fliC* mutant?

ANSWER: A *fljA* mutant lacks the repressor needed to turn off FliC. Thus, a cell will switch back and forth from making H2 flagellin to making both H1 and H2 flagellin. A *fliC* mutant, however, will switch from being motile to nonmotile. In one orientation, the invertible element will allow H2 flagellin to be made, but in the opposite orientation, no flagellin will be made, at which point the cell will not be motile.

10.7 The plaques of normal phage lambda appear as clear rings with cloudy centers of lysogenized cells. What do you think the plaque will look like in a *cI* mutant? A *cII* mutant? A *cro* mutant?

ANSWER: Both the *cI* and *cII* mutant plaques will be completely clear (no cloudy center) because without CI, the virus can only go down the lysis pathway. A *cro* mutant may not even make a plaque, since Cro is needed to stop CI transcription and allow lysis.

10.8 Predict why UV irradiation can activate lambda prophage. *Hint:* What other host system is activated by UV?

ANSWER: The RecA coprotease activated by the ssDNA molecules resulting from excessive UV irradiation not only stimulates autocleavage of the LexA repressor that controls the SOS response but also facilitates autocleavage of the lambda CI repressor. This allows transcription from lambda promoters P_L and P_R and sends the integrated prophage down the lytic path.

10.9 Predict the phenotype of a *glnB* mutant. Will it be a glutamine auxotroph or not? What about a *glnD* or a *glnE* mutant?

ANSWER: A *glnB* mutant will not dephosphorylate NtrB or remove AMP from GlnA. The cell will continue to make GlnA and fail to inactivate it. Thus, the cell will overproduce glutamine. A *glnD* mutant, however, will not add UMP to GlnB, so GlnB will not direct GlnE to remove AMP from GlnA (remember, GlnA without AMP is active). As a result, GlnA will remain inactive and the cell will likely require glutamine. The same will occur with a *glnE* mutant.

10.10 Genes encoding luciferase can be used as "reporters." What do you think would happen if the promoter for an SOS response gene were fused to the luciferase open reading frame?

ANSWER: It could serve as a real-time biosensor for an environmental stress response. You could fuse the luciferase gene to the *recA* promoter and examine a real-time increase in fluorescence after ultraviolet irradiation by inserting the whole culture into a spectrofluorometer. The opening figure in Chapter 9 illustrates this strategy, using green fluorescent protein rather than luciferase.

10.11 What do you think would happen if a culture were coinoculated with a *V. fischeri luxI* mutant and a *luxA* mutant, neither of which produces light?

ANSWER: The *luxI* mutant would glow. The *luxA* mutant would still make autoinducer as it grew. This autoinducer would accumulate in the culture medium, then diffuse and enter the *luxI* mutant cells, where it would trigger induction of the *lux* operon and production of luciferase.

10.12 Why might the mass of a protein excised from a gel fail to match any of the ORF molecular weights predicted by the genome sequence?

ANSWER: The protein might be altered by phosphorylation, acetylation, removal of a leader sequence, or otherwise proteolytically processed. Identification might still be made if certain unmodified fragments of the protein match up with predicted fragments.

Chapter 11

11.1 Why would phage T4 production require a tenfold higher rate of DNA replication than does the host cell? Why would the phage substitute all of its cytosine with an unusual base that requires greater energy to synthesize?

ANSWER: The phage T4 genome needs to replicate itself and generate progeny as fast as possible, in order to use as much of the host cell's resources as possible before the cell deteriorates. By replacing cytosine with a modified base, the phage can avoid degradation of its chromosome by its own endonucleases (which cleave host DNA) or by those of the host (which are made to cleave phage DNA).

11.2 The phage T4 chromosome is a linear piece of DNA; yet the genomic map of T4 is circular. Why?

ANSWER: Each headpiece contains just enough space to package slightly more than the length of a genome. The head-filling mechanism of DNA packaging means that successive genomes on a concatemer each get cut at different positions within the genome sequence. Thus, any map of gene order based on recombination linkages between genes, or based on the sequencing of a population of genome molecules, will generate a circular map.

11.3 Which numbered genes from Figure 11.8 might be responsible for each of the defective phage populations presented in Figure 11.9D?

ANSWER: Mutant 1 may have a defect in a gene whose product is needed for tail fiber attachment, such as gene 63. Mutant 2 may be defective for tail fiber assembly (genes 34 or 57). Mutant 3 could be defective for sheath assembly around the internal tube (gene 18).

11.4 Compare and contrast the reproductive strategies of phages T4 and M13.

ANSWER: Both species of phage aim to maximize production of progeny and sustain an unbroken chain of infection. Both recognize and attach to proteins of the cell envelope that are essential for host cell structure, and both are specific for *E. coli;* T4 attaches to OmpC, whereas M13 attaches to the F pilus. T4 injects its DNA only, discarding its capsid, whereas M13 injects its DNA and recycles its coat proteins into progeny phage. T4 immediately destroys its host genome and reshapes its host's biosynthetic apparatus to accelerate production of phage, whereas M13 moderates its rate of production so that the host will continue to grow and acquire nutrients, perhaps generating more phage in the long run. Most of T4 assembly occurs in the cytoplasm, whereas most of M13 assembly occurs in the cell membrane. T4 produces an enzyme that lyses the host to liberate all phage progeny, whereas M13 exits through a capped pore that maintains the integrity of the host, enabling gradual sustained production of phage.

11.5 Why does influenza virus have to provide its polymerase ready-made, whereas poliovirus does not?

ANSWER: The influenza viral chromosome is (–) strand RNA. When it enters the host cytoplasm, it cannot be translated by ribosomes, and no host polymerase makes RNA from RNA. Therefore, the virion must provide an RNA-dependent RNA polymerase to generate a (+) strand RNA for translation to proteins. Poliovirus, however, injects (+) strand RNA, which can immediately be translated by host ribosomes to generate RNA-dependent RNA polymerase.

11.6 Explain why the expression ($8!/8^8$) approximates the proportion of infective particles of influenza virus. What assumption might be changed to make the proportion greater or less?

ANSWER: An infective particle can start by packaging any one of the eight chromosomes. Once the first is chosen, seven possibilities remain for the second, six for the third, and so forth. Thus there are 8! ways to obtain a perfect set out of 8^8 total ways to pick eight segments at random. This expression assumes, however, that exactly eight segments are packaged in every virion. If the average number of segments packaged is less than eight, the proportion of infectives falls off. If the number of segments is usually more than eight, the proportion of virions containing at least one of each segment increases.

11.7 How do attachment and entry of HIV resemble attachment and entry of influenza virus? How do attachment and entry differ between these two viruses?

ANSWER: Attachment and entry of HIV requires the envelope spike proteins to bind receptors in the host plasma membrane, just as the influenza envelope protein hemagglutinin binds the sialic acid protein in the host membrane. In both cases, initial receptor binding signals major rearrangement of a viral envelope protein so as to insert a fusion peptide into the host membrane. The processes differ between these two virus species, in that influenza virus induces formation of an endocytic vesicle, whose acidification triggers membrane fusion and release of the core contents into the host cytoplasm. HIV virions, however, do not induce endocytosis and do not require acidification to induce membrane fusion and release of the core into the cytoplasm.

11.8 Compare and contrast the priming of chromosome replication in HIV with the priming mechanisms of poliovirus and influenza virus.

ANSWER: Poliovirus uses a viral protein (Vpg) to provide the 3′ OH needed to prime synthesis of RNA. In influenza virus, RNA synthesis is primed by "capped" fragments of host mRNA. Instead of host mRNA, HIV utilizes tRNA for primers.

11.9 Compare and contrast the fate of the HSV chromosome with that of the chromosome of HIV.

ANSWER: HSV-1 contains a DNA chromosome, which is transported to the nuclear membrane within an intact capsid. HIV contains twin RNA chromosomes, which are released in the cytoplasm upon dissolution of the capsid. The RNA chromosomes are copied to double-stranded DNA for transport into the nucleus. In HSV-1, the DNA chromosome circularizes and generates concatemeric duplicates by rolling-circle replication. In HIV, the replicated DNA circularizes but immediately integrates into the host chromosome. In both cases, the viral DNA can persist for decades in latent infection.

Chapter 12

12.1 In this postgenomic era, how might you generally design a strategy to construct a strain of *E. coli* that cannot synthesize histidine?

ANSWER: The genomic sequence of *E. coli* is known. We also know which genes encode the steps of histidine biosynthesis. The strategy today would be to engineer a plasmid containing DNA sequences (about 200 bp) that flank the histidine biosynthesis gene you want to delete, but in place of the target gene, you would instead insert an antibiotic resistance gene (e.g., kanamycin resistance). The plasmid used would be a "suicide" plasmid that cannot replicate in the strain you wish to mutate but which can replicate in other *permissive* strains (strains that produce a specific protein the plasmid needs to replicate). The permissive strain allows you to make a lot of the plasmid. The recombinant plasmid is then moved into the nonpermissive target strain by transformation, and the transformation mixture is plated on nutrient agar medium containing the antibiotic. Since the plasmid cannot replicate in this strain, the only way the target strain can become resistant to the antibiotic is if the chromosomal sequences flanking the drug marker in the plasmid undergo homologous recombination with the same DNA sequences on the actual chromosome. This double recombination event "surgically" removes the target gene from the chromosome and replaces it with the antibiotic resistance marker. In our example, the newly constructed mutant can grow in the presence of antibiotic, but only if histidine is present.

12.2 You have monitored expression of a gene fusion where *lacZ* is fused to the glutamate decarboxylase gene, *gadA*. You find that there is a 50-fold increase in expression of *gadA* (as measured for β-galactosidase) when the cells carrying this fusion are grown in media at pH 5.5 as compared to cells grown at pH 8. What additional experiment must you do to tell if the control is transcriptional or translational?

ANSWER: You must compare these results with those obtained with an operon fusion to the same gene. If both fusions show an equal 50-fold increase, then the gene is controlled at the transcriptional level. If the gene fusion shows a 50-fold increase in induction but the transcriptional fusion shows no induction, then regulation occurs postranscriptionally, most likely at the translational level.

12.3 What would you conclude if the Northern blot of the *gad* genes showed no difference in mRNA levels in cells grown at pH 7.7 and pH 5.5 but the Western blot showed more protein at pH 5.5 than at pH 7.7?

ANSWER: Regulatory control would likely be at the posttranscriptional level, either through increasing mRNA stability, translational efficiency, or protein stability.

12.4 Another regulator of glutamate decarboxylase (Gad) production does not affect the production of *gad* mRNA but is required to accumulate Gad protein. What two regulatory mechanisms might account for this phenotype?

ANSWER: Control of translation or control of protein degradation.

12.5 How could you use two-hybrid analysis to determine if *three* proteins can interact? You suspect that proteins A and C can simultaneously bind to protein B and that this interaction then allows A to interact with C in the complex.

ANSWER: Place three plasmids in the cell. One makes protein A fused to the *Gal*4 DNA-binding domain, the second plasmid makes protein C fused to the *Gal*4 activator domain, and the third plasmid simply makes protein B. If the yeast cell only contains the first two plasmids, no interaction will occur and activation of *lacZ* will not take place. If all three plasmids are in the same yeast cell, protein B will be the center of a sandwich, linking the A and C fusion proteins. The fusion proteins can then interact and activate *lacZ.*

12.6 How would you have to modify real-time PCR to quantitate the level of a specific mRNA?

ANSWER: You would have to first convert the mRNA into cDNA using the enzyme reverse transcriptase. An oligonucleotide primer hybridizing to the to the 3′ end of the mRNA is acted on by reverse transcriptase to synthesize DNA (called complementary DNA, or cDNA). Normal real-time PCR techniques can then quantitate the cDNA.

12.7 You have just employed phage display technology to select for a protein that tightly binds and blocks the eukaryotic cell receptor targeted by anthrax toxin. When this receptor is blocked, the toxin cannot get into the target cell. You suspect that the protein may be a useful treatment for anthrax. How would you recover the gene following phage display and then express and purify the protein product?

ANSWER: The gene can be cut out of the phage genome using restriction enzymes or amplified by PCR using known phage DNA sequences that flank the gene. The fragment can then be cloned into a His_6 tag expression vector. This requires that the sequence of the gene be known so that the DNA encoding the His_6 tag can be placed in-frame with the open reading frame of the receptor-blocking protein. The plasmid containing the His_6-tagged protein gene is then induced to overexpress the protein in *E. coli.* The vector will contain an inducible promoter (e.g., *lacP*) to drive expression of the gene. The His_6-tagged protein can then be purified by pouring cell extracts over a nickel column, as described in the text.

12.8 Would insect resistance to an insecticidal protein be a concern when developing a transgenic plant? Why? How would you design a transgenic plant to limit the possibility of insects developing resistance?

ANSWER: Insects have, in fact, developed resistance to single insecticidal proteins. The most common resistance mechanism involves a change in the membrane receptors in the midgut to which activated *Bt* toxins bind. Resistance can be due to a reduced number of *Bt* toxin receptors or to a reduced affinity of the receptor for the toxin. Some insects, such as the spruce budworm, can inactivate specific toxins by precipitating them with a protein complex present in the midgut.

While developing a transgenic plant, several steps could be taken to limit the development of resistance in an insect population. The insecticidal gene could be fused to a promoter that is only expressed at a time when the plant is most susceptible to attack. Alternatively, the gene could be fused to a promoter that is only expressed in a tissue of the plant that is most vulnerable to attack. This would limit the time during which the insects can develop resistance. For instance, cotton plants attacked by bollworms could produce toxin only in young boll tissues, the most important part of the plant. In addition to specifically protecting the critical plant tissue, this strategy would only affect one generation of bollworms, avoiding the constant selection pressure that hastens evolution of resistance. Another technique would be to engineer two different insecticidal proteins into the plant genome that will not exhibit cross-resistance. In other words, even if an insect develops resistance to one toxin, it will still remain susceptible to the second.

Chapter 13

13.1 Why can't photosynthesis be driven by solar microwaves or by X-rays?

ANSWER: The energy of microwaves is a hundred times lower than that of visible light and near infrared. Microwaves have too little energy to form or break chemical bonds. On the other hand, photons of higher energy such as X-rays break molecular bonds indiscriminately, in a manner that enzymes cannot control.

13.2 Methanogens are a small proportion of the microbial community in soil, and the ΔG of methanogenesis is small. Yet methanogens produce large volumes of methane, large enough to contribute significantly as a greenhouse gas to global warming. Why would methanogens produce a relatively large quantity of waste product?

ANSWER: For methanogenesis, the ΔG per reaction cycle is small. Thus, the organism must run numerous cycles in order to store sufficient energy to build biomass.

13.3 The soil bacterium *Geobacter* can metabolize acetic acid by the following reaction:

$$CH_3COOH + 2H_2O \rightarrow 2CO_2 + 4H_2$$

Yet the $\Delta G°'$ is +95 kJ/mol. What could happen in the soil enabling *Geobacter* to grow?

ANSWER: *Geobacter* must grow in the presence of different species of bacteria that oxidize the H_2 produced by *Geobacter*. Removal of H_2 drives forward the acetate catabolism. The sum of the acetate reaction plus the hydrogen oxidation yields a negative $\Delta G°'$. This joint metabolism of two species is called syntrophy. The rate of reaction in this syntrophy is further enhanced at high temperature, which magnifies the term $-\Delta RT \ln K$.

13.4 After ATP has been dephosphorylated to ADP, how else might ADP provide energy for the cell?

ANSWER: Within the cell, some enzymes can hydrolyze ADP to AMP, breaking the second high-energy phosphodiester bond.

13.5 Linking an amino acid to its cognate tRNA is driven by ATP hydrolysis to AMP plus pyrophosphate. Why release PP_i instead of P_i?

ANSWER: The formation of aminoacyl-tRNA must be irreversible until the ribosome is ready to release the tRNA. The pyrophosphate from ATP is immediately cleaved to $2P_i$, preventing the reversal of aminoacyl-tRNA formation.

13.6 In the microbial community of the bovine rumen, the actual ΔG value has been calculated for glucose fermentation to acetate:

$$C_6H_{12}O_6 + 2H_2O \rightarrow 2C_2H_3O_2^- + 2H^+ + 4H_2 + 2CO_2 \qquad \Delta G = -318 \text{ kJ/mol}$$

If the actual ΔG for ATP formation is 44 kJ/mol and each glucose fermentation yields four molecules of ATP, what is the thermodynamic efficiency of energy gain? Where does the lost energy go?

ANSWER: The energy efficiency is $(4 \times 44 \text{ kJ/mol})/(318 \text{ kJ/mol}) \times 100 = 55\%$. The remaining energy is dissipated as heat. (Kohn and Boston, 2000.)

13.7 What would happen to the cell if pyruvate kinase catalyzed PEP conversion to pyruvate but failed to couple this reaction to ATP production?

ANSWER: If PEP conversion to pyruvate occurred without ATP production, then the energy liberated by this reaction would be lost as heat. No energy would be channeled into cell function and growth.

13.8 Some bacteria make an enzyme, dihydroxyacetone kinase, that phosphorylates dihydroxyacetone to dihydroxyacetone phosphate. Why would this enzyme be useful?

ANSWER: Bacteria can obtain dihydroxyacetone from their environment, using a transporter protein, then phosphorylate the substrate and direct it into glycolysis. Some bacteria can grow on dihydroxyacetone as a sole carbon source.

13.9 In the EMP pathway, how are the two water molecules generated?

ANSWER: Each water molecule is removed from 2-phosphoglycerate, converting $R{-}CH_2OH$ to $R{=}CH_2$. The water molecule accounts for the water equivalent from incorporation of P_i during oxidation by NAD^+. The P_i ultimately is used to convert one ADP to ATP, a reaction that includes water formation.

13.10 Explain why the ED pathway generates only one ATP, whereas the EMP pathway generates two.

ANSWER: The EMP pathway primes the six-carbon sugar with two phosphoryl groups. The sugar then splits into two three-carbon units (glyceraldehyde 3-phosphate), each of which generates two ATPs for one of the original ATPs. By contrast, the ED pathway only phosphorylates the sugar once before it splits in two. The phosphorylated end yields glyceraldehyde 3-phosphate, which enters the EMP pathway to generate ATP, ending up as pyruvate. The unphosphorylated three-carbon unit yields pyruvate directly, with no ATP.

13.11 How does the structure of coenzyme A resemble that of NADH? How does it differ?

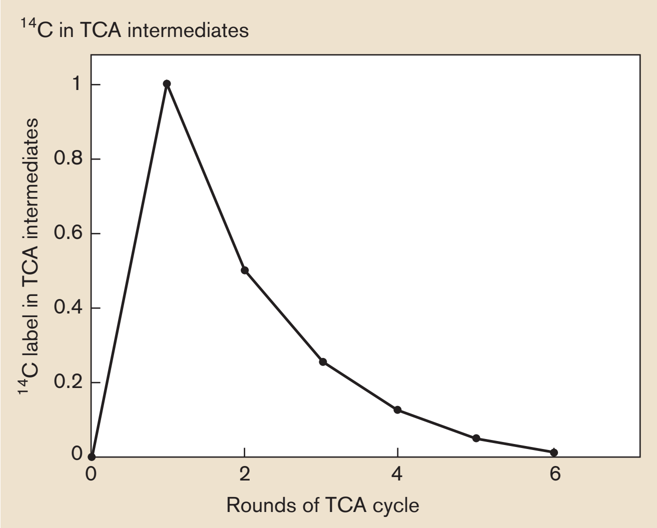
ANSWER: Coenzyme A and NADH each consist of ADP esterified to a nitrogenous compound. The linked compound for coenzyme A, however, is not nicotinamide (as in NADH) but a linear molecule terminating in a thiol (SH).

13.12 Compare the reactions catalyzed by pyruvate dehydrogenase and pyruvate formate lyase (see Section 13.4). What conditions favor each reaction, and why?

ANSWER: The pyruvate dehydrogenase complex (PDC) is favored in the presence of oxygen because the electrons transferred to NADH can enter the electron transport chain, eventually combining with oxygen to release energy. In the absence of oxygen, pyruvate formate lyase is favored to yield fermentation products that can be excreted from the cell without reducing more energy carriers. At high pH, formate and acetate production is especially favorable because the extra acid counteracts alkalinity.

13.13 Suppose a cell is pulse-labeled with ^{14}C-acetate (fed the ^{14}C label briefly, then "chased" with unlabeled acetate). Can you predict what will happen to the level of radioactivity observed in isolated TCA intermediates? Plot a curve showing your predicted level of radioactivity, as a function of number of rounds of the cycle.

ANSWER: The amount of radioactivity measured in TCA intermediates will rise steeply as labeled acetate is incorporated, then will decrease by half with each succeeding cycle, as the order of the carbons is randomized by succinate.



13.14 How might the enzymes that catalyze acenaphthene catabolism be discovered?

ANSWER: A genomic library of *Pseudomonas* strain A2279 might be used to transform another species that lacks the ability to degrade acenaphthene. If a transformant capable of degradation is found, the genes can be mapped and the deduced amino acid sequences compared with known enzymes to provide clues as to their mode of action. Other genes in the same operons might be found to catalyze other steps in the catabolic pathways.

Chapter 14

14.1 *Pseudomonas fluorescens,* a soil bacterium at neutral pH, oxidizes NADH with nitrate (NO_3^-) at the neutral pH. What is the value of $E°'$?

ANSWER: To calculate the reduction potential $E°'$:

$$NADH + H^+ + NO_3^- \rightarrow NAD^+ + NO_2^- + H_2O$$

$$E°' = 320\text{ mV} + 420\text{ mV} = 740\text{ mV}$$

14.2 Could a bacterium obtain energy from succinate as an electron donor with nitrate (NO_3^-) as an electron acceptor?

ANSWER: For nitrate reduction:

$$\text{Succinate} + NO_3^- \rightarrow \text{fumarate} + NO_2^- + H_2O$$

$$E°' = -33\text{ mV} + 420\text{ mV} = 387\text{ mV}$$

Although succinate is a relatively poor electron donor, nitrate is a strong electron acceptor. This reaction should provide energy for bacterial metabolism.

14.3 What do you think happens to $\Delta\psi$ as the cell's external pH increases or decreases? What happens to Δp in bacteria growing at a pH two or three units above their internal pH?

ANSWER: As external pH changes, ΔpH increases or decreases, affecting the magnitude of Δp. Some bacteria, such a *Bacillus* species, regulate their electrical potential with counter ions in order to maintain overall Δp at about 200 mV. Other species, such as *E. coli,* seem to tolerate a range of Δp from near zero to 250 mV. Alkaliphiles growing at high pH appear to spend much of their Δp to maintain the inverted ΔpH. How they stay energized is not understood.

14.4 Suppose that de-energized cells ($\Delta p = 0$) with an internal pH 7.6 are placed in a solution at pH 6. What do you predict will happen to the cell's flagella? What does this demonstrate about the function of Δp?

ANSWER: The flagella will rotate, driven solely by the ΔpH component of Δp. This result is consistent with the hypothesis that the trans-membrane potential Δp drives flagellar rotation.

14.5 What is the advantage of the oxidoreductase transferring electrons to a pool of mobile quinones, which then reduce the terminal reductase (cytochrome complex)? Why does each oxidoreductase not interact directly with a cytochrome complex?

ANSWER: The mobile quinone pool serves to connect diverse electron donors with diverse electron acceptors. If each oxidoreductase had to interact specifically with a different terminal oxidase, the pathways of electron transport would be limited; for example, NADH might only donate electrons to O_2, whereas succinate might only donate electrons to nitrate. Instead, all potential electron donors can be coupled with all potential acceptors.

14.6 Why are most electron transport proteins fixed within the cell membrane? What would happen if they "got loose" in aqueous solution?

ANSWER: If the electron transport proteins came away from the membrane into water solution, they could carry their energized electrons back into the cytoplasm or lose them outside the cell. In either case, they could no longer convert the electron energy to a proton gradient.

14.7 Why would bacteria evolve dehydrogenases that fail to pump protons even when sufficient donor potential exists?

ANSWER: Dehydrogenases that fail to transport protons despite sufficient reduction potential are needed for cases in which reoxidation of the donor is required but the proton gradient is already high enough to drive generation of ATP. Too high a transmembrane voltage can disrupt the membrane.

14.8 Experiments suggest that NADH dehydrogenase 2 is more often coupled with cytochrome *bo,* and dehydrogenase 1 more often with cytochrome *bd.* Why might this be the case?

ANSWER: The non-proton-pumping oxidoreductase NDH-2 may be used to moderate the amount of proton gradient generated with abundant oxygen. The proton-pumping NDH-1 may be useful under low-oxygen conditions, where the cell is forced to use the high-affinity oxidase (cyt *b/d*), which fails to pump the extra $2H^+$.

14.9 How might the bacterial cell compensate for environmental conditions in which Δp falls below 100 mV, a suboptimal level for ATP synthesis?

ANSWER: To generate sufficient ATP when Δp is low, the bacteria could synthesize a greater number of F_1F_o complexes for the membrane. The overall rate of ATP synthesis would thus be increased.

14.10 Would *E. coli* be able to grow in the presence of an uncoupler that eliminates the proton potential supporting ATP synthesis?

ANSWER: Yes, *E. coli* can grow with the proton gradient eliminated, but only with a rich supply of nutrients for substrate phosphorylation to generate ATP (for example, from glycolysis). Also, the external pH and salt levels must be maintained close to those of the cytoplasm, to minimize the need for ion transport.

14.11 The proposed scheme for uranium removal requires injection of acetate under highly anoxic conditions, with less than 1 part per million (ppm) dissolved oxygen. Why must the acetate be anoxic?

ANSWER: Oxygen is the strongest terminal electron acceptor. If O_2 is present, bacteria will use it preferentially (instead of U^{6+}) to oxidize the acetate to CO_2.

14.12 Hydrogen gas is so light that it rapidly escapes from Earth. Where does all the hydrogen come from to be used for hydrogenotrophy and methanogenesis?

ANSWER: Hydrogen is produced in substantial quantities as a by-product of fermentation. It may seem surprising that organisms would readily excrete quantities of energy-rich H_2, but in the absence of a good electron acceptor (or the enzymes to utilize electron acceptors), hydrogen may be just another waste product. Hydrogen gas trapped underground supports large communitites of methanogens and hydrogenotrophs. The human colonic bacteria generate so much hydrogen that all parts of the body show traces of hydrogen gas.

14.13 Suppose you discover bacteria that require a high concentration of Fe^{2+} for photosynthesis. Can you hypothesize what the role of Fe^{2+} may be? How would you test your hypothesis?

ANSWER: The organism uses reduced iron as an electron donor for its photosystem (Fe^{2+} ▯ Fe^{3+}). To test this, grow the organism on a defined concentration of Fe^{2+}. Measure the amount of iron oxidized and the amount of carbon fixed into biomass; if the Fe^{2+} is an electron donor for the photosystem, the two numbers should show a linear correlation.

Chapter 15

15.1 Propose a simple experiment to reveal the key intermediate to receive CO_2.

ANSWER: Add a very short pulse of [^{14}C] CO_2 to the cells. The pulse must contain sufficient CO_2 to begin fixation, but insufficient to continue beyond one "turn" of the cycle. In this case, the radiolabel will accumulate in the intermediate that needs to assimilate CO_2 for the next round. This kind of experiment ultimately identified the key intermediate, ribulose 1,5-bisphosphate.

15.2 Speculate why rubisco catalyzes a competing reaction with oxygen. Why might researchers be unsuccessful in attempting to engineer rubisco without this reaction?

ANSWER: The oxygenation reaction might have an essential function in regulation of metabolism. For example, it might help prevent excessive reduction of cell components or fixation of too much carbon to be used in biosynthesis. Given the universal existence of the oxygenation reaction in bacterial and chloroplast rubiscos, it seems unlikely that oxygenation serves no purpose. For this reason, the attempt to engineer rubisco without oxygenation may not succeed.

15.3 Why does ribulose 1,5-bisphosphate have to contain two phosphoryl groups, whereas the other intermediates of the Calvin cycle contain only one?

ANSWER: Only ribulose 1,5-bisphosphate needs to split into two molecules (3-phosphoglycerate). Each of the two products needs to have its own phosphate as a tag for the enzymes to recognize it within the cycle.

15.4 Which catabolic pathway (see Chapter 13) includes some of the same sugar-phosphate intermediates as those of the Calvin cycle? What might this suggest about the evolution of the two pathways?

ANSWER: The pentose phosphate pathway includes ribulose 5-phosphate, erythrose 4-phosphate, and sedoheptulose 7-phosphate in a similar series of carbon exchanges. Perhaps these pathways evolved from a common amphibolic pathway of sugar consumption and biosynthesis. Alternatively, the one pathway evolved earlier, then the sugar intermediates were available for evolution of the second pathway.

15.5 For a given species, uniform thickness of a cell membrane requires uniform chain length of its fatty acids. How do you think chain length may be regulated?

ANSWER: In *E. coli*, the chain length of a growing fatty acid appears to be limited by beta-ketoacyl-ACP synthase, which binds only precursor acyl-ACPs shorter than 18 carbons.

15.6 Suggest two reasons why transamination is advantageous to cells.

ANSWER: Transamination enables cells to store amine groups in nontoxic form, readily available for biosynthesis. The availability of multiple enzymes of transamination from different amino acids enables cells to quickly recycle existing resources into the amino acids most needed by the cell in a given environment. For example, if a sudden supply of glutamine appears, cells can immediately distribute its amines into all twenty amino acids.

15.7 Which energy carriers (and how many) are needed to make arginine from 2-oxoglutarate? (See **Fig. 15.24**.)

ANSWER: Arginine biosynthesis requires three ATP molecules and three NADPH molecules (including two for converting two molecules of 2-oxoglutarate to glutamate). An additional ATP is spent converting acetate to acetyl-CoA.

15.8 Why are purines and pyrimidines not synthesized separately from the sugar phosphate?

ANSWER: Purines and pyrimidines are highly hydrophobic, insoluble in the cytoplasm. The ribose phosphate component solubilizes the molecule, enabling synthesis to occur in the cytoplasm, where needed to make RNA and DNA.

15.9 Why are the ribosyl nucleotides synthesized first, then converted to deoxyribonucleotides as necessary? What does this suggest about the evolution of nucleic acids?

ANSWER: Ribonucleic acid is believed to be the original chromosomal material of cells. Cells evolved to synthesize RNA first; then later, as DNA was used, pathways evolved to synthesize it by modification of RNA, which the cell already had the ability to make.

Chapter 16

16.1 Why do the lipid components of food experience relatively little breakdown during fermentation?

ANSWER: Lipids are highly reduced molecules, largely hydrocarbon with relatively low oxidizing potential. Thus, lipids cannot undergo as many intramolecular redox reactions as do sugars, which readily generate energy through anaerobic fermentation.

16.2 Why does oxygen allow excessive breakdown of food, compared with anaerobic processes?

ANSWER: Oxygen functions as the terminal electron acceptor for the complete breakdown of all kinds of organic molecules to water and CO_2.

16.3 In an outbreak of listeriosis from unpasteurized cheese, only the refrigerated cheeses were found to cause disease. Why would this be the case?

ANSWER: In the cheeses kept at room temperature, other naturally occurring bacteria outgrew the pathogenic *Listeria,* whereas in the refrigerator, only the *Listeria* could grow. (Note, however, that many other potential pathogens, such as *Salmonella,* are inhibited by refrigeration.)

16.4 Cow's milk contains 4% lipid (butterfat). What happens to the lipid during cheese production?

ANSWER: Lipids undergo little catabolism, because the fermentation conditions are anaerobic. During coagulation, lipid droplets become trapped in the network of denatured protein and are largely retained in the bulk of the cheese. "Low-fat" cheeses are made from skim milk, which eliminates the lipids before fermentation.

16.5 In traditional fermented foods, without pure starter cultures, what determines the kind of fermentation that occurs?

ANSWER: The fermentation can be controlled by introducing a crude starter culture obtained from a previous batch of the food product or from a natural source of a particular microbe; for example, rice straw is a source of *Bacillus natto* for natto production. The fermentation type can be manipulated by the addition of factors, such as brine, that retard growth of all but a few strains. In pidan, for example, the high concentration of sodium hydroxide limits bacterial growth to alkali-tolerant strains of *Bacillus*.

16.6 Compare and contrast the role of fermenting organisms in the production of cheese and bread.

ANSWER: In cheese production, fermentation causes major biochemical changes in the food, such as the buildup of acids and the breakdown of proteins to smaller peptides and amino acids. Minor by-products, such as methanethiols and esters accumulate to levels that confer flavors. In yeast bread, by contrast, the only significant product of fermentation is the carbon dioxide that leavens the dough. The small amount of ethanol produced evaporates during cooking. A form of bread in which extended fermentation does generate flavor is injera, for which the dough ferments for three days.

16.7 Compare and contrast the role of low-concentration by-products in the production of cheese and beer.

ANSWER: In both cheese and beer, minor by-products such as esters contribute flavor. In both cases, oxidation leads to off-flavors. In cheese, however, the exclusion of oxygen usually prevents off-flavors. In beer, the yeast requires a low level of oxygen; thus, significant amounts of acetaldehyde and diacetyl are produced and must be eliminated by a secondary fermentation.

16.8 Why would bacteria convert trimethylamine oxide (TMAO) to trimethylamine? Would this kind of spoilage be prevented by exclusion of oxygen?

ANSWER: TMAO acts as a terminal electron acceptor—that is, an alternative to oxygen for anaerobic respiration, as discussed in Chapter 14. Exclusion of oxygen inhibits only aerobic bacteria; TMAO respirers continue to grow and can spoil the fish.

16.9 Is it possible for physical or chemical preservation methods to completely eliminate microbes from food? Explain.

ANSWER: Preservation methods either slow microbial growth or induce microbial death. Microbial death follows a negative exponential curve, as discussed in Chapter 5. In theory, the exponential curve never reaches zero, so total exclusion of microbes is impossible. In practice, there is a high probability of totally eliminating microbes if the treatment time extends several "half-lives" beyond the time at which microbial concentration declines to less than one per total volume.

16.10 Why would different industrial strains or species be used to express different kinds of cloned products?

ANSWER: Different industrial strains have biochemical systems that favor different products. Some fungi naturally possess the highly complex pathways to generate antibiotics, as well as regulatory timing to turn on these pathways after the culture has grown to high population density. On the other hand, bacteria such as *B. subtilis* are the most genetically tractable and predictable in their growth cycles and the easiest to manipulate to express recombinant products such as human genes.

16.11 Why would an herbicide resistance gene be desirable in an agricultural plant? What long-term problems might be caused by microbial transfer of herbicide resistance genes into plant genomes?

ANSWER: Introduction of an herbicide resistance gene allows application of higher amounts of herbicide to crops in order to control growth of weeds. But the higher concentrations of herbicide may also have greater side effects on animals and on human consumers of the crop. In the long run, the herbicide resistance gene is likely to escape into weed plants through natural genetic transfer mechanisms. Thus, eventually the weeds may require still higher concentrations of herbicide. While the costs versus benefits of new gene modifications remain poorly understood, it must be recognized that all modern crops today are the product of many generations of genetic manipulation.

Chapter 17

17.1 What would have happened to life on Earth if the sun were a different stellar class, substantially hotter or colder than it is now?

ANSWER: If the sun were hotter, too much ultraviolet and gamma radiation would reach the Earth, breaking chemical bonds of living organisms so rapidly that life could not be sustained. If the sun were colder, too little radiation with sufficient energy would be available to drive photosynthesis. In either case, life as we know it could not have evolved on Earth.

17.2 Outline the strengths and limitations of each model of the origin of living cells. Which aspects of living cells does each model explain?

ANSWER: The three models are complementary in that each explains aspects of modern cells not addressed by the others. The prebiotic soup model accounts for the major classes of compounds used by cells, such as nucleosides, TCA cycle intermediates, amino acids, and fatty acids. It also suggests the origin of membranes as soap bubble-like micelles. It does not, however, account for the evolution of metabolic pathways and replication of genetic information. The metabolist model accounts for the prevalence of major cellular reactions such as carbon fixation and the TCA cycle. It does not explain the evolution of membranes and genetic material. The RNA world accounts for the central role of RNA in living cells; of all molecular classes, RNA and ribonucleotides probably serve the widest range of functions as information carriers, agents of catalysis, and genetic regulators. The origin of membranes is not addressed.

17.3 Suppose living organisms were to be found on Mars. How might such a find shed light on the origin and evolution of life on Earth?

ANSWER: If life on Mars were to show a completely different basis than that of Earth—for example, based on silicon polymers instead of carbon—such a find would support the view that life originated independently on each planet, rather than traveling from one planet to the other; or that both planets were seeded from somewhere else. If life on Mars is based on similar macromolecules, perhaps even showing the same genetic code, this would support the view that life arose on Mars first; or that both planets were seeded from the same source.

17.4 Based on **Figure 17.18,** what would be the identification of a straight, nonsheathed gram-negative bacterium that has sulfur granules, is motile, and is 1.0 μm wide? What would happen if you happened to assign the bacterium a width of 0.9 μm?

ANSWER: The bacterium would key out as *Beggioatoa* sp. If the cell width were measured as 0.9 μm, however, the identification would proceed down a completely different, wrong track, at the first step of the key. This is one disadvantage of the dichotomous key.

17.5 In **Figure 17.19B**, were any test results atypical for *Salmonella enterica*? What would happen if another atypical result had been obtained? What would happen if the actual isolate had not been one of those in the database?

ANSWER: The negative result for dulcitol fermentation is atypical. If you multiply the probabilities, for most of the tests a second atypical result will decrease the score for *S. enterica* by about an order of magnitude but will still leave it at the top of the list. Thus the probabilistic indicator is relatively tolerant of atypical results for species within the database. On the other hand, if an organism outside the database is isolated it cannot be correctly identified.

17.6 What kind of DNA sequence changes have no effect on gene function?

ANSWER: Base substitutions that do not change the amino acid specified by the codon have no effect on gene function. For example, CUA → CUG still encodes leucine. Additionally, it turns out that a majority of the amino acids in any given protein can be replaced by an amino acid of similar form (for example leucine □ valine) without significantly affecting function of the gene.

17.7 Solve the three alignment problems shown in **Figure 17.22.** How could errors or ambiguities in alignment lead to mistakes in interpreting the molecular clock?

ANSWERS:

A. Add the new sequence from organism F to this alignment:

Seq A	C C C C A G C U U C G G C U G G G G G A G G
Seq B	C C U U A G C G A A A G C U – A A G G A G G
Seq C	C C U C A G C G U G A G C U – G A G G A G G
Seq D	C C C A A G C U U U – G C U A U G G G A G G
Seq E	C C – – A G C U U U G G C U – – – G G A G G
Seq F	**C C – A A G C G A G A G C U – U G G – A G G**

B. Make an alignment of these RNAs:

RNA 1	**– G G G G G U U C G C C C C C A A –**
RNA 2	**– G G G A G U U U G C U C C C A A –**
RNA 3	**– G A G G G U U C G C C C U C A U –**
RNA 4	**– G G G A G G A A A C U C C C A C A**
RNA 5	**– G A G G G G U G A C U C U C A C A**
RNA 6	**G G A G G G U U U – C C C U C A U –**

C. Which group of Archaea does 'Isolate X' most likely belong to based on the RNA shown?

ANSWER:

Position Number	Isolate X	Crenarchaea	Euryarchaea	Korarchaea
4	**C**	(C or U)	C	U
5	**A**	U	U	A
8	**G**	A	G	C
11	**G**	C	G	G
15	**C**	R (A or G)	C	U
18	**U**	U	U	C
19	**G**	A	G	Y (C or U)
20	**A**	A	A	U
21	**A**	A	A	Y (C or U)
22	**G**	G	G	A

Isolate X shows 9/10 key positions in common with the Euryarchaea, as compared with 5/10 Crenarchaea and 2/10 Korarchaea. Thus Isolate X most likely belongs to the Euryarchaean clade.

Errors in alignment could lead to overestimate of the time of divergence between organisms. For example, if position 15 were aligned by counting bases in Isolate X without skipping the loop extension, base 15 could be given as G, which would lead to only 8/10 positions in common with Euryarchaea.

17.8 What are the major sources of error in constructing phylogenetic trees?

ANSWER: Phylogenetic trees are affected by variability in the number of substitutions, or rate of mutation in different strains. The tree is distorted by errors in sequence alignment, and by systematic errors due to failure of the fundamental assumptions of the molecular clock. These assumptions include the constant rate of mutation for all branches; constant generation time; and true orthology of the gene chosen (that is, the encoded product has the same function and hence the same degree of selection pressure in all taxa under consideration).

17.9 What are the limits of evidence for horizontal gene transfer in ancestral genomes? What alternative interpretation might be offered?

ANSWER: Horizontal gene transfer is inferred based on the appearance of genes in clade A that are absent from other members of the clade but present in clade B. The degree of similarity between genes in the two clades, however, must be high enough to exclude the possibility that the genes in question were retained from a common ancestor of the two clades, but lost from other members of clade A. This possibility is difficult to exclude in the case of deep-branching clades, where all genes have had a long time to diverge. For example, the large number of archaean genes present in deep-branching thermophilic bacteria such as *Thermatoga* may include some inherited from the last common ancestor.

17.10 Besides mitochondria and chloroplasts, what other kinds of entities within cells might have evolved from endosymbionts?

ANSWER: Some of the large"megaplasmids"found in bacteria and protists are as large as genomic chromosomes and contain numerous housekeeping genes. These megaplasmids may have originated as endosymbiotic cells that lost all their membranes through reductive evolution. Similarly, some of the giant viruses such as Mimivirus and smallpox, as well as phages such as T4, possess a wide spectrum of housekeeping genes. These viruses may have originated as cellular parasites that underwent reductive evolution.

Chapter 18

18.1 Which taxonomic groups in **Table 18.1** stain gram-positive and which gram-negative? Which group contains both gram-positive and gram-negative species? For which groups is the Gram stain undefined, and why?

ANSWER: See **Table 18.1**. Most Firmicutes and Actinobacteria stain gram-positive, as do the Cyanobacteria. These bacteria have relatively thick cell walls that retain the stain. The Proteobacteria, Nitrospira, and Bacteroides/Chlorobi groups stain gram-negative. The Thermus/Deinococcus group includes both gram-positive and gram-negative staining members. For Chlamydia and Planctomyces, the

Gram stain is irrelevant because they lack the cell wall that retains the stain. For Spirochetes, many species are too narrow to observe the stain under light microscopy.

18.2 Which groups of species share common structure and physiology within the group? Which groups show extreme structural and physiological diversity?

ANSWER: Cyanobacteria all share oxygenic photosynthesis through thylakoid membranes. Their overall cell structure and organization, however, takes diverse forms. Spirochetes all share the common structure of sheathed flexible spiral with internal flagella; most share anaerobic or facultative heterotrophy. Chlamydia and Planctomyces groups of species each share general structural features. Other groups, particularly Firmicutes and Actinomycetes, show considerable diversity of form and physiology. The Proteobacteria display more extreme diversity of metabolism than any other division.

18.3 What taxonomic questions are raised by the apparent high rate of gene transfer between archaea and thermophilic bacteria?

ANSWER: If gene transfer results in a species containing a quarter of its genes from organisms outside its domain, such a mosaic genome raises questions of how to define the species and the domain. How can a species be defined if its genome contains large portions from distantly related sources? Other interesting questions relate to the means of gene transfer. How do such distantly related organisms as bacteria and archaea maintain a compatible mechanism of gene transfer?

18.4 What are the relative advantages and disadvantages of propagation by hormogonia, as compared with akinetes?

ANSWER: Hormogonia are motile, and thus capable of active chemotaxis toward a more favorable environment. On the other hand, hormogonia have active metabolism that requires nutrition; if the environment lacks nutrients, the hormogonia will die. Akinete cells can persist until environmental conditions improve, but they cannot actively seek out a new location.

18.5 What are the relative advantages and disadvantages of the different strategies for maintaining separation of nitrogen fixation and photosynthesis?

ANSWER: Temporal separation has the advantage that all cells possess both capacities for nitrogen fixation and photosynthesis. On the other hand, it eliminates the ability of a chain of cells to conduct both processes simultaneously—the benefit of heterocysts. Heterocysts face the problem of operating in close proximity to photosynthetic cells generating toxic oxygen; this problem may be solved by associated respiring bacteria. Globular clusters of cells can bury their nitrogen fixers within the cluster; this arrangement effectively excludes oxygen, but it may lack flexibility during environmental change. Endosymbiotic nitrogen fixation within a respiring eukaryote is probably the most effective strategy of all, as the host provides oxygen-removing proteins such as leghemoglobin. Endosymbiosis, however, requires the presence of an appropriate host organism.

18.6 Why would *Streptomyces* produce antibiotics targeting other bacteria?

ANSWER: *Streptomyces* species may produce antibiotics to curb the growth of bacterial competitors with smaller genomes and faster rates of reproduction. The lysed cells release nutrients that feed growing mycelia of *Streptomyces*.

18.7 Why might genes for the proteorhodopsin retinal photopump be more likely to transfer horizontally than the bacteriochlorophyll-based photosystems PS I and PS II?

ANSWER: Proteorhodopsin requires only the one gene encoding the pump, plus one or two genes to produce retinal. This involves a relatively small amount of sequence to transfer, and the encoded products generate proton potential on their own, without requiring interaction with recipient enzymes. By contrast, PSI and PSII each involve multiple electron carriers that must function together and interact with the recipient electron transport chain.

18.8 Why do you think it took many years of study to realize that *Escherichia coli* and other Proteobacteria can grow as a biofilm?

ANSWER: *E. coli* and its relatives grow exceptionally well in liquid culture. Liquid culture is attractive because it enables quantitative measurement of defined aliquots of microbial population. However, repeated subculturing in liquid medium selects for planktonic (non-biofilm) cells. Eventually, the biofilm-forming property may be lost if mutants outgrow the original genotype in liquid medium.

18.9 Compare and contrast the formation of cyanobacterial akinetes; firmicute endospores; actinomycete arthrospores; and myxococcal myxospores.

ANSWER: An endospore forms as the daughter product (forespore) of a single cell. Within the same cell, endospore development is supported by the motherspore, which disintegrates after release of the endospore. Endospores have tough coatings of calcium picolinate; they are heat-resistant. By contrast, arthrospores and myxospores are less durable and are not heat-resistant, although they can persist in the environment for an extended period. Arthrospores form through binary fission of actinomycete filaments. Myxospores are formed by a multicellular fruiting body. In all three cases, spore formation can be induced by depletion of nutrients; and the spore-producing entity is left behind to die.

Chapter 19

19.1 If two deeply diverging clades each show a wide range of growth temperature, what does this suggest about the evolution of thermophily or psychrophily?

ANSWER: The two clades diverged before temperature adaptation occurred, and adaptations to high or low temperature must have evolved independently in the two clades.

19.2 What might be the advantages of flagellar motility for a hyperthermophile living in a thermal spring or in a black smoker vent? What would be the advantages of growth in a biofilm?

ANSWER: Flagellar motility enables isolated cells to detect a new nutrient source, or an approximate temperature range, and approach it through chemotaxis. Growth in a biofilm attached to a substrate prevents the microbes from floating away from the nutrient source, or from being carried away in the flow from the vent.

19.3 What problem with cell biochemistry is faced by acidophiles that conduct heterotrophic metabolism?

ANSWER: Heterotrophic metabolism generates fermentation products such as acetate and lactate, which act as permeant acids. Permeant acids become protonated outside the cell, at low pH; the protonated forms then permeate the membrane, returning into the cell. Given the high transmembrane pH difference maintained by *Sulfolobus,* one would expect even small traces of fermentation acids to cross the membrane in the protonated form, then dissociate and accumulate to toxic levels of organic acids. It is unknown how *Sulfolobus* solves this problem.

19.4 What conclusions might be drawn if viruses of mesophilic archaea are found to have RNA genomes? What if they all have DNA genomes only?

ANSWER: If mesophilic viruses show RNA genomes, then it is likely that only double-stranded DNA is sufficiently stable for viruses to persist in the environment of hyperthermophiles. If only double-stranded DNA viruses are found throughout the archaea, this would suggest that all archaeal viruses evolved from viruses infecting a common ancestral cell that was a thermophile. The latter hypothesis would require supporting evidence from archaeal cell physiology and phylogeny.

19.5 What do the multiple metal requirements suggest about the evolution of methanogens?

ANSWER: The requirement for so many different metals may suggest that methanogens evolved in habitats such as geothermal vents where superheated water carries up high concentrations of dissolved metal ions.

19.6 Compare and contrast the metabolic options available for *Pyrococcus* and for the crenarchaeote *Sulfolobus.*

ANSWER: *Sulfolobus* catabolizes sugars and amino acids aerobically, using O_2 as terminal electron acceptor. *P. abyssi* catabolizes sugars and amino acids anaerobically, using S^0 as terminal electron acceptor. *Sulfolobus* oxidizes sulfur lithotrophically, from S^{2-} to S^0, $SO_3{}^{2-}$, and ultimately $SO_4{}^{2-}$. *P. abyssi,* however, reduces sulfur lithotrophically with H_2 to form H_2S.

19.7 Compare and contrast sulfur metabolism in *Pyrococcus* and in *Ferroplasma.*

ANSWER: *Pyrococcus* species reduce S^0 with hydrogens from organic substrates, forming HS^- and H_2S. *Ferroplasma* species oxidize sulfur in the form of FeS_2 (using oxidant Fe^{3+}) forming sulfuric acid. The result is extreme acidification of their environment.

Chapter 20

20.1 Why would yeasts remain unicellular? What are the relative advantages and limitations of hyphae?

ANSWER: Yeast grow in environments with sufficient dissolved nutrients to absorb from the medium. The advantage of forming hyphae is that they enable penetration of other organisms, and hence provide access to nutrients. On the other hand, hyphae formation limits the rate of dispersal of progeny cells. Since yeasts grow in environments where dissolved nutrients can be absorbed from the medium, they do not need to produce hyphae and can proliferate more rapidly than mycelial fungi.

20.2 Why would some fungi have lost their sexual life cycle? What are the advantages and limitations of sexual reproduction?

ANSWER: The sexual life cycle involves significant genetic and metabolic costs to the organism. Reductive evolution leading to loss of sexual reproduction might eliminate an energy drain and perhaps enable greater proliferation with fewer resources. On the other hand, the sexual life cycle provides a valuable means of generating diversity through genetic recombination, so that the population may respond to environmental change. Asexual fungi, like prokaryotes, must rely on mutation and gene transfer by viruses and mobile sequence elements to generate genetic diversity.

20.3 What are the advantages and limitations of motile gametes, as compared to non-motile spores?

ANSWER: Motile gametes have the advantage of rapid dispersal on their own and the potential for chemotaxis toward a food source or toward a gamete of the opposite mating type. On the other hand, motility uses up energy that could alternatively be invested in production of a greater number of non-motile gametes. Motile gametes are especially useful in a watery habitat, but are little use in a terrestrial habitat, where air currents or animal hosts must be used for dispersal.

20.4 Compare the life cycle of an oomycete (**Figure 20.17C**) with that of a chytridiomycete (**Figure 20.11C**). How are they similar, and how do they differ?

ANSWER: Both chytridiomycetes and oomycetes undergo alternation of generations. Each possesses the alternative route of an asexual diploid cycle between mycelium, motile zoospores and cysts. At the cellular and molecular level, however, the two kinds of organism differ radically. The chytridiomycete flagellum differs from the oomycete paired flagella, one of which has brush-like side hairs. The oomycete gametes have highly specialized forms that fuse by a process completely different from that of chytridiomycete zoospore fusion.

20.5 How are coralline algae able to grow at greater depths than coral?

ANSWER: Corals generally grow symbiotically with green algae, which contain chlorophyll but lack accessory photopigments. Corallines are red algae, possessing both chlorophyll and phycoerytherins. The latter absorb blue and green light that are not absorbed by green algae, and thus coralline algae penetrate deeper in the water column.

20.6 What might happen when an ameba phagocytoses algae?

ANSWER: If light is available, the algae may be retained as endosymbionts providing energy through photosynthesis. For example, *Chlorachnion* possesses obligate chloroplast-bearing endosymbionts descended from green algae. Alternatively, the ameba may digest all but the algal chloroplast, which persists for some time providing photosynthetic products.

20.7 What kind of habitats would favor a flagellated ameba?

ANSWER: A dilute watery habitat would favor flagella, which allow more rapid propulsion than pseudopods. Pseudopod motility requires a solid substrate.

20.8 Compare and contrast the processes of conjugation in ciliates and in bacteria.

ANSWER: Conjugation in ciliates is a completely different process from conjugation in bacteria, although the purpose (genetic exchange) is similar. In ciliates, two cells form a bridge allowing cytoplasm to flow directly between them, whereas in bacteria, a donor cell attaches to another (by pili in some cases), then a protein complex transfers DNA across both cell envelopes, without direct cytoplasmic contact. In bacterial conjugation, DNA is transferred unidirectionally from the donor cell to the recipient, whereas in ciliates there is reciprocal exchange of DNA. A donor bacterium generally transfers only part of its genome, whereas ciliates exchange entire copies of theirs.

20.9 For ciliates, what are the advantages and limitations of conjugation, as compared with gamete production?

ANSWER: The process of conjugation avoids the necessity of dissolving the intricate cell structure of the ciliate in order to form gametes that fuse or fertilize each other. On the other hand, conjugation requires two diploid organisms to find each other and make contact for several hours, during which time feeding is suspended and the pair is vulnerable to predation.

Chapter 21

21.1 From Chapters 13–15, give examples of microbial metabolism that fit patterns of assimilation and dissimilation.

ANSWER: Microbes can assimilate carbon either by reducing carbon dioxide or by oxidizing methane. Dissimilation of organic carbon occurs by fermentation and respiration. Nitrogen is assimilated by N_2 fixation, and by incorporation of NH_4^+ into glutamine and glutamate. Nitrogen is dissimilated by deamination of amino acids, and by lithotrophic oxidation.

21.2 Does "viable but nonculturable" mean that growth is permanently shut down?

ANSWER: Nonculturable bacteria might be induced to grow again, perhaps when the correct growth conditions are discovered. Some "unculturable" isolates have been made to grow by new methods after decades of attempts. Alternatively, some nonculturable cells may come from multicellular assemblages such as biofilms in which reproductive growth is limited to a portion of the cells. In this case, some of the population is permanently prevented from growth, but other cells continue to grow.

21.3 How do viruses select for increased diversity of microbial plankton? Why would this be so?

ANSWER: Since viruses tend to infect only a narrow host range, their existence favors the evolution of a large number of different species with highly dispersed populations. Highly dispersed populations minimize the chance of viral transmission from one host to another.

21.4 Design an experiment to test the hypothesis that the presence of mycorrhizae enhances plant growth in nature.

ANSWER: Such an experiment requires a control based on the natural environment, where various unknown factors may be very different than in the laboratory. One possibility is to compare the growth of seedlings in natural soil versus sterilized natural soil. However, this experiment would not prove that fungi are the cause of enhanced growth in unsterile soil. The sterilization procedure (usually involving heat and pressure) could break down key nutrients in the soil. A follow-up experiment might be to grow the plants in the presence of a fungus inhibitor in sterilized and unsterilized soil.

21.5 High levels of nitrate or ammonium ion corepress the *nod* genes through NodR. Why?

ANSWER: Nitrate and ammonia are the main forms of nitrogen assimilated by plants. If they are abundant in the soil, the plant does not need rhizobial symbionts; therefore, development of rhizobia-legume symbiosis is inhibited.

21.6 One unanswered question is, how do symbiotic rhizobia reproduce? Why do bacteroids develop if they cannot proliferate?

ANSWER: Various answers have been proposed. Not all of the invading bacteria become bacteroids; some continue to undergo cell division, particularly within senescing tissues of the plant. These bacteria benefit from plant growth, which is sustained by the bacteroids whose genes they share. Alternatively, the entire plant-bacteroid system may benefit rhizobia that grow just outside the plant, in the rhizosphere.

21.7 Compare and contrast the processes of plant infection by rhizobia and by fungal haustoria.

ANSWER: Both rhizobial bacteria and fungal haustoria penetrate the volume of a plant cell, but they keep the plant cell membrane intact, its invagination always surrounding the invading cell. Rhizobia establish a complex, highly regulated exchange of nutrients with the host, receiving catabolites and oxygen in exchange for ammonium and cycling the components of amino acids. By contrast, haustoria establish one-way removal of nutrients such as sucrose, while providing no nutrients in return. Fungal pathogens weaken the structure of the host plant and decrease or halt its growth.

21.8 Why does ruminant fermentation leave food value for the animal host? How is the animal able to obtain nourishment from waste products that the microbes could not use?

ANSWER: The rumen interior is anaerobic. In the absence of oxygen as a terminal electron acceptor, microbes are forced to generate waste products in which the electrons are put back onto the electron donors (fermentation; see Chapter 13). When the short-chain fatty acid wastes enter the animal's bloodstream, the blood is full of oxygen, which enables complete digestion to CO_2 and water.

21.9 How do you think cattle feed might be altered or supplemented to decrease methane production?

ANSWER: Several methods have been proposed to limit methanogenesis. One is to feed cattle the antibiotic monensin, an inhibitor of sodium transport, which is required for methanogenesis. Another approach is to feed cattle an electron acceptor for H_2, such as fumarate, which bacteria use to generate short-chain acids instead of methane. These approaches have been used with only partial success—not surprising given the complexity of the system.

Chapter 22

22.1 Why is oxidation state critical for the acquisition, usability, and potential toxicity of cycled compounds? Cite examples based on your study of microbial metabolism.

ANSWER: Many examples can be cited. In the case of carbon, CO_2 can be fixed by many species with substantial input from photosynthesis or hydrogen donors. The reduced form methane, however, can be assimilated only by methanotrophic bacteria, usually with oxygen as electron acceptor. Nitrogen gas can be assimilated only by nitrogen-fixing bacteria and archaea, whereas NH_4^+ can be assimilated by many plants and microbes. But NH_4^+ can also be oxidized by lithotrophs to NO_3^-, a substance potentially toxic to humans.

22.2 What would happen if wastewater treatment lacked microbial predators? Why would the result be harmful?

ANSWER: Without predators, too many planktonic bacteria would remain in the wastewater after sedimentation of the sludge. The bacteria could be killed by chlorination, but the treated water would have significant BOD because the bacterial remains provide an organic carbon source for respirers.

22.3 How many kinds of biomolecules can you recall that contain nitrogen? What are the usual oxidation states for nitrogen?

ANSWER: Amino acids, nucleotide bases, polyamines for DNA stabilization, peptidoglycan (both amino sugar and peptide chains), and the heme derivatives of cytochromes, chlorophyll, and vitamin B_{12} all include nitrogen (as do many other blochemicals). The oxidation states of nitrogen in living organisms are nearly always reduced, either $R{-}NH_2$, $R{=}NH$, or $R{-}N{=}R$. An exception is the neurotransmitter NO (nitric oxide).

22.4 In the laboratory, which kind of bacteria would likely grow on artificial medium including NH_2OH as the energy source: *Nitrosomonas* or *Nitrobacter*?

ANSWER: *Nitrosomonas* is more likely to utilize NH_2OH, since it performs the intermediate oxidation of NH_2OH during nitrification of ammonia.

22.5 The nitrogen cycle has to be linked with the carbon cycle, since both contribute to biomass. How might the carbon cycle of an ecosystem be affected by increased input of nitrogen?

ANSWER: One hypothesis is that the injection of nitrogen into an ecosystem accelerates growth of producers (phytoplankton in the ocean or trees in a forest) and therefore facilitates net removal of CO_2 from the atmosphere. Overall, however, the additional fixed carbon may end up dissipated by consumers and decomposers.

22.6 Compare and contrast the cycling of nitrogen and sulfur. How are the cycles similar? How are they different?

ANSWER: Both nitrogen and sulfur cycling involve interconversion between different oxidation states. Most of these interconversion reactions are performed solely by microbes, many of them solely by bacteria. Examples include nitrification of ammonia and denitrification to N_2, as well as sulfide oxidation and photolysis. In both cases, oxidation produces strong acids (HNO_3, H_2SO_4). The major sources and sinks differ; nitrogen is obtained primarily from the atmosphere as N_2, whereas sulfur is at high levels in the ocean and soil. Sulfur is rarely limiting, whereas nitrogen frequently is. Sulfur participates extensively in phototrophy; nitrogen shows little involvement in phototrophy; phototrophy based on nitrate reduction has been observed.

22.7 Compare and contrast the cycling of nitrogen and phosphorus. How are the cycles similar? How are they different?

ANSWER: Nitrogen and phosphorus are both limiting nutrients in many ecosystems—marine, aquatic, and terrestrial. Addition of either element into an aquatic system may cause algal bloom and eutrophication. On the other hand, the two elements differ in their major sources: the atmosphere for nitrogen, and crustal rock for phosphate. Within biomass, nitrogen exists almost entirely in reduced form, whereas phophorus is entirely oxidized. Phosphorus cycles through the biosphere mainly as inorganic or organic phosphates, whereas nitrogen cycles through a broad range of oxidation states, from NH_3 to NO_3^-.

22.8 Do you think that iron fertilization would succeed in maintaining lowered atmospheric CO_2? What consequences might you predict for widespread iron fertilization?

ANSWER: The algal bloom could occur in a population of toxin-producing algae, which would cause massive die-off of fish. Alternatively, if iron fertilization were widespread, the increased population density of algae would lead to increased viral predation, which would mineralize the algae, returning their carbon to the atmosphere. Other scenarios are possible, but it appears unlikely that iron fertilization would lead to a sustained decrease in atmospheric CO_2.

Chapter 23

23.1 How can an anaerobic microorganism grow on skin or in the mouth, both of which are exposed to air?

ANSWER: Facultative organisms living in proximity to the anaerobes will deplete oxygen in the environment, especially around nooks and crannies (e.g., between teeth and gums, gingival pockets) that would ordinarily prevent anaerobes from growing. These small spaces have limited access to oxygen.

23.2 What can a person with mitral valve prolapse do to prevent formation of subacute bacterial endocarditis when visiting the dentist?

ANSWER: Take antibiotics prophylactically. A high dose of antibiotic (usually amoxicillin or acephalosporin) taken 1 hour before the procedure will produce a high enough blood level to kill bacteria. A patient that is hypersensitive to β-lactam antibiotics such as amoxicillin will be prescribed an alternate antibiotic such as azithromycin.

23.3 Why do many gram-positive microbes that grow on the skin, such as *S. epidermidis*, grow poorly or not at all in the gut?

ANSWER: Bile salts present in the intestine (not on the skin) easily gain access to and destroy cytoplasmic membranes of gram-positive organisms (unless the organism possesses bile hydrolases). Gram-negative microbes have an extra protection in the form of an outer membrane and so can survive better in the intestine.

23.4 How might normal flora escape the intestine and cause disease at other body sites?

ANSWER: Normal flora can escape through intestinal perforations resulting from gunshot or knife wounds, surgery, or cancer.

23.5 Why can the colon be considered a fermenter?

ANSWER: The contents are continually flowing through the intestinal tube, with food containing substrates for fermentation ingested at one end and waste containing fermentation products removed from the other.

23.6 Why do defensins have to be so small?

ANSWER: They need to be small so they can get through the outer membrane of gram-negative organisms and the thick peptidoglycan maze of gram-positive organisms.

23.7 If NK cells can attack infected host cells coated with antibody, why won't neutrophils?

ANSWER: Actually, neutrophils (PMNs) *can* attack infected cells coated with antibody—but the killing mechanism is different than ADCC. Human neutrophils do not make perforin nor the other ADCC-related compounds, called granzymes, used by NK cells to kill target cells. In addition to that difference, NK cells possess a type of Fc receptor not found on neutrophils, which means the intracellular signaling pathways are different between NK cells and neutrophils. Neutrophils can, however, be activated when their Fc receptors bind antibody. Activated neutrophils make reactive oxygen products and can release a variety of peptides including defensins, cathelicidin, and myeloperoxidase, which can all damage target cells.

23.8 If increased fever limits bacterial growth, why would bacteria make pyrogenic toxins?

ANSWER: The pyrogenic toxins have other effects that compromise and damage the host. The toxins can induce cytokines that damage local host cells or confuse the immune system. This can provide the pathogen with nutrients and help it hide from the immune system longer. Pyrogenic toxins include lipopolysaccharide and protein toxins such as toxic shock syndrome toxin (see Chapter 25).

Chapter 24

24.1 Two different stretches of amino acids in a single protein form a three-dimensional antigenic determinant. Will the specific immune response to that three-dimensional antigen also respond to one of the amino acid stretches alone?

ANSWER: Most likely no. It is the three-dimensional shape formed by the two stretches that is recognized as an antigen. A denatured protein that contains both amino acid stretches will not possess the three-dimensional shape of the antigen. On the other hand, there can be other specific immune responses that involve different subsets of lymphocytes that individually recognize each of the amino acid stretches that form the three-dimentional antigenic determinant. As an analogy, take a computer image of a friend's face and shuffle the facial features. Turn the nose upside down, exchange the eyes with the mouth, and lower the ears. Since you were programmed to respond to the original facial configuration, you likely would not recognize the rearranged face as a whole. But you might find that the nose looks familiar.

24.2 How does a neutralizing antibody that recognizes a viral coat protein prevent infection by the associated virus?

ANSWER: Neutralizing antibodies usually bind attachment proteins on the virus and sterically prevent them from binding to host cell receptors (see **Fig. 24.4**). Some antibodies to enveloped viruses might trigger the complement cascade (see later in the chapter), destroying the membrane.

24.3 There are immune disorders in which an individual overproduces a specific class of antibody, for example hypergammaglobulinemia. How could the radial immunodiffusion technique be used to identify what class of antibody is in excess?

ANSWER: Because they are proteins, immunoglobulin antibodies are also antigens. Therefore, antibodies can be made that react to epitopes in the heavy chains. Antibodies to human IgG can be raised in rabbits, for example. Radial immunodiffusion using agarose impregnated with rabbit anti-human IgG antibodies can be used to measure the concentration of human IgG in serum loaded into a well. The larger the diameter of the resulting ring, the more IgG there is in the serum sample. A patient that has an unusually high amount of IgG antibody relative to other antibody isotypes, as compared to a normal healthy person, would be diagnosed with IgG hypergammaglobulinemia.

24.4 The mother of a newborn was found to be infected with rubella, a viral disease. Infection of the fetus could lead to serious consequences for the newborn. How could you determine if the newborn was infected while in utero?

ANSWER: Since maternal IgM antibodies cannot cross the placenta, finding IgM antibodies to rubella antigens in the newborn's circulation indicates that the fetus was infected and initiated its own immune response. If the newborn has only IgG antibodies to rubella (no IgM antibodies), this indicates that the child was not infected and that maternal IgG crossed the placenta.

24.5 Why does the delta region have no switch region?

ANSWER: Because B cells at the early stages have both IgM and IgD surface antibodies. Recombination at the DNA level is not involved because alternative RNA-splicing events after transcription determine whether an IgM or IgD molecule is made.

24.6 Why do individuals with type A blood have anti-B and not anti-A antibodies?

ANSWER: Because the B-cell population that would react to type A antigen was deleted during B-cell maturation.

24.7 Why do immunizations lose their effectiveness over time?

ANSWER: Because memory B cells eventually die. Without some exposure to antigen, those memory cells will not be replaced.

24.8 Transplant rejection is a major consideration when transplanting most tissues because host T_C cells can recognize allotypic MHC on donor cells. So why are corneas easily transplanted from a donor to just about any other person?

ANSWER: The cornea is not normally vascularized. So even though corneal cells express MHC proteins, circulating host T cells do not have an opportunity to interact with them. The cornea will not be rejected. This is called an immune privileged site.

24.9 Why does attaching a hapten to a carrier protein allow production of anti-hapten antibodies?

ANSWER: B cells with anti-hapten surface antibody (as part of the B-cell receptor) can take up hapten but cannot present the hapten to a helper T cell. The same B cell can also take up the hapten bound to a carrier molecule, and because the carrier molecule is larger than the hapten, the B cell will present the carrier epitope to the helper T cell. The helper T cell stimulates the B cell, which was already programmed to make anti-hapten antibody, to differentiate into plasma and memory B cells.

24.10 Do bone marrow transplants in a patient with severe combined immunodeficiency require immunosuppressive chemothereapy?

ANSWER: No. Since the patient has no T cells to recognize foreign antigens, the transplant is not rejected.

24.11 How can a stem cell be differentiated from a B cell at the level of DNA?

ANSWER: Gene splicing will have taken place in the B cell but not the stem cell. Thus, the B cell will have fewer cassettes for each of the V, D, and J regions, while the stem cell will have all of them. PCR techniques can be used to view those differences.

Chapter 25

25.1 Is a microbe with an LD_{50} of 5×10^4 more or less virulent than a microbe with an LD_{50} of 5×10^7?

ANSWER: Because it takes fewer cells to cause disease, the microbe with the smaller LD_{50} (5×10^4) is the more virulent.

25.2 Antibodies to which subunit of cholera toxin will best protect a person from the toxin's effects?

ANSWER: Antibodies to the B subunit will be more protective. Inactivating the B subunit will prevent binding of the toxin to cell membranes. The A subunit active site is typically sequestered in these toxins and inaccessible to antibody. Furthermore, once the A subunit has entered a host cell, antibodies cannot enter and neutralize it.

25.3 Would patients with iron overload (excess free iron in the blood) be more susceptible to infection?

ANSWER: Withholding iron from potential pathogens is a host defense strategy because when iron is plentiful, the microbe does not have to expend energy to get it and so can readily grow. On the other hand, low iron can also be a signal to express various virulence genes, so for some organisms, high iron might hinder infection.

25.4 How might you experimentally determine if a pathogen secretes an exotoxin?

ANSWER: The microbe can be grown in liquid culture and the cells removed either by centrifugation or filtration. If the organism makes an exotoxin, it may well be present in the cell-free supernatant. The presence of a toxin can be determined by injecting the supernatant into an animal model (e.g., mice) and examining the result (death or altered function; see tetanus toxin below). Alternatively, the supernatant can be administered to a layer of tissue culture cells and the health of the monolayer noted.

25.5 Internet problem: What other toxins are related to the cholera enterotoxin A subunit? B subunit?

ANSWER: Go to Pub-med (http://www.ncbi.nlm.nih.gov/PubMed/) In the search pop-down window mark "Protein." Then type "cholera enterotoxin" or "cholera B subunit." Click on the appropriate result. Highlight and copy the amino acid sequence at the bottom of the document. Then, back at the NCBI home page, click on "Blast", select "Protein-Protein Blast," paste the B subunit sequence into the Search box and click "Blast." After clicking "Format" on the next page, all the homology results will be displayed. Items with E-values having large negative numbers represent the most significant homologies. Note that the toxin of *Citrobacter freundii,* another gram-negative rod, possesses a B subunit similar to that of cholera, but not a similar A subunit (you must perform a second "Blast" for this). Scroll down the page to find the actual alignments between the query protein and homolog.

25.6 Protein and DNA have very different structures. Why would a protein secretion system be derived from a DNA-pumping system?

ANSWER: Conjugation systems actually move DNA that is attached to a pilot protein at the 5′ end. A pilot protein is made by the conjugation system, then binds to the 5′ end of the DNA to be transferred, and "pilots" the DNA through the conjugation pore. So a modified conjugation system that moves protein only is not as much of a leap as might initially be thought.

25.7 How can one determine if a bacterium is an intracellular parasite?

ANSWER: Microscopic examination to see if bacteria are found within cultured mammalian cells is usually not satisfactory. The difficulty lies in determining if the organism is inside the host cell or just bound to its surface—or, if it is inside, whether it is a live or dead bacterium. One commonly used approach is to add to infected cell monolayers an antibiotic that can kill the microbe but will not penetrate the mammalian cells. The protein synthesis inhibitor gentamicin is typically used. A bacterium that invades a host cell will gain sanctuary from gentamicin and grow intracellularly. Extracellular bacteria and bacteria attached to the outside of the host cell are killed. Counting viable colony-forming units of bacteria released from the mammalian cells by gentle detergent treatments at various times will reveal if the organism grew intracellularly. Of course, this will only work if the microorganism is not an obligate intracellular parasite.

25.8 Why would killing a host be a bad strategy for a pathogen?

ANSWER: The goal of any microbe is to maintain its species. If a microbe does not have an opportunity to easily spread to a new host, killing its host would be tantamount to suicide.

25.9 Why do rhinovirus infections fail to progress beyond the nasopharynx?

ANSWER: For one thing, rhinoviruses are susceptible to acid pH (pH 3.0), so they are unable to replicate in the gastrointestinal tract. They also grow best at 33°C, which may help explain their predilection for the cooler environs of the nasal mucosa.

Chapter 26

26.1 Why would treatment of an infection sometimes require multiple antibiotics?

ANSWER: Sometimes treatment is initiated before knowing the infecting microbe or its susceptibility to different drugs. Without knowing the antibiotic susceptibility of the infecting agent, a physician will use multiple antibiotics to ensure that one will kill or inhibit the growth of the microbe. Combinations of antibiotics are also used because different antibiotics are effective against different sets of microbes (e.g., gram-positive vs. gram-negative, or aerobe vs. anaerobe).

26.2 Why do you think most urinary tract infections occur in women?

ANSWER: The major reason is anatomy. Most bladder UTIs come from access through the urethra. Since the urethra in men is longer than in women, it usually takes a catheter to introduce bacteria into a male bladder. The trip for the infecting organism in women is much shorter. However, in people older than 50, UTIs become more common in both men and women, with less difference between the sexes. The reason is not clear.

26.3 Urine samples collected from six hospital patients were placed on a table at the nurse's station awaiting pickup from the microbiology lab. Several hours later, a courier retrieved the samples and transported them to the lab. The next day, the lab reported that four of the six patients had UTI. Would you consider these results reliable? Should you start treatment based on these results?

ANSWER: Because urine is good growth media for many bacteria, the delay of several hours in picking up the samples gave the organisms time to replicate and increase their numbers. Consequently, the lab results should be viewed with suspicion.

26.4 Considering that *N. gonorrhoeae* is exquisitely sensitive to ceftriaxone, why do you suppose the patient was also treated with tetracycline? And why can one person be infected repeatedly with *N. gonorrhoeae?*

ANSWER: Because STDs often travel in pairs and because the initial symptomolgy is similar, the clinician will want to "cover" the patient for possible chlamydia infection. Chlamydiae are not susceptible to ceftriaxone. The large, single dose of ceftriaxone (as opposed to smaller multiple injections given over days) was given because patients with gonorrhea are typically poorly compliant and fail to return for subsequent injections. A person who experiences gonorrhea is not protected from reinfection because the organism's surface antigens undergo phase variations (see Section 10.6) and may downregulate the immune system (see **Fig 26.13C**).

26.5 Human immunodeficiency virus was discussed in this section and in Chapter 25. Like the plague, it is a blood-borne disease. Why, then, do fleas and mosquitoes fail to transmit HIV?

ANSWER: When insect vectors take a blood meal, they typically defecate or regurgitate simultaneously. So theoretically, they could serve as a vector for HIV. Pathogens such as the West Nile virus that are transmitted by insect vectors actually grow in their insect hosts; however, HIV does not. Because it is unusually fragile, HIV will die quickly. There have been no cases of HIV transmitted by insect vectors.

26.6 Normal cerebral spinal fluid is usually low in protein and high in glucose. The protein and glucose content does not change much during a viral meningitis, but bacterial infection leads to greatly elevated protein and lowered glucose levels. What could account for this?

ANSWER: There are several explanations. Bacteria and infiltrating PMNs will consume glucose and alterations in the blood-brain barrier can lead to decreased transport of glucose into the spinal fluid. As a result of these factors, glucose levels plummet. Growth of the bacteria and infiltration of PMNs accounts for the increase in CSF protein levels. Viruses are very small and consist mostly of nucleic acids, so even at high numbers, they will not significantly add to CSF protein content. Since viruses do not grow in CSF directly, they will not consume glucose. In addition, viral meningitis does not cause a great infiltration of PMNs into the CSF, another reason glucose levels remain high and protein levels remain low.

26.7 Knowing the symptoms of tetanus, what kind of therapy would you use to treat the disease?

ANSWER: At the first sign of muscle spasm, antitoxin should be given. If tetany is severe, muscle relaxants can relieve spasms.

26.8 How do the actions of tetanus toxin and botulinum toxin actually help the bacteria colonize or obtain nutrients?

ANSWER: This is a difficult question to answer. Few scientists have speculated. Recall that the toxins are encoded by genes in resident bacteriophages that became part of the clostridial genome through horizontal transfer from some other source. Since the organisms normally reside in soil, the actual function of these toxins may have something to do with survival in that habitat. The toxin's effects on humans may simply be an unfortunate accident. However, with tetanus toxin, there may be benefit in that muscle spasms could limit oxygen delivery to infected tissues, enabling a more anaerobic environment for growth. Cell death may also release iron or other nutrients useful to *C. tetani.*

26.9 If *C. botulinum* is an anaerobe, how might botulism toxin get into foods?

ANSWER: The most common way botulism toxin gets into food today is via home canning. The canning process involves heating food in jars to very high temperatures. The heat destroys microorganisms and drives out oxygen; both processes help to preserve foods. If the jars are not heated to sterilization conditions, spores of *C. botulinum* will survive. When the jars are cooled for storage at room temperature, the spores germinate; the organism then grows in the anaerobic medium and releases the toxin. When the food is eaten, the toxin is eaten, too.

26.10 A patient presenting with high fever and in an extremely weakened state is suspected of having a septicemia. Two sets of blood cultures are taken from different arms. One bottle from each set grows *Staphylococcus aureus* yet the laboratory report states that the results are inconclusive. New blood cultures are ordered. Why might this be?

ANSWER: There must have been something different about the two strains of staphylococci grown in the separate bottles. For example, they may have different antibiotic susceptibility patterns when tested against a battery of antibiotics. One strain may be sensitive to penicillin while the other strain is resistant. Since the expectation is that a single strain initiated the infection, both isolates should exhibit the same drug susceptibility pattern. The laboratory suspects contamination from separate sources.

Chapter 27

27.1 The drug tobramycin is added to a concentration of 1,000 μg/ml in a tube of broth from which serial twofold dilutions were made. Including the initial tube (tube 1), there are a total of ten tubes. Twenty-four hours after all the tubes are inoculated with *Listeria monocytogenes,* turbidity is observed in tubes 6–10. What is the MIC?

ANSWER: 62.5 μg/ml, the concentration in tube 5, the last tube with no growth. (Relative to tube 1, tube 5 has been diluted 2^4 (16-fold dilution: 1,000/500/250/125/62.5.)

27.2 What additional test performed on an MIC series of tubes will tell you whether a drug is bacteriostatic or bactericidal?

ANSWER: Streaking a portion of the broth from the dilution tubes showing no growth. If the drug is bacteriostatic, colonies will form on the agar plate because during streaking, the bacteria are removed from the presence of the drug. If the antibiotic is bactericidal, no colonies will form because the organisms are dead before plating. This method determines the minimum bactericidal concentration (MBC) of an antibiotic. MBC would be defined as the lowest dilution that did not yield viable cells.

27.3 You are testing whether a new antibiotic will be a good treatment choice for a patient with a staph infection. The Kirby-Bauer test using the organism from the patient shows a zone of inhibition of 15 mm around the disk containing this drug. Clearly, the organism is susceptible. But you conclude that the drug would not be effective in the patient. What would make you draw this conclusion?

ANSWER: If the average attainable tissue level of the drug is below the MIC, the drug will not be effective.

27.4 When treating a patient for an infection, why would combining a drug such as erythromycin with a penicillin be counterproductive?

ANSWER: Erythromycin, a bacteriostatic drug, will stop growth, which indirectly stops cell wall synthesis and renders the microbe insensitive to penicillin.

27.5 The enzyme DNA gyrase, a target of the quinolone antibiotics, is an essential protein in DNA replication. The quinolones bind to and inactivate this protein. Research has proved that quinolone-resistant mutants contain mutations in the gene encoding DNA gyrase. If the resistant mutants contain a mutant DNA gyrase and DNA gyrase is essential for growth, why are these mutations not lethal?

ANSWER: The mutations cause changes in DNA gyrase that have little to no effect on function but that do prevent the drug from binding. Thus, the mutant organism will continue to twist its DNA and grow well with or without the drug.

27.6 Why might a combination therapy of an aminoglycoside antibiotic and cephalosporin be synergistic?

ANSWER: The two drugs given together could act synergistically because the cephalosporin can weaken the cell wall and allow the aminoglycoside easier access to the cell interior, where it can attack ribosomes. This is especially useful in organisms that have some resistance to both drugs.

27.7 Could genomics ever predict the drug resistance phenotype of a microbe? If so, how?

ANSWER: Yes. If the organism's genome possesses genes whose deduced protein sequences harbors significant similarity to antibiotic resistance proteins from other organisms, one can predict a similar drug resistance. Definitive proof of drug resistance requires actual in vitro testing.

27.8 Fusaric acid is a cation chelator that normally does not penetrate the *E. coli* membrane, which means *E. coli* is typically resistant to this compound. Curiously, cells that develop resistance to tetracycline become *sensitive* to fusaric acid. Resistance to tetracycline is usually the result of an integral membrane efflux pump that pumps tetracycline out of the cell. What might explain the development of fusaric acid sensitivity?

ANSWER: Fusaric acid is imported by the tetracycline efflux pump. This phenomenon can be used to isolate mutants with deletions of transposons encoding tetracycline resistance. Transposons, such as Tn*10*, which carries tetracycline resistance, can spontaneously delete at around a frequency of 10^{-6}, but finding one out of a million tetracycline-susceptible cells is impossible without a positive selection. Fusaric acid provides that positive selection, since the cell with the Tn*10* deletion will be resistant to fusaric acid.

27.9 Mutations in the ribosomal protein S12 (encoded by *rpsL*) confer resistance to streptomycin. Given a cell containing both *rpsL*$^{+}$ and *rpsL*^{R} genes, would the cell be streptomycin resistant or sensitive? (Recall that genes encoding ribosome proteins for the small subunit are designated *rps*. A + indicates the wild-type allele, while R indicates a gene whose product is resistant to a certain drug.

ANSWER: This merodiploid cell would contain two sets of ribosomes, one set, containing normal S12, would be sensitive to streptomycin; another set, containing the resistant S12, would be resistant. Because streptomycin causes mistranslation of mRNA on sensitive ribosomes, inappropriate proteins that can kill the cell would still be synthesized. Thus, the cell would remain sensitive to streptomycin. Note, however, that the recessive nature of antibiotic resistance seen in this case is not the norm. Resistance is a dominant trait in a majority of cases.

Chapter 28

28.1 Use **Figure 28.6** to identify the organism from the following case. A sample was taken from a boil located on the arm of a 62-year-old man. Bacteriological examination revealed the presence of gram-positive cocci that were also catalase-positive, coagulase-positive, and novobiocin resistant.

ANSWER: *Staphylococcus aureus.* The novobiocin test is irrelevant in this situation.

28.2 Why does finding IgM to West Nile virus indicate current infection? Why wouldn't finding IgG do the same?

ANSWER: Upon infection with any organism, IgM antibodies are the first to rise. After a short time the levels of IgM decline as IgG levels rise. IgG, however, can remain in serum for years, making it a poor prognosticator of current infection.

28.3 Why does adding albumin or powdered milk prevent false positives in ELISA?

ANSWER: Antibodies are proteins. They can stick to plastic just as easily as the antigen being tested. Without blocking all the possible binding sites on plastic with albumin, any antibody from the patient's serum could stick to the plastic instead of to the antigen and react with the secondary enzyme-conjugated antihuman antibody.

28.4 Specific antibodies against an infectious agent can persist for years in the bloodstream. So how is it possible that antibody titers can be used to diagnose diseases such as infectious mononucleosis?

ANSWER: During the course of a disease, the body's immune system will increase the amount of antibody made specifically against the infectious agent. Thus, one compares the antibody titer in a blood sample taken from a patient in the active, or acute, phase of disease with the antibody titer several weeks later, when the patient is in the recovery, or convalescent, stage. Seeing a greater than fourfold rise in a specific antibody titer (for example, in mononucleosis) indicates that the patient's immune system was responding to the specific agent. Remember, simply finding IgG against an organism or virus in serum only indicates that the patient was exposed to that microbe at some time in the past.

28.5 Two blood cultures, one from each arm, were taken from a patient with high fever. One culture grew *Staphylococcus epidermidis,* but the other blood culture was negative (no organisms grew out). Is the patient suffering from septicemia caused by *S. epidermidis*?

ANSWER: Probably not. *S. epidermidis* is a common inhabitant of the skin and could easily have contaminated the needle when blood was taken from the patient. The fact that only one of the two cultures grew this organism supports this conclusion. If the patient had really been infected with *S. epidermidis,* both blood cultures would have grown this organism.

28.6 A 30-year-old woman with abdominal pain went to her physician. After the examination, the physician asked the patient to collect a midstream urine sample that they would send to the lab across town for analysis. The woman complied and handed the collection cup to the nurse. The nurse placed the cup on a table at the nurse's station. Three hours later, the courier service picked up the specimen and transported it to the laboratory. The next day, the report came back "greater than 200,000 CFUs/ml; multiple colony types; sample unsuitable for analysis." Why was this determination made?

ANSWER: Although the CFU number is high enough to consider relevant, UTIs are typically caused by a single organism. The fact that the lab found many different colony types suggests a problem with specimen collection. In this case, not refrigerating the sample allowed the small number of urethral contaminants to overgrow the specimen.

28.7 Methicillin, a beta-lactam antibiotic, is very useful in treating staphylococcal infections. The development of methicillin-resistant strains of *Staphylococcus aureus* (MRSA) is a very serious development because there are few antibiotics that can kill these strains. Imagine a large metropolitan hospital in which there have been eight serious nosocomial infections with MRSA and you are responsible for determining the source of infection so it can be removed. How would you accomplish this using common bacteriological and molecular techniques?

ANSWER: Samples from all the affected patients and from the hospital staff would be screened for the presence of *S. aureus* resistant to methicillin. Each strain would then be analyzed for restriction fragment length polymorphisms (RFLP). Strains from all the patients will likely have identical restriction patterns if they came from the same source. The source is then identified by determining which staff member possesses MRSA with the same pattern. The source may also be inanimate, such as surgical equipment or ventilation apparatus. A connection between patients and specific staff members or instruments would also have to be demonstrated.

28.8 What are some reasons why some diseases spread quickly through a population while others take a long time?

ANSWER: There are several factors. One is mode of transmission; airborne diseases can spread more quickly than food-borne disease, for instance. Sexually transmitted diseases spread slower still. Herd immunity is another factor. Herd immunity is based on the number of individuals within a population that are resistant to a disease. Someone immune to the disease cannot pass it on. The more immune people there are in a population (or herd), the slower the spread of the epidemic to susceptible people.

28.9 Using the "Maps of Outbreaks" provided on the ProMed-mail website, identify the countries considered to have anthrax epidemics.

ANSWER: The latest map available at the time this was written was drawn from reported occurrences in 2003. At that time, 14 countries had epidemic occurrences of anthrax (Turkey, Niger, Chad, Guinea, Sierra Leone, Liberia, Ivory Coast, Ghana, Togo, Ethiopia, Zambia, Zimbabwe, Myanmar, and Commonwealth of Independent States). Many others, such as Mexico, are endemic. The United States has sporadic cases of anthrax. Note that the ProMed-mail website as of 2008 has an interactive map that shows the locations of specific disease outbreaks that have taken place during the past 30 days across the globe.

This page intentionally left blank

Glossary

AB toxin A bacterial toxin containing two protein subunits, A and B. Subunit A is the toxic protein and subunit B binds host cell receptors.

ABC transporter An ATP powered transport system that contains an ATP binding cassette.

aberration An imperfection in a lens.

abiotic Produced without organisms; occurring in the absence of life.

absorption In optics, the capacity of a material to absorb light.

acceptor end The amino acid attachment site at the 3′ end of tRNAs.

acceptor site (A site) The region of the ribosome that binds an incoming charged tRNA.

accessory protein A protein found in the viral capsid or tegument that is needed early in the viral life cycle.

acid-fast stain A diagnostic stain for mycobacteria, which retain the dye fuchsin due to the presence of mycolic acids in the cell wall.

acidophile An organism that grows fastest in acid (generally defined as below pH 5).

acquired immunodeficiency syndrome (AIDS) A disease caused by HIV that leads to the destruction of T cells and the inability to fight off opportunistic infections.

Actinobacteria A phylum of high GC content gram-positive bacteria.

activated sludge Organic material concentrated from wastewater, containing microbes that digest the material to inorganic compounds.

activation energy The energy needed for reactants to reach the transition state between reactants and products.

activator A protein that increases gene transcription.

active transport An energy-requiring process that moves molecules across a membrane against their electro-chemical gradient.

acyl carrier protein (ACP) A protein that can carry an acetyl group for anabolic pathways such as fatty acid synthesis.

adaptive immune response See **adaptive immunity**.

adaptive immunity Immune responses activated by a specific antigen and mediated by B cells and T cells.

adenosine triphosphate (ATP) A ribonucleotide with three phosphates and the base adenine. It has many functions in the cell including precursor for RNA synthesis and energy carrier.

adenylate cyclase An enzyme that converts ATP into cyclic adenosine monophosphate, cAMP.

adherence The ability of an organism to attach to a substrate.

adhesin Any cell surface factor that promotes attachment of an organism to a substrate.

ADP-ribosyltransferase A bacterial toxin that enzymatically transfers the ADP-ribose group from NAD^+ to target proteins, altering the target protein's structure and function.

adsorb The attachment of virions to a host cell.

aerated (A) horizon The layer of soil below the organic horizon, containing decomposed organic particles and minerals.

aerial mycelium A hypha that extends above the surface and produces spores at its tip.

aerobic respiration The use of oxygen as the terminal electron acceptor in an electron transport chain. A proton gradient is generated and used to drive ATP synthesis.

agar A polymer of galactose that is used as a gelling agent.

Airy disk A bright central point surrounded by rings of light and dark caused by the pattern of interference of spherical wavefronts converging at the focal point.

akinete A specialized spore cell formed by some filamentous cyanobacteria.

alga A microbial eukaryote that contains chloroplasts.

algal bloom An overgrowth of algae on the water surface, caused by an increase in a limiting nutrient.

alkaline fermentation Bacterial fermentation in conjunction with proteolysis and amino acid catabolism that generates ammonia in amounts that raise pH.

alkaliphile An organism with optimal growth in alkali (generally defined as above pH 9).

allergen An antigen that causes an allergic hypersensitivity reaction.

allograft The transplantation of tissue from a donor with one type of major histocompatibility complex (MHC) protein into a recipient with a different type of MHC.

allosteric site A regulatory site on a biological molecule distinct from the ligand/substrate binding site.

allotype An amino acid sequence in the antibody constant region that is shared by some, but not all, members of a species.

alternation of generations A life cycle that alternates between a haploid cell population and a diploid cell population.

alveolar macrophage Macrophages, located in the lung alveoli, that phagocytose foreign material.

Alveolata (alveolate) A group of ciliated or flagellated protists with complex cortical structure.

ameba (or amoeba) A protist that moves via pseudopods.

amensalism An interaction between species that harms one partner but not the other.

amino acid The monomer unit of proteins. Each amino acid contains a central carbon covalently bound by a hydrogen, an amino group, a carboxylic acid group and a side chain. An exception is proline, in which the side chain is cyclized with the central carbon.

aminoacyl-tRNA transferase An enzyme that attaches a specific amino acid to the correct tRNA thereby charging the tRNA.

aminoglycosides Bacteriocidal protein synthesis inhibitors used as antibiotics.

ammonification The generation of ammonia from organic nitrogen.

Amoebozoa A taxonomic class of unshelled amebas that move via lobed pseudopods. Also known as Lobosea.

amphibolic Metabolic pathways that are reversible and can be used for both catabolism and anabolism.

amphipathic A molecule with both hydrophilic and hydrophobic portions.

amphotericin B An anti-fungal drug that binds the fungal specific sterol ergosterol and destroys membrane integrity.

anabolism The building up of complex biomolecules from smaller precursors.

anaerobic photosystem I A protein complex that harvests light from a chlorophyll, splits an electron from a small molecule such as H_2S or H_2O, and stores energy in the form of NADPH.

anaerobic photosystem II A protein complex that splits an electron from bacteriochlorophyll and stores energy in the form of a proton potential.

anaerobic respiration The use of a molecule other than oxygen as the final electron acceptor of an electron transport chain.

anammox reaction The anaerobic oxidation of ammonium to nitrogen gas (using nitrate as electron acceptor); yields energy.

anaphylaxis A severe hypersensitivity reaction caused by chemically induced contraction of smooth muscles and dilation of capillaries.

anaplerotic reaction Metabolic reactions, occurring in all organisms, that fix small amounts of CO_2 to regenerate TCA cycle intermediates.

angle of aperture The width of a light cone (theta, □) that projects from the midline of a lens. Greater angles of aperture increase resolution.

anion A negatively charged ion.

annotation Deciphering genome sequences, including identification of genes and prediction of gene function.

antenna complex A complex of chlorophylls and accessory pigments in the photosynthetic membrane that collects photons and funnels them to a reaction center.

anthropogenic Caused by humans.

anti-anti-sigma factor A protein that inhibits an anti-sigma factor, allowing the target sigma factor to participate in initiating transcription.

anti-attenuator stem loop An mRNA secondary structure whose formation prevents assembly of a downstream transcriptional termination stem loop. The anti-attenuator stem permits transcription of the downstream structural genes.

antibiotic A molecule that can kill or inhibit the growth of selected microorganisms.

antibody A host defense protein produced by B cells in response to a specific antigenic determinant. Antibodies bind to their corresponding antigenic determinant.

antibody stain The attachment of a stain to an antibody to visualize cell components recognized by the antibody with high specificity.

antibody-dependent cell-mediated cytotoxicity (ADCC) The process by which natural killer cells destroy viral protein expressing antibody-coated host cells.

anticodon Three nucleotides in the middle loop of a tRNA that base pair with a codon in mRNA.

antigen A compound, recognized as foreign by the cell, that elicits an adaptive immune response.

antigenic determinant A small segment of an antigen that is capable of eliciting an immune response. An antigen can have many different antigenic determinants.

antigenic shift A genetic change in a pathogen's surface protein that prevents recognition by antibodies and host immune cells produced in response to the previous version of the protein.

antigen-presenting cell (APC) An immune cell that can process antigens into antigenic determinants and display those determinants on the cell surface for recognition by other immune cells.

antimicrobial agent A chemical substance that can kill microbes or slow their growth.

antiparallel The orientation of the two strands in opposite directions. Commonly refers to a nucleic acid double helix with one strand in the 5′ to 3′ orientation and the other strand in the 3′ to 5′ orientation.

antiport A transport protein in which the molecules being transported move in opposite directions across the membrane.

antisense RNA A non-coding RNA that binds to a complementary sequence of protein-coding RNA and (usually) prevents its translation.

antisepsis The removal of pathogens from living tissues.

antiseptic A chemical that kills microbes.

anti-sigma factor A protein that inhibits a specific sigma factor, preventing transcription initiation.

AP endonuclease An enzyme that cleaves the DNA backbone at regions missing a nitrogenous base.

AP site A position in DNA where there is no base attached to the sugar of the backbone.

apical complex A specialized structure that facilitates entry of Apicomplexan parasites into host cells.

Apicomplexa A taxonomic group of parasitic alveolates that possess an apical complex used for entry into a host cell.

apicoplast An organelle unique to Apicomplexans, derived from genetic reduction of a chloroplast, that no longer performs photosynthesis but provides an essential function in fatty acid metabolism.

apurinic site A DNA site missing a purine base due to hydrolysis of the bond linking the base to the sugar.

aquaporin A membrane-embedded channel that increases the rate of water diffusion across the membrane.

arbuscules The structure formed by penetrating hyphae of endomycorrhizae.

archaea Prokaryotic organisms that are members of the domain *Archaea*.

Archaea One of the three domains of life, consisting of organisms with a last common ancestor not shared with members of *Bacteria* or *Eukarya*. Organisms are prokaryotic (lacking nuclei, unlike eukaryotes) and possess ether-linked phospholipid membranes (unlike bacteria).

Archaean eon The second eon (major time period) of Earth's existence, from 3.8 to 2.5 gigayears (Gyr, 10^9 years) before the present. The earliest geological evidence for life dates to this eon.

archaeon See *pl.* **archaea**.

aromatic A ring-shaped organic molecule with □ electrons delocalized equally around the ring.

arthrospore A small vegetative cell, produced by mature mycelia, that gets dispersed.

artifact A structure viewed through a microscope that is incorrectly interpreted.

Ascomycota (ascomycete) A taxonomic group of fungi whose mycelia form paired nuclei. Haploid ascospores are produced in pods called asci.

ascospore The spore produced by an Ascomycete fungus.

ascus *pl.* **asci** A spore-containing pod produced by Ascomycete fungi.

aseptic An environment that is free of microbes.

assembly The packaging of a viral genome into the capsid to form a complete virion.

assimilation An organism's acquisition of an element, such as carbon from CO_2, to build into body parts.

assimilatory nitrate reduction The uptake of nitrate by plants and bacteria for use in biosynthetic pathways.

atomic force microscopy (AFM) A technique that maps the three dimensional topography of a object using van der Waals forces between the object and a probe.

atomic mass The mass (in grams) of one mole of an element.

atomic number The number of protons in an atom, it is unique for each element.

ATP synthase A protein complex that synthesizes ATP from ADP and inorganic phosphate using energy derived from the transmembrane proton potential. It is located in the prokaryotic cell membrane and in the mitochondrial inner membrane.

attach See **adsorb**.

attenuator stem loop An intramolecular mRNA structure consisting of a base-paired stem connected by a single-strand loop. The stem loop structure causes transcription to terminate. Its formation requires efficient translation of a leader peptide sequence.

autoclave An appliance that uses pressurized steam to sterilize materials by raising the temperature above the boiling point of water at standard pressure.

autoimmune response A pathology caused by lymphocytes that can react to self antigens.

autoinducer A secreted molecule that induces quorum sensing behavior in bacteria.

autoradiography The visualization of a radioactive probe by exposing the probed material to X-ray film, followed by photographic development of the film.

autotroph An organism that can reduce carbon dioxide to produce organic carbon for biosynthesis.

axenic growth The ability of an organism to grow in the absence of any other species, as, for example, in a pure culture.

azidothymidine (AZT) A nucleotide analog that inhibits reverse transcriptase and was the first drug clinically used to fight HIV infections.

B cell An adaptive immune cell that can give rise to antibody-producing cells.

bacillus *pl.* **bacilli** A bacterium with a linear, rod-like shape.

bacitracin A topical antibiotic that affects cell wall synthesis.

bacteremia A bacterial infection of the blood.

bacteria *sing.* **bacterium** Prokaryotic organisms that are members of the domain

Bacteria One of the three domains of life, consisting of organisms with a last common ancestor not shared with members of *Archaea* or *Eukarya*. Organisms are prokaryotic (lacking nuclei, unlike eukaryotes) and possess ester-linked phospholipid membranes (unlike archaea).

bactericidal An agent that kills bacterial cells.

bacteriochlorophyll The chlorophylls of anaerobic phototrophs; they absorb photons most strongly in the far red end of the light spectrum.

bacteriophage (phage) A virus that infects bacteria.

bacteriorhodopsin (BR) An archaeal membrane-embedded protein that contains retinal and acts as a light-driven proton pump; homologous to the bacterial proteorhodopsin.

bacteriostatic An agent that inhibits the growth of bacterial cells.

bacterium See *pl.* **bacteria**.

bacteroid Cell-wall-less, undividing, differentiated rhizobial cell within a plant cell. The bacteroid provides fixed nitrogen for the plant.

Bacteroidetes A phylum of gram-negative bacteria; nearly all their members are obligate anaerobes.

banded iron formation A geological formation consisting of layers of oxidized iron (Fe^{3+}) which indicates formation under oxygen-rich conditions.

barophile See **piezophile**. An organism that requires high pressure to grow.

base excision repair A DNA repair mechanism that cleaves damaged bases off the sugar-phosphate backbone. After endonuclease activity at the AP site, a new correct DNA strand is synthesized complementary to the undamaged strand.

Basidiomycota (basidiomycete) A clade of fungi that form mushrooms.

basidiospore A haploid spore formed by a basidiomycete through meiosis of a basidium.

basidium A diploid cell, formed by the fusion of paired nuclei, that lines the gills of mushrooms (Basidiomycota).

basophile A white blood cell, stained by basic dyes, that secretes compounds that aid innate immunity.

batch culture The growth of bacteria in a closed system without inputs of nutrients.

B-cell receptor A B-cell membrane protein complex containing an antibody in association with the Igα and Igβ immunoglobulins.

B-cell tolerance The exposure of B cells to a high antigen dose, preventing future antibody production against that antigen.

bedrock The region of the Earth's crust where the soil layer ends.

benthic organism Organisms that live on the ocean floor or within the sediment.

beta barrel A cylinder of beta-sheets, found for example in a porin protein.

binary fission The process of replication in which one cell divides to form two daughter cells of equal size.

bioburden The microorganisms that normally inhabit a particular body ecosystem.

biofilm A community of microbes growing on a solid surface.

biogeochemical cycles The recycling of elements needed for life (such as carbon or nitrogen) through the biotic and abiotic components of the biosphere.

biogeochemistry The metabolic interactions of microbial communities with the abiotic (mineral) components of their ecosystems.

bioinformatics A discipline at the intersection of biology and computing that analyzes gene and protein sequence data.

biological oxygen demand (BOD) The amount of oxygen removed from an environment by aerobic respiration.

biological signature See **biosignature**.

biomass The mass found in bodies of living organisms.

bioprospecting The search for organisms with potential commercial applications.

bioremediation The use of microbes to detoxify environmental contaminants.

biosignature (biological signature) A chemical indicator of life.

biosphere The area containing the sum total of all life on Earth.

biosynthesis See **anabolism**. The building up of complex biomolecules from smaller precursors.

biotic Referring to processes caused by living organisms.

black smoker An oceanic thermal vent containing high concentrations of minerals such as iron sulfide.

borreliosis A tick-borne disease caused by *Borrelia burgdorferi*, which may involve skin lesions and arthritis; also known as Lyme disease.

botulism A food-borne disease caused by a *Clostridium botulinum* toxin, involving muscle paralysis.

bradykinin A cell signaling molecule that promotes extravasation, activates mast cells, and stimulates pain perception.

bright-field microscopy A type of light microscopy in which the specimen absorbs light and appears dark against a light background.

bubonic plague A disease caused by the bacterium *Yersinia pestis*; characterized by swollen lymph nodes that often turn black.

budding A form of reproduction in which mitosis of the mother cell generates daughter cells of unequal size.

burst size The number of virus particles released from a lysed host cell.

calorimetry A technique to measure the amount of heat released or absorbed during a reaction.

Calvin cycle (Calvin-Benson cycle, Calvin-Benson-Bassham cycle, CBB cycle) The metabolic pathway of carbon fixation in which the CO_2 condensing step is catalyzed by rubisco. Found in chloroplasts and in many bacteria.

candidate species A newly described microbial isolate that may become accepted as an official species.

capsid A protein shell that surrounds a virion's nucleic acid.

capsule A slippery outer layer composed of polysaccharides that surrounds the cell envelope of some bacteria.

carbon dioxide fixation The enzymatic covalent incorporation of inorganic carbon dioxide (CO_2) into an organic compound.

carbon monoxide reductase pathway The carbon fixation process in methanogenic archaea, so called because the key enzyme can fix CO as well as CO_2.

carbon sink An ecosystem that removes carbon dioxide from the atmosphere, for example by fixation into biomass or by dissolving into marine water.

carboxysome A protein-bounded compartment containing rubisco to fix CO_2 .

cardiolipin (diphosphatidylglycerol) A double phospholipid linked by glycerol.

carotenoids Accessory photosynthetic pigments that absorb photons in the green end of the spectrum.

catabolism The cellular breakdown of large molecules into smaller molecules, releasing energy.

catabolite repression The inhibition of transcription of an operon encoding catabolic proteins in the presence of a more favorable catabolite, such as glucose.

catalytic RNA An RNA capable of enzymatic reactions. Also known as a ribozyme.

catenane Linked rings of DNA found immediately after replication of circular chromosomes.

cathelicidin An antimicrobial peptide that is synthesized as an inactive precursor and activated extracellularly.

cation A positively charged ion.

cell membrane (plasma membrane, cytoplasmic membrane) The phospholipid bilayer that encloses the cytoplasm.

cell surface receptor A transmembrane protein that senses a specific extracellular signal and may be the docking site for a specific virus.

cell wall A rigid structure external to the cell membrane. The molecular composition depends on organism; composed of peptidoglycan in bacteria.

cell-mediated immunity A type of adaptive immunity, employing mainly T cell lymphocytes.

cellular slime mold A slime mold in which the individual cells retain their own cell membranes.

cellulolytic bacteria Bacteria that catabolyze cellulose; found in the rumen of cattle fed a high cellulose diet.

Cercozoa A taxonomic group of shelled amebas that have thin, filamentous pseudopods.

chain of infection The serial passage of a pathogenic organism from an infected individual to an uninfected individual, thus transmitting disease.

chancre A painless, hard lesion due to an inflammatory reaction at the site of infection with *Treponema pallidum*, the causative agent of syphilis.

chaperone A protein that helps other proteins fold into their correct tertiary structure.

cheddared curd Curd that has been cut and piled in order to remove the liquid whey.

cheese A solid or semi-solid food product prepared by coagulating milk proteins. Its production commonly involves microbial fermentation.

chemoautotroph An organism that oxidizes inorganic compounds to yield energy and reduce carbon dioxide.

chemoautotrophy The oxidation of inorganic compounds to yield energy used to reduce carbon dioxide.

chemoheterotroph An organism that oxidizes organic compounds to yield energy.

chemoheterotrophy The oxidation of organic compounds to yield energy without the use of light.

chemokine An attractant for white blood cells that is produced by damaged tissues.

chemokine receptor (CCR) A human T-cell membrane protein that binds chemokine hormones, but is also used by HIV for attachment and infection.

chemolithotroph (lithotroph, chemoautotroph) See **chemoautotroph**.

chemostat A continuous culture system in which the introduced media contains a limiting nutrient.

chemotaxis The ability of organisms to move towards or away from specific chemicals.

chemotrophy Metabolism that yields energy from oxidation-reduction reactions without using light energy.

Chlamydia A phylum of intracellular parasitic bacteria that lose most of their cell envelope during intracellular growth and generate multiple spore-like structures that escape to infect the next host.

Chlorobi A phylum of gram-negative bacteria. They are obligate anaerobes, "green sulfur" phototrophs that photolyze sulfides or H_2.

chlorophyll A magnesium-containing pigment that captures light energy at the start of photosynthesis.

chloroplast An organelle of endosymbiotic origin that conducts oxygenic photosynthesis; found in algae and plant cells.

chlorosome A membranous photosynthetic organelle found in bacterial groups such as *Chloroflexus*.

choanoflagellate A microbial opisthokont closely related to animals and fungi.

cholesterol A sterol lipid found in eukaryotic cell membranes.

chromatin Chromosomal DNA complexed with proteins. Usually refers to a eukaryotic chromosome.

chromophore A light-absorbing redox cofactor.

chrysophyte A clade of flagellated heterokont protists possessing chloroplasts as secondary endosymbionts; also known as "golden algae."

Chydridomycota (chytridiomycete) A taxonomic group of fungi that produce flagellated zoospores. Includes ruminal endosymbionts and parasites of amphibians.

ciliate An Alveolate that has paired cilia.

cistron A functional unit of RNA, containing the information from a single gene.

clade See **monophyletic**.

class switching See **isotype switching**.

classical complement pathway An antibody-mediated pathway for complement activation.

classification The recognition of different forms of life and their placement into different categories.

clonal A population of genetically identical cells, all descendants of a single cell.

clonal selection The rapid proliferation of a subset of B cells during the primary or secondary antibody responses.

cloning vector A small genome that can carry specific genes for cloning.

cloning The insertion of DNA into a plasmid where it can be replicated.

CO_2-concentrating mechanism (CCM) The inducible expression and insertion of CO_2 and bicarbonate (HCO_3^-) transporters into carboxysomes to enhance CO_2 levels near rubisco.

coastal shelf Shallow regions of the ocean less than 200 meters deep.

coccus *pl.* **cocci** A spherically shaped microbial cell.

codon A set of three nucleotides that encodes a particular amino acid.

coenzyme A (CoA) A non-protein cellular organic molecule that can carry acetyl groups and participates in metabolism.

coevolution The evolution of two species in response to one another.

cofactor A metallic ion or a coenzyme required by an enzyme to perform normal catalysis.

cointegrate A DNA molecule formed by a single site recombination event joining two participating circular DNA molecules.

colony A visible cluster of microbes on a plate, all derived from a single founding microbe.

commensal organism An organism that benefits from, but neither helps nor harms the host. In medical usage, some commensals benefit the host. Commensal organisms are normally found at various nonsterile host body sites.

commensalism An interaction between two different species that only benefits one partner.

compatible solute A small non-toxic molecule that can accumulate in a cell to prevent cell water loss in hypertonic environments.

competence factor A species-specific secreted bacterial protein that induces competence for transformation.

competent A cell that is able to take up DNA from the environment.

complement Innate immunity proteins in the blood that form holes in bacterial membranes, killing the bacteria.

complementary DNA (cDNA) A DNA synthesized complementary to an RNA template via reverse transcriptase.

complex medium A nutrient-rich growth solution including undefined chemical components such as beef broth.

complex transposon A transposon containing a gene for the transposase enzyme which is needed for replicative transposition.

composite transposon A transposon containing genes in addition to those of transposition, such as antibiotic resistance or catabolic functions.

compound microscope A microscope with multiple lenses to compensate for lens aberration and increase magnification.

compromised host An animal with a weakened immune system.

condensation A chemical reaction that joins two molecules and produces a water molecule.

condenser A lens that focuses parallel light rays from the light source onto a small area of the specimen to improve the resolution of the objective lens.

conditional lethal mutation A mutation that leads to death under one growth condition but permits growth under a second condition.

confluent A lawn of organisms that have completely covered a surface.

congenital syphilis Syphilis contracted in utero.

conjugation Horizontal gene transmission involving cell-cell contact. In bacteria, pili draw together the donor and recipient cell envelopes, and a protein complex transmits DNA across. In ciliated eukaryotes, a conjugation bridge forms between two cells connecting their cytoplasm, through which micronuclei are exchanged.

conjugative transposon A transposon that can be transfered from one cell to another via conjugation.

consensus sequence A sequence of nucleotides or amino acids with a common function at many nucleic acid or protein positions. Consists of the base pair or amino acid most frequently found at each position in the sequence.

constant region The region of an antibody that defines the class of a heavy chain or a light chain.

consumers Organisms that acquire nutrients from producers, either directly or indirectly.

contig Overlapping fragments of cloned DNA that are contiguous along a chromosome.

continuous culture A culture system in which new medium is continually added to replace old medium.

contractile vacuole An organelle in eukaryotic microbes that pumps water out of the cell.

contrast Differential absorption or reflection of electromagnetic radiation between an object and background that allows the object to be distinguished from the background.

coral bleaching The death or expulsion of coral algal symbionts. One cause is an increase in temperature.

coralline alga An algal species that calcifies its fronds into hardened shapes similar to corals.

core particle A viral capsid enclosing its nucleic acid genome.

core polysaccharide A sugar chain that attaches to the glucosamine of lipopolysaccharides and extends outside the cell.

coreceptor A cell surface receptor needed for viral entry along with a primary receptor.

corepressor A small molecule that must bind to a repressor to allow the repressor to bind operator DNA.

cortical alveolus One of the vesicles that forms a network in the outer covering of an alveolate.

cotransduced Genes that are transferred together to a recipient cell during transduction.

Coulter counter A device to count cells based on increasing electrical resistance as cells pass through a small hole.

counterstain A secondary stain used to visualize cells that do not retain the first stain.

coupled transport The movement of a substance against its electrochemical gradient (from lower to higher concentration, or from opposite charge to like charge) using the energy provided by the simultaneous movement of a different chemical down its electrochemical gradient.

C-reactive protein A peptide that stimulates the complement cascade, induced by cytokines in the liver. Elevated levels in the blood may be associated with heart disease.

Crenarchaeota One of the two major divisions of Archaea, containing sulfur thermophiles and marine mesophiles.

cross-bridge An attachment that links parallel molecules such as the peptide link between glycan chains in peptidoglycan.

cryocrystallography X-ray crystallography on crystals that are flash-cooled in liquid nitrogen.

cryoelectron microscopy (cryo-EM) Electron microscopy in which the sample is cooled rapidly in a cryoprotectant medium that prevents freezing. The sample does not need to be stained.

cryptogamic crust A low-growing ground cover consisting of an algal-fungal symbiont, similar to lichens.

curd Coagulated milk proteins produced by the combined action of lactic acid-producing bacteria and stomach enzymes of certain mammals such as cattle.

Cyanobacteria A phylum of photoautotrophic bacteria containing chlorophylls a and b. They are closely related to chloroplasts.

cyclic photophosphorylation A photosynthetic process in which chlorophyll serves as both the initial electron donor and the final electron acceptor. ATP is produced via the proton potential from an electron transport system, but no NADPH is generated.

cycloserine A polypeptide antibiotic that inhibits peptidoglycan synthesis.

cystic fibrosis transmembrane conductance regulator (CFTR) A chloride channel found in respiratory epithelia. Mutations in the CFTR gene lead to cystic fibrosis.

cytochrome A membrane protein that donates and receives electrons.

cytokine A small, secreted host protein that binds to receptors on various endothelial and immune system cells, regulating the cells responses.

cytoplasm (cytosol) The aqueous solution contained by the cell membrane in all cells and outside the nucleus (in eukaryotes).

cytoskeleton A collection of filamentous proteins that impart structure to and aid movement of cells; in a eukaryote, these include intermediate filaments, microtubules and microfilaments.

cytotoxic T cell (T_C cell) T cells that express CD 8 on their cell surface and can secrete toxic proteins such as perforin and granzymes.

dark-field microscopy The detection of microbes too small to be resolved by light rays by observing the light they scatter.

dead zone An anoxic region of an ocean, devoid of most fish and invertebrates.

death phase The period of cell culture following stationary phase, in which cells die faster than they replicate.

death rate The rate at which cells die; exponential during the death phase.

decay-accelerating factor A host cell membrane protein that stimulates decay of complement factors and prevents their deposition at the cell surface.

decimal reduction time (D-value) The length of time it takes for a treatment to kill 90% of a microbial population, and hence a measure of the efficacy of the treatment.

decolorizer A chemical that removes loosely bound stain from a specimen.

decomposer Organism that consumes dead biomass.

defensins Small, positively charged peptides, produced by animal tissues, that destroy the cell membranes of invading microbes.

defined minimal medium A solution of known compounds for organismal growth that contains only the minimal components required for growth.

degradosome complex A multi-enzyme complex that degrades RNA.

degranulate The release of antimicrobial granule contents by the fusion of granule membranes to cytoplasmic or vacuolar membranes.

degron A degradation signal contained within a protein.

dehalorespiration The reduction of halogenated organic molecules by H_2.

deletion The loss of nucleotides from a DNA sequence.

denature The loss of secondary and tertiary structure in a protein or nucleic acid due to high temperature or chemical treatment.

dendritic cell An antigen-presenting white blood cell that primarily takes up small soluble antigens from its surroundings.

denitrification Energy-yielding metabolism that involves the reduction of nitrate (NO_3^-) to nitrite (NO_2^-), diatomic nitrogen, N_2, and in some cases ammonia (NH_3).

denitrifying bacterium A heterotrophic bacterium that uses nitrate (NO_3^-) as the final electron acceptor in an electron transport chain and produces nitrogen gas, N_2, or ammonia.

depth of field A region of the optical column over which a specimen appears in reasonable focus.

derepression An increase in gene expression caused by the decrease in concentration of a corepressor.

desensitization A clinical treatment to reduce allergic reactions by exposing patients to small doses of the allergen.

detection The ability to determine the presence of an object.

detritus Discarded biomass that can be consumed by decomposers.

diaphragm A device in a microscope to vary the diameter of the light column, changing the amount of light admitted.

diatom A taxonomic group of protists (Bacillariophyta) known for intricate, silica-containing bipartite shells.

diauxic growth A biphasic cell growth curve caused by the depletion of the favored carbon source and a metabolic switch to the second carbon source.

dichotomous key A tool for identifying organisms, in which a series of yes/no decisions successively narrows down the possible categories of species.

differential medium A growth medium that can distinguish between various bacteria based on metabolic differences.

differential stain A stain that differentiates among objects by staining only particular types of cells or specific sub-cellular structures.

diffusion The energy independent net movement of a substance from a region of high concentration to a region of lower concentration.

dilution streaking A method of spreading of bacteria on a plate in order to obtain colonies arising from an individual bacterium.

Dinoflagellata (dinoflagellate) A taxonomic group of tertiary endosymbiont alveolates with two flagella, one of which is wrapped distinctively around the cell equator.

dioxygenase An enzyme that coordinately oxygenates two adjacent ring carbons.

diphosphatidylglycerol See **cardiolipin**.

diplococcus The paired cocci of *Neisseria* species.

direct repeat Two identical sequences in a DNA molecule, aligned in the same direction.

Discicristata (discicristate) A protist taxonomic group whose members have mitochondria with distinctive disc-shaped cristae.

disinfection The removal of pathogenic organisms from inanimate surfaces.

dissemination The movement of virions from the initial site of infection to other regions of the body.

dissimilation An organism's catabolism or oxidation of nutrients to inorganic minerals that are released into the environment.

dissimilatory denitrification Metabolic reduction of nitrate or nitrite to yield energy; anaerobic respiration of nitrate or nitrite.

dissimilatory metal reduction A type of anaerobic respiration that uses metal cations as terminal electron acceptors.

dissimilatory nitrate reduction The reduction of nitrate and nitrite through a series of decreased oxidation states back to atmospheric nitrogen and/or ammonia.

dissimilatory nitrate reduction to ammonia (DNRA) A metabolic pathway in which nitrate serves as an electron acceptor and hydrogen gas (H_2) as the electron donor forming water and ammonia.

D-loop formation A triplex DNA molecule that forms as an intermediary structure during generalized recombination.

DNA control sequence A region of DNA, such as the promoter region, that controls the expression of structural genes but is not itself transcribed to RNA.

DNA ligase An enzyme cells use to create a covalent bond at a nick in the phosphodiester backbone. Also used in molecular biology laboratories to join pieces of DNA.

DNA microarray (or microchip) A microchip containing short DNA sequences corresponding to all the open reading frames in an organism affixed to specific locations. It can be used to measure the amount of specific mRNA molecules transcribed in cells.

DNA probe A labeled DNA sequence that hybridizes only to a particular complementary DNA sequence.

DNA reverse-transcribing virus A virus with a double-stranded DNA genome that generates an RNA intermediate and thus requires reverse transcriptase to generate progeny DNA genomes.

DNA sequencing A technique to determine the order of bases in a DNA sample.

DNA shuffling A technique in which fragments of similar genes are combined to generate new genes with potentially new or improved functions.

domain 1. One of the three major taxonomic groups of living organisms. 2. A region of a protein with a particular structure and function.

dormant cell A vegetative cell that has entered a physiological state where it remains metabolically active but fails to replicate or form colonies. Also called the viable-but-nonculturable state, it is distinct from spore forms such as endospores.

doubling time The generation time of bacteria in culture. The amount of time it takes for the population to double.

downstream processing The recovery and purification of the commercial product produced by industrial microbes.

dry weight The weight of a population of cells after the water has been removed.

early gene A viral gene expressed early in the infectious cycle.

eclipse period The time after viral genome injection into host cell but before complete virions are formed.

ecosystems Communities of species plus their environment (habitat).

ectomycorrhizae Mycorrhizae that colonize the surface of plant roots. Their mycelia do not penetrate the root cells.

ectoparasite A harmful organism that colonizes the surface of a host.

edema Tissue swelling due to fluid accumulation.

edema factor (EF) A component of anthrax toxin with adenylate cyclase activity.

electrochemical potential A type of potential energy formed by the combined concentration gradient of a molecule and the electrical potential across a membrane.

electrogenic A transport system that results in a net movement of charged molecules across a membrane.

electron acceptor An oxidized molecule (e.g., NAD^+) that can accept electrons.

electron donor A reduced molecule (e.g., NADH) that can donate electrons.

electron microscope A microscope that obtains high resolution and magnification by focusing electron beams on samples using magnetic lenses.

electron transport chain See **electron transport system**.

electron transport system (ETS) (electron transport chain) A collection of membrane proteins that converts the energy of redox reactions into a proton potential.

electronegativity The affinity of an atom for electrons. The greater the electronegativity, the stronger the attraction for electrons.

electroneutral A transport system that does not result in any net change in charge across the membrane.

electrophoresis A technique to separate charged proteins and nucleic acids based on how rapidly they migrate in an electric field through a gel.

electrophoretic mobility shift assay (EMSA) A technique to observe DNA-protein interactions based on the ability of a bound protein to slow the voltage-driven migration of DNA through a gel.

electroporation A laboratory technique that temporarily makes the cell membrane more leaky to allow the uptake of DNA.

elementary body The endospore-like form of Chlamydia transmitted outside host cells.

eluviated horizon The soil layer below the aerated horizon that periodically experiences water saturation from rain.

Embden-Myerhof-Parnas (EMP) pathway A glycolytic pathway in which glucose-6-phosphate isomerizes to fructose-6-phosphate, ultimately yielding 2 pyruvate, 2 ATP, and 2 NADH.

emission wavelength The wavelength of light emitted by a fluorescent molecule. It is of a lower energy and longer wavelength than the excitation wavelength.

empty magnification Magnification without an increase in resolution.

endemic A disease that is always present in a population, although the frequency of infection may be low.

endemic area The geographical region where an pathogenic organism or virus is found, usually colonizing or infecting animals indigenous to the area.

endergonic A reaction that requires an input of energy to proceed.

endocarditis An inflammation of the heart's inner lining.

endocytosis The budding in of the cell membrane to form a vesicle that contains extracellular material.

endogenous retrovirus A retroelement that contains *gag*, *env*, and *pol* genes.

endoliths Bacteria that grow within the crystals of solid rock.

endomycorrhizae Mycorrhizae in which fungal hyphae penetrate plant root cells.

endoparasite A parasite that lives inside the host.

endophyte An endosymbiont of vascular plants.

endosome A vesicle formed from the pinching in of the cell membrane.

endospore A durable, inert, heat-resistant spore that can remain viable for thousands of years.

endosymbiont An organism that lives as a symbiont inside another organism.

endosymbiosis An intimate association between different species in which one partner population grows within the body of another organism.

endosymbiosis theory The theory that mitochondria and chloroplasts were originally free-living prokaryotes that formed an internal symbiosis with early eukaryotes.

endotoxin Lipopolysaccharides in the outer membrane of gram negative bacteria that become toxic to the host after the bacterial cell has lysed.

energy The ability to do work.

energy carrier Molecules in the cell, such as ATP and NADH, that serve as energy currency. They are produced during catabolic reactions, and can be used to drive energy-requiring reactions.

enhancer A non-coding DNA region in eukaryotes that can lead to activation of transcription when bound by the appropriate transcription factor. Its location on the chromosome can be far removed from the regulated gene.

enriched medium A growth solution for fastidious bacteria, consisting of complex media plus additional components.

enrichment culture The use of selective growth media to allow only certain microbes to grow.

enterotoxins Proteins that damage the intestine of the host and cause diarrhea, produced by some gram-negative pathogens.

enthalpy A measure of the heat energy in a system.

Entner-Doudoroff (ED) pathway A glycolytic pathway in which glucose-6-phosphate is initially oxidized to 6-phospho-gluconate, and ultimately yields 1 pyruvate, 1 ATP, 1 NADH and 1 NADPH.

entropy A measure of the disorder in a system.

envelope Structures external to the cell membrane such as a cell wall or outer membrane.

enzyme A biological catalyst; a protein or RNA that can speed up the progress of a reaction without itself being changed.

eosinophil A white blood cell that stains with the acidic dye eosin, and secretes compounds that facilitate innate immunity.

epidemic A disease outbreak in which large numbers of individuals in a population become infected over a short time.

epidermis The outer protective cell layer in most multicellular animals.

epilimnion Warm upper layer of a freshwater lake, above the thermocline, a region where temperature drops steeply.

episome A DNA element that can exist as part of the chromosome or independently, as a plasmid.

epitope See **antigenic determinant**.

equilibrium A dynamic state in which there is no net change in a reaction.

equilibrium density gradient centrifugation A technique to separate cell components based on their differential densities. During centrifugation, cell fractions migrate to locations in the centrifuge tube that match their density.

equivalence The antigen:antibody ratio that leads to immunoprecipitation of large, insoluble complexes.

error-prone repair Low accuracy DNA repair mechanisms that allow mutations.

error-proof repair DNA repair mechanisms that minimize the formation of mutations.

erythema migrans A bulls' eye rash characteristic of borreliosis (Lyme disease).

essential nutrient A compound that an organism cannot synthesize and must acquire from the environment in order to survive.

ethanolic fermentation A fermentation reaction yielding 2 ethanol and 2 CO_2 as products.

ether link A covalent attachment of two organic molecule through an oxygen, C—O—C. Found in archaeal phospholipids between the glycerol and the fatty acids.

Eukarya One of the three domains of life, consisting of organisms with a last common ancestor not shared with members of *Archaea* or *Bacteria*. Cells possess nuclei, unlike cells of bacteria and archaea.

eukaryote *pl.* **eukaryotes** A cell that contains a nucleus and is a member of the domain *Eukarya*.

Eumycota True fungi, a taxonomic group of opisthokont eukaryotes with chitinous cell walls; the group most closely related to animals.

euphotic (photic) zone The region of the ocean that receives light capable of supporting photosynthesis. Also known as the photic region.

Euryarchaeota One of the two major divisions of Archaea, containing methanogens, halophiles, and extreme acidophiles.

eutrophic lake A lake in which overgrowth of heterotrophic microbes has eliminated oxygen, leading to a decrease in animal life.

eutrophication A sudden increase of a formerly limiting nutrient in an aquatic environment, leading to overgrowth of algae and grazing bacteria and subsequent oxygen depletion.

Excavata A protist group that shows extensive evolutionary reduction and lacks mitochondria.

excitation wavelength The wavelength of light that must be absorbed by a molecule in order for the molecule to fluoresce.

exergonic A spontaneous reaction that releases free energy.

exit site (E site) The region of the ribosome that holds the uncharged, exiting tRNA.

exocytosis Fusion of vesicles with the cell membrane to release vesicle contents extracellularly.

exon An expressed or protein-coding portion of a eukaryotic gene.

exonuclease An enzyme that cleaves DNA from the end.

exopolysaccharide (EPS) A thick extracellular matrix of polysaccharides and entrapped materials that forms around the microbes in a biofilm.

exotoxin Protein toxin, secreted by bacteria, that kills or damages host cells.

exponential A mathematical function that is raised to a power. It gives a curve whose slope continually increases.

exponential phase A phase in bacterial cell culture when bacteria are growing at their maximal possible rate given the conditions, usually exponentially. Same as log phase.

extravasation The movement of immune cells out of blood vessels and into surrounding infected tissue.

extremophile An organism that only grows in an extreme environment; that is, an environment including one or more conditions that are "extreme" relative to the conditions for human life.

F^- cell The DNA recipient cell in conjugation

$F(ab)_2$ region The amino-terminus variable "arms" of an antibody that bind to a specific antigen.

F^+ cell The DNA donor cell that transmits the fertility factor F^+ to an F^- cell during conjugation.

factor H A normal serum protein that prevents the inadvertent activation of complement in the absence of infection.

facultative An organism that can grow in the presence or absence of a given environmental factor, such as oxygen.

facultative aerobe (facultative anaerobe) An organism that can grow either in the presence or absence of oxygen.

facultative anaerobe See **facultative aerobe**.

facultative intracellular pathogen A pathogen that can live either inside host cells or outside host cells.

fatty acid synthase complex A collection of all the enzymes and binding proteins necessary for fatty acid synthesis.

Fc region The region of an antibody that binds to specific receptors on host cells in an antigen-independent manner. It is found in the carboxy-terminal "tail" region of the antibody.

feline leukemia virus (FeLV) A retrovirus that is a major cat pathogen.

femtoplankton Marine or aquatic viruses.

fermentation The production of ATP via substrate level phosphorylation, using organic compounds as both electron donors and electron acceptors.

fermentative metabolism See **fermentation**.

fermented food Food products that are biochemically modified by microbial growth.

ferredoxin An iron- and sulfur-containing protein that transfers electrons in electron transport systems.

fertility factor (F factor) A specific plasmid (transferred by an F^+ donor cell) that contains the genes needed for pilus formation and DNA export.

field The background observed in microscopy as opposed to the specimen of interest.

filamentous virus A viral structure type consisting of a helical capsid surrounding a single stranded nucleic acid.

filopodium A needle-shaped pseudopod.

fimbria *pl.* **fimbriae** See **pilus**.

Firmicutes A phylum of low GC content gram-positive bacteria.

fixation The adherence of cells to a slide by a chemical or heat treatment.

flagellate An alveolate that has paired flagella.

flagellum *pl.* **flagella** A filamentous structure for motility. In prokaryotes, a helical protein filament attached to a rotary motor; in eukaryotes, an undulating cell membrane-enclosed complex of microtubules and ATP driven motor proteins.

flavin adenine dinucleotide ($FADH_2$, FAD^+) An energy carrier in the cell that can donate ($FADH_2$) or accept (FAD^+) electrons.

flavonoids Signaling molecules released from legumes to attract nitrogen-fixing rhizobia.

flocs Biofilms formed on microbial filaments and the soluble organic content of wastewater.

fluid mosaic model A model of the cell membrane in which proteins are free to diffuse laterally within the membrane.

fluorescence The emission of light from a molecule that absorbed light of a shorter, higher energy wavelength.

fluorescence resonance energy transfer (FRET) The detectable transfer of fluorescent energy from one molecule to another. Since the participating molecules must be near each other, FRET can be used to monitor protein-protein interactions in cells and is also used in real time PCR.

fluorescence-activated cell sorter (FACS) A device that can count cells and sort them based on differences in fluorescence.

fluorescent-focus assay An assay to detect viruses that do not kill host cells, based on intracellular detection of viruses using anti-viral antibodies or green fluorescent protein modified viruses.

fluorophore A fluorescent molecule used to stain specimens for fluorescent microscopy.

focal plane A plane that contains the focal point for a given lens.

focal point The position at which light rays that pass through a lens intersect.

focus A group of cells infected by a virus.

folate (folic acid) A heteroaromatic cofactor, that is required by some enzymes.

fomite An inanimate object on which pathogens can be transmitted from one host to another.

food contamination See **food poisoning**.

food irradiation The exposure of food to ionizing radiation, sterilizing the food for long-term storage.

food poisoning The presence of human disease-causing microbial pathogens or toxins in food.

food spoilage Microbial changes that render a food unfit or unpalatable for consumption.

food web A network of interactions in which organisms obtain or provide nutrients for each other, for example by predation or by mutualism.

foraminiferan An ameba with a calcium carbonate shell and a helical arrangement of chambers.

forespore In sporulation of gram-positive bacteria, the smaller cell compartment formed through asymmetrical cell division; it develops into the endospore.

fossil fuels Ancient organismal remains that have been converted to hydrocarbons through microbial digestion followed by reduction under high pressure underground; extracted and burned by humans for energy.

F-prime (F′) factor or F′ plasmid A fertility factor plasmid that contains some chromosomal DNA.

frameshift mutation A gene mutation involving the insertion or deletion of nucleotides that cause a shift in the codon reading frame.

frank pathogen See **primary pathogen**.

freeze-drying The removal of water from food, by freezing under vacuum, to limit microbial growth.

fruiting body A multicellular fungal or bacterial reproductive structure.

frustule The silica bipartite shell produced by diatoms.

functional group A cluster of covalently bound atoms that behaves with specific properties and functions as a unit.

fungus *pl.* **fungi** A heterotrophic opisthokont eukaryote with chitinous cell walls. Mainly includes Eumycota, but traditionally may refer to fungus-like protists such as the oomycetes.

fusion peptide A portion of a viral envelope protein that changes shape to facilitate envelope fusion with the host cell membrane.

gain-of-function mutation A mutation that enhances the activity or allows new activity of a gene product. Contrast with **loss-of-function mutation**.

gamogony The differentiation of parasitic haploid cells into male and female gametes.

gas chromatography A technique to separate and quantify gasses in a sample.

gas vesicle An organelle that traps gasses to increase buoyancy of aquatic microbes.

GC content The proportion of an organism's genome consisting of guanine-cytosine base pairs.

gene fusion A technique to measure control of gene transcription or translation by inserting a reporter gene into a target gene. The reporter relies on both the promoter and the ribosome binding site of the target gene. Also known as reporter fusion.

gene silencing The inhibition of transcription from an mRNA by a complementary small interfering RNA. Also known as RNA interference or RNAi.

gene splicing The cutting and pasting of DNA to produce new gene variants.

generalized recombination Recombination between two DNA molecules that share long regions of DNA homology.

generalized transduction A phage-mediated gene transfer process in which any donor gene can be transferred to a recipient cell.

generation time The species-specific time period for doubling of a population (for example, by bacterial cell division) in an given environment, assuming no depletion of resources.

genetic analysis Determination of the function of cell RNAs and proteins based on the phenotype of cells in which the gene encoding the RNA or protein is mutated.

genome The complete genetic content of an organism. The sequence of all the nucleotides in a haploid set of chromosomes.

genomic island A region of DNA sequence whose properties indicate that it has been transferred from another genome. Usually comprises a set of genes with shared function, such as pathogenicity or symbiosis support.

genus name A taxonomic rank consisting of closely related species.

geochemical cycling The global interconversion of various inorganic and organic forms of elements.

geomicrobiology See **biogeochemistry**.

geosmin A molecule released from decaying *Streptomyces* cells; it causes the characteristic odor of soil and can affect the taste of drinking water.

germ theory of disease The theory that many diseases are caused by microbes.

germicidal A substance that kills cells but not spores.

germination The activation of a dormant spore to generate a vegetative cell.

Gibbs free energy change (ΔG) In a chemical reaction, a measure of how much energy available to do work is released or required as the reaction proceeds.

gliding motility The movement of cells individually or as a collective over surfaces using pili.

global warming The overall rise in temperature of our biosphere over the past hundred years.

glucosamine A glucose modified with an amine group.

glutamate dehydrogenase (GDH) An enzyme that condenses NH_4^+ with 2-oxoglutarate to form glutamate. The condensation requires reduction by NADPH.

glutamate synthase (GOGAT) An enzyme that converts 2-oxoglutarate plus glutamine into two molecules of glutamate.

glutamine synthetase (GS) An enzyme that condenses NH_4^+ with glutamate to form glutamine.

glycan See **polysaccharide**.

glycolysis The catabolic pathway of glucose oxidation to pyruvate, generating ATP and NADH.

glyoxalate bypass An alternative to the tricarboxylic acid cycle, induced under low glucose conditions.

gnotobiotic animal An animal that is germ-free or colonized by a known set of microbes.

Golgi complex A series of membrane stacks that modifies proteins and helps sort them to the correct eukaryotic cell compartment.

Gram stain A differential stain that distinguishes between cells that possess a thick cell wall and retain a positively-charged stain (gram-positive) from cells with a thin cell wall and outer membrane that fail to retain the stain (gram-negative).

gramicidin A peptide antibiotic that disrupts membrane integrity.

gram-negative Cells that do not retain the Gram stain.

gram-negative bacteria Bacteria that fail to retain the Gram stain because they have a thin cell wall.

gram-positive Cells that do retain the Gram stain and appear dark purple after staining.

gram-positive bacteria Bacteria that retain the Gram stain by virtue of their thick cell wall reinforced by teichoic acids.

granuloma A thick lesion formed around a site of infection.

granzyme A cytotoxic T cell-secreted enzyme that damages target cells.

grazers The first level of consumers that feed directly on producers.

green alga (chlorophyte) Microbial eukaryotes containing chloroplasts; primary endosymbionts, closely related to plants (Viridiplantae).

greenhouse effect The trapping of solar radiation heat in the atmosphere by CO_2; a cause of global warming.

griseofulvin An anti-fungal antibiotic that inhibits cell division.

group translocation A form of active transport in which the transported molecule is modified after it enters the cell, thus keeping a favorable inward concentration gradient for the unmodified extracellular molecule.

growth factor A compound needed for the growth of only certain cells.

growth rate The rate of increase in population number or biomass.

gut-associated lymphoid tissue (GALT) Lymphatic tissues such as tonsils and adenoids that are found in conjunction with the gastrointestinal tract and contain immune cells.

Haber process Industrial nitrogen fixation, in which dinitrogen is hydrogenated by methane (natural gas) under extreme heat and pressure to form ammonia.

habitat The environment where a particular species grows.

Hadean eon The first period of Earth's existence, from 4.5 to 3.8 gigayears (10^9) ago.

half-life The amount of time it takes for one half of a radioactive sample to decay.

haloarchaeon An archaeal species that inhabits high salt environments.

Halobacteriales An order of Euryarchaeota that contains haloarchaea.

halophile An organism that requires a high extracellular sodium chloride concentration for optimal growth.

halorhodopsin (HR) An archaeal light-driven chloride pump.

hapten A small compound that must be conjugated to a larger carrier antigen in order to elicit production of an antibody that binds to it.

haustorium A bulbous hyphal extension of a fungal plant pathogen into the host cell.

heat-shock protein A chaperone protein that is induced by high temperature stress.

heat-shock response A coordinated response of cells to higher than normal temperatures. It includes changes in the membrane and expression of heat shock genes.

heavy chain The larger protein that comprises an antibody. An antibody contains two identical heavy chain and two light chain proteins.

helicase A protein that unwinds the DNA helix.

helper T cell (T_H cell) A T lymphocyte that secretes cytokines that modulate B-cell class switching.

heme An organic molecule containing a ring of conjugated double bonds surrounding an iron atom. It is involved in redox reactions and oxygen binding.

hepatitis An inflammation of the liver, caused by infection or by exposure to a toxic substance.

herd immunity The slowing of disease spread due to some population members being immune and thus unable to infect other members.

heteroaromatic Aromatic rings containing non-carbon atoms such as the nitrogenous bases found in nucleotides.

heterocyst A specialized nitrogen-fixing cell in filamentous cyanobacteria that maintains a reduced environment and excludes O_2.

Heterokonta (heterokont) A taxonomic group of protists whose flagellated members possess two flagella of unequal length.

heterolactic fermentation A fermentation reaction in which the products are lactic acid, ethanol and CO_2.

heterotroph An organism that relies on external sources of organic carbon compounds for biosynthesis.

Hfr A high frequency recombination bacterial strain, caused by the presence of a chromosomally integrated F factor.

high-performance liquid chromatography (HPLC) A technique for the high-resolution separation of chemical products through columns packed with beads of various physical properties.

histone A protein that helps compact eukaryotic chromosomes in nucleosomes.

holdfast Adhesion factors secreted by the tip of a stalk to firmly attach an organism to a substrate.

Holliday structure (junction) A cross-like configuration of recombining DNA molecules that forms during generalized recombination.

homologous Genes that derived from a common ancestral gene.

hopane (hopanoid) Five-ringed hydrocarbon lipids found in bacterial cell membranes.

horizontal gene transfer The passage of genes from one cell into another mature cell.

horizontal transfer See **horizontal gene transfer**.

horizontal transmission The transfer of a pathogen from one organism into another, non-progeny organism.

hormogonium A short motile chain of three to five cells produced by filamentous bacteria to disseminate their cells.

host range The species that can be infected by a given pathogen.

human immunodeficiency virus (HIV) A human-specific retrovirus that is the causative agent of AIDS.

humic material Phenolic molecules, derived from lignin, that are resistant to degradation and hence very stable in soil.

humoral immunity A type of adaptive immunity mediated by antibodies.

humus Organic breakdown products of lignin that are found in the soil.

hybridization The annealing of a nucleic acid strand with another nucleic acid strand containing a complementary sequence of bases. The binding of one nucleic acid strand with a complementary strand.

hydric soil Soil that undergoes periods of anoxic water saturation.

hydrogen bond An electrostatic attraction between a hydrogen bound to an oxygen or nitrogen and a second, nearby oxygen or nitrogen.

hydrogenosome Found in some eukaryotes, an organelle that ferments carbohydrates in a pathway generating H_2; may have evolved from mitochondria.

hydrogenotrophy The use of molecular hydrogen (H_2) as an electron donor for a variety of electron acceptors.

hydrological cycle The cyclic exchange of water between atmospheric water vapor and the Earth's bodies of liquid water.

hydrolysis The cleaving of a bond by the addition of a water molecule.

hydrophilic Soluble in water. Includes ionic and polar molecules.

hydrophobic Non-polar; insoluble in water.

3-hydroxypropionate cycle A carbon fixation pathway that condenses hydrated CO_2 and acetyl-CoA to form 3-hydroxypropionate.

hyperthermophile An organism with optimum growth at extremely high temperatures (generally considered as above 80°).

hypertonic An environment that has more solutes than another environment separated by a membrane. Water will tend to flow towards the hypertonic solution.

hypha Thread-like filaments forming the mycelium of a fungus.

hypolimnion The lower, colder region of a body of freshwater, below the epilimnion.

hypotonic An environment that has fewer solutes than another environment separated by a membrane.

hypoxia A state of lower than normal oxygen concentration.

identification The recognition of the class of a microbe isolated in pure culture.

idiotype Amino acid differences in hypervariable regions (N-terminus of heavy and light chains) within a single antibody class in an individual that allow recognition of different antigens.

IgA An antibody class containing the alpha heavy chain. It can be secreted and found in tears, saliva, breast milk, etc.

IgD An antibody isotype that contains the delta heavy chain and is found on B cell membranes.

IgE An antibody isotype that contains the epsilon heavy chain and is involved in degranulation of mast cells.

IgM The first antibody isotype detected during the early stages of an immune response. It contains the Mu heavy chain and is found as a pentamer in serum.

immersion oil An oil with a refractive index similar to glass that minimizes light ray loss at wide angles, thereby minimizing wavefront interference and maximizing resolution.

immune avoidance The changing of cell surface proteins by pathogens to prevent antibody detection and prolong infection.

immune system An organism's cellular defense system against pathogens.

immunity The resistance to a specific disease.

immunization The stimulation of an immune response by deliberate inoculation with a weakened pathogen, in hopes of providing immunity to disease caused by the pathogen.

immunogen See **antigen**.

immunogenicity A measure of the effectiveness of an antigen in eliciting an immune response.

immunoglobulin A member of a family of proteins that contain a 110-amino-acid domain with an internal disulfide bond. Members include antibodies and major histocompatibility proteins.

immunological specificity The ability of antibodies produced in response to a particular epitope to bind that epitope almost exclusively. Antibodies made to one epitope bind only weakly, if at all, to other epitopes.

immunomodulin A protein made by normal bacterial flora that influences the host immune response by modifying the secretion of host proteins, such as a cytokine.

immunoprecipitation The antibody mediated cross-linking of antigens to form large, insoluble complexes. Immunoprecipitation is used in research labs and is normally only seen in vitro.

in vivo expression technology (IVET) A laboratory technique to uncover bacterial genes that are only expressed during growth within a host.

incubation stage The time after infection when an organism multiplies but the patient remains asymptomatic.

index case Also known as patient zero, the first case of an infectious disease and an important piece of data for helping contain the spread of disease.

indigenous flora Microbes found naturally in a particular location, often in association with a food substrate.

inducer A molecule that binds to a repressor and prevents repressor binding to the operator sequence.

inducer exclusion The ability of glucose to cause metabolic changes that prevent the cellular uptake of less favorable carbon sources that could cause unnecessary induction.

induction Increased transcription of target genes due to an inducer binding to a repressor and preventing repressor-operator binding.

industrial fermenter The equipment used to grow microbes on an industrial scale.

industrial microbiology The commercial exploitation of microbes.

industrial strain A microbial strain whose characteristics are optimized for industrial use.

infection The growth of a pathogen or parasite in or on a host.

infection cycle The route a pathogen takes as it passes from one host into another.

infection thread A column of rhizobial cells that projects down a tube into a plant root cell during the early stages of the rhizobia-legume symbiosis.

infectious dose (ID_{50}) The number of microbes required to cause disease symptoms in half of an experimental group of hosts.

informational gene A DNA sequence that encodes a product essential for transcription or translation.

infrared chemical analysis A technique based on infrared spectrometry that can identify small molecules in a sample; it can be used to measure levels of gasses in the upper atmosphere.

initiation factors Proteins required for initiation of protein synthesis in bacteria.

injera A highly fermented Ethiopian flat bread using the grain teff.

innate immunity See **non-adaptive immunity**.

inner leaflet The layer of the cell membrane phospholipid bilayer that faces the cytoplasm.

inner membrane In gram-negative bacteria, the membrane in contact with the cytoplasm, equivalent to the cell membrane.

insertion The addition of nucleotides into the middle of a DNA sequence.

insertion sequence (IS) A simple transposable element that consists of a transposase gene flanked by short, inverted repeat sequences that are the target of transposase.

integrase An enzyme that catalyzes the integration, via a double cross-over, of one DNA molecule into another at a specific sequence.

integron A large transposon that can contain many different antibiotic resistance genes.

interference The interaction of two wave fronts. Interference can be additive (amplitudes in phase, constructive) or subtractive (amplitudes out of phase, destructive).

interference microscopy Observation of an object using contrast enhanced by superimposing interference bands upon an image to accentuate small differences in refractive indexes.

interferon A host-secreted immuno-modulatory protein that inhibits viral replication.

interleukin 1 (IL-1) A cytokine release by macrophages.

intermediate filament A eukaryotic cytoskeletal protein that is composed of various proteins depending on the cell type.

intimin A pathogenic *E. coli* adhesion protein that binds tightly to an *E. coli*-produced receptor injected into host cells.

intracellular parasite A parasite that lives within a host cell.

intron In eukaryotic genes, an intervening sequence that does not code for protein and is spliced out of the mRNA prior to translation.

inversion A flipping of a DNA fragment within a chromosome. Inversion may allow or repress the transcription of a particular gene.

inverted repeat A DNA sequence that is found in an identical but inverted form at two sites on the same double helix (e.g., 5′ ATCGATCGnnnnnnCGATCGAT 3′).

ionophore A small organic molecule that binds to an ion and solubilizes it in the membrane, allowing the ion to move down its electrochemical gradient.

irradiation The exposure of a substance to high-energy electromagnetic radiation, usually for the purpose of sterilization.

isoelectric focusing A technique that separates proteins based on their charge.

isoelectric point The pH at which there is no net charge on an amino acid or a protein.

isolate A microbe that has been obtained from a specific location and grown in pure culture.

isoprenoid Condensed isoprene chains, found in archaeal membrane lipids.

isotonic A state in which two solutions separated by a semipermeable membrane are in osmotic balance. A cell in an isotonic environment will neither gain nor lose water.

isotope An atom of an element with a specific number of neutrons. For example carbon-12, carbon-13, and carbon-14 are all isotopes of carbon.

isotope ratio The ratio of amounts of two different isotopes of an element. The isotope ratio may serve as a biosignature if the ratio between certain isotopes of a given element is altered by biological activity.

isotype A species-specific antibody class, defined by the structure of the heavy chain. IgG, IgA, and IgE are examples of isotypes.

isotype switching (class switching) A change in the predominant antibody isotype produced by a cell.

joules (J) The standard SI unit for energy.

Kaposi's sarcoma A malignancy originating in endothelial or lymphatic cells that is often found in late stage AIDS patients.

kelp A heterokont protist, also known as "brown algae," that grows as multicellular sheets at the water's surface.

kimchi A popular Korean food based on brine-fermented cabbage.

Kirby-Bauer test Method for determining antibiotic susceptibility. Antibiotic-impregnated disks are placed on an agar plate whose surface has been confluently inoculated with a test organism. The antibiotic diffuses away from the disk and inhibits growth of susceptible bacteria. The width of the inhibitory zone is proportional to the susceptibility of the organism.

knockout mutation A mutation that completely eliminates the activity of the gene product.

Koch's postulates Four criteria that should be met for a microbe to be designated the causative agent of an infectious disease.

Korarchaeota A deeply branching division of Archaea.

labile toxin (LT) An *E. coli* enterotoxin, destroyed by heat, that increases cellular cAMP concentrations.

lactate fermentation A fermentation reaction that generates lactic acid from reduction of pyruvic acid.

lactic acid fermentation See **lactate fermentation**.

lag phase A phase of slow growth or no growth right after bacteria are inoculated into new media.

lamellar pseudopod A pseudopod with a sheet-like morphology.

laminar flow biological safety cabinet An air filtration appliance that removes pathogenic microbes from within the cabinet.

Langerhans cell Specialized, phagocytic dendritic cells that are the predominant cell type in skin-associated lymphatic tissue.

laser scanning confocal microscopy A type of fluorescence microscopy in which the excitation and emitted light are focused together, producing high resolution images.

late gene A gene that is expressed late in the viral infectious cycle, such as genes for capsid proteins or lysozyme.

latent period The time in the viral life cycle when progeny virions have formed but are still within the host cell.

latent state When a pathogenic agent is dormant in the host and can not be cultured.

late-phase anaphylaxis Anaphylaxis caused by leukotrienes released by eosinophils recruited by mast cells.

lateral transfer See **horizontal gene transfer**.

law of mass action The tendency of a reaction at equilibrium to return to equilibrium after the concentrations of products or reactants is altered.

leaching The process of metal dissolution from ores.

leader sequence A short DNA sequence preceding a structural gene. In amino acid operons it contains multiple codons for the amino acid synthesized by the downstream structural genes. The leader sequence and translating ribosome help determine whether the structural genes are transcribed.

leaflet One of the two lipid layers in a phospholipid bilayer. The inner leaflet of the cell membrane faces the cytoplasm.

leaven The generation of air spaces in bread due to carbon dioxide production by yeast fermentation.

leghemoglobin An iron-bearing plant protein that sequesters oxygen to maintain an anoxic environment for nitrogenase within cells containing bacteroids.

lentivirus A member of a family of retroviruses that propagate slowly. An example is HIV.

lethal dose (LD_{50}) A measure of virulence, it is the number of bacteria or virions required to kill 50% of an experimental group of hosts.

lethal factor (LF) A component of anthrax toxin that cleaves host protein kinases.

lichen An organism formed by a mutualistic relationship between algae and fungi.

light chain The smaller of the two different proteins comprising an antibody. Each antibody contains two heavy chains and two light chains.

light microscopy Observation of a microscopic object based on light absorption and transmission.

lignin A complex aromatic organic compound that forms the key structural support for trees and woody stems.

limiting nutrient A nutrient that is in short supply and limits growth.

lipopolysaccharide (LPS) Structurally unique phospholipids found in the outer leaflet of the outer membrane in gram-negative bacteria. Many are endotoxins.

lithotroph (chemolithotroph) An autotrophic organism that gains energy by oxidizing inorganic compounds. See **chemoautotroph**.

lithotrophy (chemolithotrophy) Energy-yielding metabolism that uses an inorganic electron donor; usually includes fixation of CO_2 into biomass.

littoral zone The upper water layer of aquatic habitats that light can penetrate.

logarithmic (log) phase See **exponential phase**.

long terminal repeat (LTR) A repeated nucleic acid sequence at the 5′ and 3′ ends of a provirus.

loss-of-function mutation A mutation that eliminates or decreases the function of the gene product.

lumen The interior of an intracellular membrane-bound compartment.

lymph node A secondary lymphatic organ, formed by the convergence of lymphatic vessels, that traps foreign particles from local tissue and presents them to resident immune cells.

lyophilization A method to freeze-dry microbes or food for long term storage.

lysate The contents of broken cells; may include virus particles.

lyse To break open cells by disruption of their cell membrane.

lysis The rupture of the cell by a break in the cell membrane.

lysogen A bacterial cell that harbors a complete, yet quiescent, phage genome. Depending on the phage, the phage genome may be integrated into the bacterial chromosome or exist as an autonomous plasmid in the cell.

lysogeny A viral life cycle in which the viral genome integrates into and replicates with the host genome, but retains the ability to initiate host cell lysis.

lysosome An acidic eukaryotic organelle that aids digestion of molecules. Not found in plant cells.

lytic A viral life cycle in which the virus produces new virions and lyses the cell, releasing virions.

M cell A phagocytic innate immune cell (microfold cell) found between intestinal epithelial cells.

MacConkey medium A differential, selective medium that selects for gram-negative bacteria and can differentiate between lactose fermenters and non-fermenters.

macronucleus A form of nucleus found in ciliates, derived from gene amplification and rearrangement of micronuclear DNA, that contains actively transcribed genes.

macronutrient A nutrient an organism needs in large quantities.

macrophage A mono-nuclear, phagocytotic, antigen presenting cell of the immune system.

magnetosome An organelle containing the mineral magnetite that allows microbes to sense a magnetic field.

magnetotaxis The ability to direct motility along magnetic field lines.

magnification An increase in the apparent size of a viewed object as an optical image.

major histocompatibility complex (MHC) Transmembrane cell proteins important for recognizing self and for presenting foreign antigens to the adaptive immune system.

malaria A disease caused by the apicomplexan *Plasmodium falciparum*, transmitted by mosquitoes.

malolactic fermentation Fermentation of L-malate (a side product of glucose fermentation) by *Oenococcus oeni* bacteria, an important process in wine making.

marine snow Microbial biofilms on inorganic particles suspended in marine water.

mast cell White cells that secrete proteins that aid innate immunity. Mast cells reside in connective tissues and mucosa and do not circulate in the bloodstream.

matrix protein A protein found in some viruses that is located between the capsid and the membrane envelope.

mean generation time The reciprocal of the mean growth rate constant; the mean time period for doubling of a population.

mean growth rate constant The number of organismal generations per unit time, *k*.

mechanical transmission A nonspecific mode of viral entry into damaged tissue.

membrane attack complex (MAC) A cell-destroying pore produced in the membrane of invading bacteria by the host cell complement cascade.

membrane potential Energy stored as an electrical voltage difference across a membrane.

membrane-permeant organic acid See **membrane-permeant weak acid**.

membrane-permeant weak acid An acid that exists in charged and uncharged forms such as acetic acid. The uncharged form can cross the membrane.

membrane-permeant weak base A base that exists in charged and uncharged forms such as methylamine. The uncharged form can dissolve in the membrane.

memory B cell A long-lived type of lymphocyte preprogrammed to produce a specific antibody. After encountering its activating antigen, memory B cells differentiate into antibody-producing plasma cells.

merodiploid A partial diploid strain with chromosomal and F-prime factor copies of particular genes.

merozoite The form of *Plasmodium falciparum*, the causative agent for malaria, which invades red blood cells.

mesocosm A small controlled model ecosystem.

mesophile An organism with optimal growth between 20°C and 40°C.

messenger RNA (mRNA) An RNA molecule that encodes a protein.

metabolist model A model of early life in which the central components of intermediary metabolism arose from self-sustaining chemical reactions based on inorganic chemicals.

metastatic lesions Lesions of infection, or of cancerous cells, that develop at secondary sites away from the initial site of infection.

metazoan A multicellular animal with cells organized into tissues.

methane gas hydrate A crystalline material in which methane molecules are surrounded by a cage of water molecules. This molecular configuration is found in the deep ocean.

methanogen An organism that uses hydrogen to reduce CO_2 and other single-carbon compounds to methane, yielding energy.

methanogenesis An energy-yielding metabolic process that produces methane. It is unique to archaea.

methanotroph An organism that oxidizes methane to yield energy.

methanotrophy The metabolic oxidation of methane to yield energy.

methyl mismatch repair A DNA repair system that fixes misincorporation of a nucleotide after DNA synthesis. The unmethylated daughter strand is corrected to complement the methylated parent strand.

methylene blue A cationic dye commonly used as a simple stain for bacteria.

methylotrophy The ability of an organism to oxidize single-carbon compounds such as methanol, methylamine, or methane.

metranidazole An antibiotic activated by anaerobic bacteria that kills cells by nicking the DNA.

MHC restriction The ability of T lymphocytes to only recognize antigens complexed to self-MHC molecules.

microaerophilic An organism that requires oxygen at a concentration lower than that of the atmosphere, and can not grow in high oxygen environments.

microbe An organism or virus too small to be seen with the unaided human eye.

microcolony A small colony of bacteria only visible with the aid of a microscope.

microfilament A eukaryotic cytoskeletal protein composed of polymerized actin.

microfossil A microscopic fossil in which calcium carbonate deposits have filled in the form of ancient microbial cells.

micronucleus A form of nucleus found in ciliates that contains a diploid set of chromosomes and undergoes meiosis for sexual exchange by conjugation.

micronutrient A nutrient that an organism needs in small quantity, typically a vitamin or a mineral.

microplankton Plankton consisting of cells 20–200 μm in diameter.

microscope A tool that increases the magnification of specimens to enable viewing at higher resolution.

microtubule A eukaryotic cytoskeletal protein composed of polymerized tubulin.

minicell A small spherical cell fragment lacking DNA, generated by improper septation near a pole.

minimal inhibitory concentration (MIC) The lowest concentration of a drug that will prevent the growth of an organism.

miso A Japanese condiment, made from ground soy and rice, salted and fermented by the mold *Aspergillus oryzae*.

missense mutation A point mutation that alters the sequence of a single codon, leading to a single amino acid substitution in a protein.

mitochondrion A eukaryotic organelle that produces ATP through the use of an electron transport chain to produce a proton motive force. O_2 is the final electron acceptor to produce H_2O.

mitosis The orderly replication and segregation of eukaryotic chromosomes, usually prior to cell division.

mitosporic fungus A species of fungus that generates spores by mitosis and lacks a known sexual cycle.

mixotrophic An organism that can switch among metabolic strategies, such as heterotrophy and phototrophy, depending on the environmental conditions.

mixotrophs Organisms capable of both photosynthetic and heterotrophic metabolism.

modulon A group of genes, operons and regulons that is coordinately activated in response to a particular stimulus.

molarity A unit of concentration measured as the number of moles of solute per liter of solution.

molecular clock The use of DNA or RNA sequence information to measure the time of divergence among different species.

molecular formula A notation that indicates the number and type of atoms in a molecule. For example H_2O is the molecular formula for water.

molecular mimicry A structural similarity between two different molecules.

monocistronic The RNA produced from a single gene.

monocyte A white cell with a single nucleus that can differentiate into macrophages or dendritic cells.

monophyletic A group of organisms that includes an ancestral species and all of its descendents.

monophyletic group See **monophyletic**.

monosaccharide The monomer unit of sugars. Monosaccharides have a molecular formula of CH_2O.

mordant A chemical binding agent that causes specimens to retain stains better.

mother cell The larger cell that forms during the asymmetric cell division leading to spore formation. The mother cell will engulf the forespore.

motherspore See **mother cell**.

motility The ability of a microbe to generate self-directed movement.

mucociliary elevator The ciliated mucus lining of the trachea, bronchi, and bronchioles that sweeps foreign particles up and away from the lungs.

Mueller-Hinton agar A specialized, standardized, para-amino benzoic acid-free media used for the Kirby-Bauer test.

multidrug resistance (MDR) efflux pump A transmembrane protein pump that can export many different kinds of antibiotics with little regard for structure.

multiplex PCR A polymerase chain reaction that uses multiple pairs of oligonucleotide primers to amplify several different DNA sequences simultaneously.

murein See **peptidoglycan**.

murein lipoprotein The major lipoprotein that connects the outer membrane of gram-negative bacteria to the peptidoglycan cell wall.

mutagen A chemical that damages DNA and leads to mutations.

mutation A heritable change in the DNA sequence.

mutation frequency The fraction of mutant cells (defective in a given gene) within the total cell population.

mutation rate The number of mutations introduced into DNA per generation (cell doubling).

mutator strain A strain of cells with a high mutation rate, usually due to a mutation in a DNA repair enzyme.

mutualism A symbiotic relationship in which both partners benefit.

mycelia See **mycelium**.

mycelium *pl.* **mycelia** A fungal hypha that projects into the air (aerial mycelium) or into the growth substrate (substrate mycelium).

mycolic acid One of a diverse class of sugar-linked fatty acids found in the cell envelopes of mycobacteria.

mycology The study of fungi.

mycorrhizae A symbiotic relationship between plant roots and fungi.

myxospore Durable spherical cells produced by the fruiting body of Myxobacteria.

Nanoarchaeota A deeply branching division of Archaea; includes thermophilic cells of extremely small size.

nanoplankton Plankton consisting of cells 2–20 μm in diameter.

nasopharynx The area leading from the nose to the oral cavity.

native conformation The fully folded, functional form of a protein.

natto A soybean product, similar to tempeh, produced by alkaline fermentation.

necrotizing fasciitis A severe skin infection, also know as flesh-eating disease, usually caused by the gram-positive coccus *Streptococcus pyogenes*.

negative selection The destruction of T cells bearing T-cell receptors (TCRs) that bind strongly to self-MHC proteins displayed on thymus epithelial cells.

negative-sense (–) strand (see also template strand) Single-stranded RNA whose sequence is complementary to that of mRNA. Also the DNA strand that is complementary to an mRNA.

negative stain A stain that colors the background and leaves the specimen unstained.

neuraminidase inhibitors Anti-influenza drugs that target neuraminidase on the viral envelope and decrease the number of virus particles released.

neutralophile An organism with an optimal growth range in environments between pH 5 and 8.

neutrophil An innate immune system white blood cell that can phagocytose and kill microbes.

niche A description of an organism's environmental requirements for existence and its relations with other members of the ecosystem.

nicotinamide adenine dinucleotide (NADH, NAD^+) An energy carrier in the cell that can donate (NADH) or accept (NAD^+) electrons.

nitrification The oxidation of reduced nitrogen compounds to nitrite or nitrate.

nitrifier An organism that converts reduced nitrogen compounds to nitrite or nitrate.

nitrifying bacterium A bacterium that performs nitrification, gaining energy by oxidizing ammonium (NH_4^+) to nitrate (NO_3^-).

nitrogen fixation The ability of some prokaryotes to reduce inorganic diatomic nitrogen gas (N_2) to two molecules of ammonium ion ($2\ NH_4^+$).

nitrogenase The enzyme that catalyzes the conversion of dinitrogen (N_2) to two molecules of ammonium ion (NH_4^+).

nitrogen-fixing bacterium A bacterium that can reduce diatomic nitrogen gas, N_2, into ammonium ion (NH_4^+).

Nitrospirae A phylum of gram-negative bacteria, many of which are lithotrophs, oxidizing nitrite to nitrate.

Nod factors Signaling molecules released by rhizobial cells and sensed by legumes that help initiate the rhizobia-legume symbiosis.

nomenclature The naming of different taxonomic groups of organisms.

non-adaptive immunity (innate immunity) Non-specific mechanisms for protecting against pathogens.

nonpolar covalent bond A covalent bond in which the electrons in the bond are shared equally by the two atoms.

non-ribosomal peptide antibiotic Secondary metabolite with antimicrobial activity synthesized by modular enzymes and not by ribosomes.

nonsense mutation A mutation that changes an amino acid codon into a premature stop codon.

nonsense suppressor An altered (mutant) tRNA molecule whose anticodon will bind to a nonsense codon (premature stop codon) in a mutant mRNA and allow translation to proceed.

nori A Japanese food obtained from the red algae *Porphyra* sp.

normal flora The resident population of harmless organisms normally present at nonsterile body sites (e.g. the intestine).

Northern blot A technique to detect specific RNA sequences. Sample RNA is subjected to gel electrophoresis, transferred to a blot, and probed with a labeled cDNA that will hybridize to target RNA sequences.

nosocomial Hospital-acquired.

N-terminal rule The tendency of the N-terminal amino acid of a protein to influence protein stability.

nuclear magnetic resonance (NMR) A technique that provides structural information based on the absorption and emission of electromagnetic radiation resulting from changes in the spin state of atomic nuclei.

nucleocapsid protein (NP) A protein that coats a viral genome.

nucleoid The looped coils of a bacterial chromosome.

nucleolus A region inside the nucleus where ribosome assembly begins.

nucleotide The monomer unit of nucleic acids, consisting of a five-carbon sugar, a phosphate and a nitrogenous base.

nucleotide excision repair (NER) A DNA repair mechanism that cuts out damaged DNA. New correct DNA is synthesized by DNA polymerase I.

nucleus A eukaryotic organelle that contains the DNA.

numerical aperture (NA) The product of the refractive index of the medium and sin . As NA increases the magnification increases.

O polysaccharide A sugar chain that connects to the core polysaccharide of lipopolysaccharides.

objective lens In a compound microscope, the lens closest to the specimen that generates the initial magnification.

ocular lens In a compound microscope, the lens situated closest to the observer's eye. It is also called the eyepiece.

Okazaki fragments Short fragments of DNA that are synthesized on the lagging strand during DNA synthesis.

oligotroph An organism that can only grow in environments containing extremely low concentrations of organic nutrients.

oligotrophic lake A lake having low concentration of organic nutrients, the opposite of eutrophic.

oncogene A gene that through mutation or inappropriate expression can lead to cancer.

oncogenic virus A virus that causes cancer.

Oomycetes A taxonomic group of heterkont protists whose life cycle resembles that of fungi; they were formerly classified as fungi.

open reading frame (ORF) A DNA sequence predicted to encode a protein.

operational gene A DNA sequence that encodes a product not essential for transcription or translation but involved in cell functions such as metabolism, stress response, or pathogenicity.

operator A DNA sequence that binds a repressor protein, preventing transcription of a gene downstream. (Less common, refers to a sequence binding an activator protein.)

operon A collection of genes that are in tandem on a chromosome and are transcribed into a single RNA.

operon fusion A technique to monitor transcriptional regulation by fusing a reporter gene containing its own ribosome binding site to the 3′ end of an operon. Unlike the "gene fusion" technique, only the promoter of the target gene directs expression of the reporter.

opine A specialized amino acid used as a carbon and nitrogen source by the plant pathogen *Agrobacterium tumefasciens*.

Opisthokonta The eukaryotic clade that contains fungi, multicellular animals, and some protist-like organisms.

opportunistic pathogen A microbe that normally is not pathogenic but can cause infection or disease in an immune compromised host organism.

opsonization The coating of pathogens with antibodies that aid pathogen phagocytosis by innate immune cells.

opsonize The binding of IgG antibodies to microbes to enhance microbial phagocytosis by host immune cells.

optical density A measure of how many particles are suspended in a solution based on light scattering by the suspended particles.

optical isomer Also known as a stereoisomer, a molecule that has a mirror image. Molecules that contain a chiral carbon can have optical isomers.

oral groove A ciliate structure for food uptake.

organelle A membrane-bound compartment within eukaryotic cells that serves a specific function.

organic horizon The top, surface layer of the soil.

organic molecule A molecule that contains a carbon-carbon bond.

organotrophy Metabolism of organic compounds to yield usable energy.

origin (*oriC*) The region of a bacterial chromosome where DNA replication initiates.

origin of replication (*ori*) A DNA sequence at which DNA replication initiates. In a bacterial chromosome this site is also attached to the cell envelope.

oropharynx The area between the soft palate and the upper edge of the epiglottis.

ortholog See **orthologous gene**.

orthologous Genes present in more than one species that derived from a common ancestral gene and encode the same function.

orthologous gene A gene present in more than one species that derived from a common ancestral gene and encodes the same function.

osmolarity A measure of the number of solute molecules in solution.

osmosis The diffusion of water from regions of high water concentration (low solute) to regions of low water concentration (high solute) across a semi-permeable membrane.

osmotic pressure Pressure exerted by the osmotic flow of water through a semipermeable membrane.

outer leaflet The layer of the cell membrane phospholipid bilayer that faces away from the cytoplasm.

outer membrane A membrane external to the cell wall in gram-negative bacteria.

oxidative burst A large increase in the oxygen consumption of immune cells during phagocytosis of pathogens as the immune cells produce oxygen radicals to kill the pathogen.

oxidative phosphorylation An electron transport chain that uses diatomic oxygen as a final electron acceptor and generates a proton gradient across a membrane for the production of ATP via ATP synthase.

oxidized, oxidation An oxidized compound is one that has lost electrons. Oxidation is the loss of electrons.

oxidoreductase An electron transport system protein that accepts electrons from one molecule (oxidizing that molecule), and donates electrons to a second molecule, thereby reducing the second molecule.

oxygenic Z pathway An ATP-producing photosynthetic pathway consisting of photosystems I and II. Water serves as the initial electron donor (generating O_2) and $NADP^+$ is the final electron acceptor, generating NADPH.

palindrome A DNA sequence in which the top and bottom strands have the same sequence in the 5′ to 3′ direction.

pandemic An epidemic that occurs over a wide geographic area.

panspermia The hypothesis that life forms originated elsewhere and "seeded" life on Earth.

paper chromatography A technique to separate compounds based on their differential migration in a solvent that wicks up through paper. Compounds are separated based relative solubility in the solvent.

paralogous Genes that arise by gene duplication within a species and evolve to carry out different functions.

parasite Bacteria, viruses, fungi, or protozoan (protist) that colonizes and harm its host; the term usually refers to protozoa.

parasitism A symbiotic relationship in which one member benefits and the other is harmed.

parfocal In a microscope with multiple objective lenses, having the objective lenses set at different heights that maintain focus when switching among lenses.

passive transport Net movement of molecules across a membrane without energy expenditure by the cell.

pasteurization The heating of food at a temperature and time combination that will kill spores of *Mycobacterium tuberculosis* and *Coxiella burnetii*.

pathogen A bacterial, viral, or fungal agent of disease.

pathogenesis The processes through which microbes cause disease in a host.

pathogenicity The ability of a microorganism to cause disease.

pathogenicity island A type of **genomic island**, a stretch of DNA that contains virulence factors and may have been transferred from another genome.

pelagic Referring to the open ocean.

pellicle A thick, flexible cell covering found in protists.

penicillin An antibiotic, produced by the *Penicillium* mold, that blocks cross-bridge formation during peptidoglycan synthesis.

penicillin-binding proteins Bacterial proteins, involved in cell wall synthesis, that are targets of the penicillin antibiotic.

pentose phosphate shunt (PPS) An alternate glycolytic pathway in which glucose-6-phosphate is first oxidized, then decarboxylated to ribulose-5-phosphate, ultimately generating 1 ATP and 2 NADPH.

peptide bond The covalent bond that links two amino acid monomers.

peptidoglycan (murein) A polymer of peptide-linked chains of amino sugars; a major component of the bacterial cell wall.

peptidyltransferase The rRNA enzymatic ability to form peptide bonds.

peptidyl-tRNA site (P site) The ribosomal site that contains the growing protein attached to a tRNA.

perforin A cytotoxic protein, secreted by T cells, that forms pores in target cell membranes.

peripheral membrane protein A protein that is associated with a membrane but does not transverse the phospholipid bilayer.

permease A substrate-specific carrier protein in the membrane.

permissive temperature A temperature at which a temperature-sensitive mutation in a gene is masked, permitting growth of the organism.

peroxisome A eukaryotic organelle that converts hydrogen peroxide to water.

petechiae Pinpoint capillary hemorrhages due to the absence of clotting factors; may indicate the presence of endotoxin.

petri dish A round dish with vertical walls covered by an inverted dish of slightly larger diameter. The smaller dish can be filled with a substrate for growing microbes.

phage display A technique in which a phage particle contains recombinant coat proteins expressed by genes encoding a coat protein fused to the protein of interest, such as a vaccine antigen.

phagocytosis A form of endocytosis in which large extracellular particles are brought into the cell.

phagosome A large intracellular vesicle that forms as a result of phagocytosis.

phase variation A gene regulatory mechanism that changes the amino acid sequence of a protein from one antigenic type to another. One mechanism involves site specific recombination that flips a DNA sequence in a chromosome.

phase-contrast microscopy Observation of a microscopic object based on the differences in the refractive index between cell components and the surrounding medium. Contrast is generated as the difference between refracted light and transmitted light shifted out of phase.

phenol coefficient test A test of the ability of a disinfectant to kill bacteria; the higher the coefficient the more effective the disinfectant.

phenol red broth test A clinical test for particular bacterial fermentation pathways, indicating the presence or absence of particular species, based on fermentative acids changing a pH indicator.

phosphatidate A negatively charged phosphate head group of a phospholipid.

phosphatidylethanolamine A type of phospholipid with a positively charged ethanolamine attached to the phosphate group.

phosphatidylglycerol A type of phospholipid with a glycerol attached to the phosphate group.

phosphodiester bond The bond that covalently attaches to adjacent nucleotides in a nucleic acid.

phospholipid The major component of membranes. A typical phospholipid is composed of a core of glycerol to which two fatty acids and a modified phosphate group are attached.

phospholipid bilayer Two layers of phospholipids; the hydrocarbon fatty acids tails face the interior of the bilayer, and the charged phosphate groups face the cytoplasm and extracellular environment.

phosphorylation The enzyme-catalyzed addition of a phosphoryl group onto a molecule.

phosphotransferase system (PTS) A group translocation system that uses phosphoenol pyruvate to transfer phosphoryl groups onto the incoming molecule.

photoautotroph Organisms that perform photosynthesis, using light energy to reduce carbon dioxide.

photoautotrophy The reduction of carbon dioxide using light as an energy source.

photoheterolithotroph An organism that can use heterotrophy, lithotrophy, or photosynthesis for energy production, depending on environmental conditions.

photoheterotrophy The production of energy by the photolysis of organic compounds.

photolysis The first energy-yielding phase of photosynthesis, the light-driven separation of an electron from a molecule coupled to an electron transport system.

photoreactivation A light-induced, photolyase-catalyzed repair of pyrimidine dimers.

photosynthesis The metabolic ability to absorb and convert solar energy into chemical energy for biosynthesis; a precise definition includes CO_2 fixation.

photosystem I and II See **anaerobic photosystem I and II**.

phototroph A general term for organisms that can obtain metabolic energy through light absorption, with or without CO_2 fixation.

phototrophy Obtaining energy from chemical reactions triggered by the absorption of light.

phycobilisome A protein complex that captures light in photosynthetic bacteria.

phycoerythrin A photopigment that give red algae their characteristic color.

phylogenetic tree A diagram depicting estimates of the relative amounts of evolutionary divergence among different species.

phylogeny A measurement of genetic relatedness. The classification of animals based on their genetic relatedness.

phylum The taxonomic rank one level below domain; a group of organisms sharing a common ancestor that diverged early from other groups.

phytoestrogens See **flavonoids**.

phytoplankton Phototrophic marine bacteria, algae, and protists, the primary producers in pelagic food webs.

picoplankton Plankton consisting of cells 0.3–2 μm in diameter.

picornavirus A class of icosahedral RNA viruses such as poliovirus.

piezophile See **barophile**. An organism that requires high pressure to grow.

pilin The protein monomer that polymerizes to form a pilus.

pilus *pl.* **pili (fimbria,** *pl.* **fimbriae)** A straight protein filament composed of a tube of protein monomers that extend from the bacterial cell envelope.

pinocytosis A form of endocytosis in which only extracellular fluid and small molecules are brought into the cell.

Planctomycetes A phylum of free-living bacteria that have stalked cells and reproduce by budding. Their nucleoid is surrounded by a membrane.

plankton Organisms that float in water.

planktonic cells Isolated cells, growing individually in a liquid without connections to other cells.

plaque A cell-free zone on a lawn of bacterial cells caused by viral lysis.

plaque assay An assay to determine the presence of bacteriophages based on their ability to form plaques.

plaque-forming unit (PFU) A measure of the concentration of phage particles in liquid culture.

plasma cell A short-lived antibody-producing cell.

plasmid An extrachromosmal genetic element that may be present in some cells.

plasmodesma *pl.* **plasmodesmata** A membrane channel in plants that connects adjacent plant cells.

plasmodial slime mold A slime mold in which the mass of aggregating cells becomes a multinucleate single cell.

plasmodium The giant multinucleate cell formed by plasmodial slime molds.

pneumonic plague A highly virulent and contagious *Yersinia pestis* lung infection.

point mutation A change in a single nucleotide within a nucleic acid sequence.

poliomyelitis (polio) The paralytic disease caused by the poliovirus.

poliovirus A picornavirus that is the causative agent of poliomyelitis.

poliovirus receptor (Pvr) The cell surface receptor unique to humans and simians through which poliovirus gains entry to cells.

polyamine A positively charged molecule containing multiple amine groups.

polycistronic An RNA produced from an operon containing several genes and hence containing several functional sequences (usually encoding different proteins).

polymerase chain reaction (PCR) A method to amplify DNA in vitro using many cycles of DNA denaturation, primer annealing, and DNA polymerization with a heat-stable polymerase.

polyphyletic An organism or group of organisms that have multiple evolutionary origins.

polysaccharide A polymer of sugars.

polysome A cell structure consisting of multiple ribosomes performing translation on the same mRNA molecule.

porin A transmembrane protein complex that allows movement of specific molecules across the cell membrane or the outer membrane.

positive selection Growth of a population under a condition that favors a particular genotype and prevents growth of other genotypes. In immunology: the survival of T cells bearing T-cell receptors (TCRs) that don't recognize self-MHC proteins displayed on thymus epithelial cells.

positive-sense (+) strand A molecule of of DNA that has the same sequence as mRNA (except for T replacing U). In virology: a molecule of RNA (mRNA) that can be directly translated into viral proteins.

pour plate Also known as a Petri dish, a round, shallow-sided container into which molten agar is poured and subsequently cooled.

prebiotic soup A model for the origin of life based on the abiotic formation of fundamental biomolecules and cell structures such as membranes out of a "soup" of nutrients present on early Earth.

predator A consumer that feeds on grazers.

preliminary mRNA transcript (pre-mRNA) A eukaryotic messenger RNA prior to intron removal.

primary antibody response The production of antibodies upon first exposure to a particular antigen. B cells become activated and differentiate into plasma cells and memory B cells.

primary endosymbiont A lineage of organisms derived from a single endosymbiotic event.

primary latent stage The period of syphilis infection between the chancre of primary syphilis and the rash of secondary syphilis.

primary pathogen A disease-causing microbe that can breach the defenses of a healthy host. Same as a frank pathogen.

primary producer An organism that produces biomass (reduced carbon) from inorganic carbon sources such as CO_2.

primary recovery The initial isolation of commercial product from industrial microbes.

primary structure The first level of organization of polymers, consisting of the linear sequence of monomers, for example the sequence of amino acids in a protein or nucleotides in a nucleic acid.

primary syphilis The initial inflammatory reaction (chancre) at the site of infection with *Treponema pallidum*.

primase An RNA polymerase that synthesizes short RNA primers complementary to a DNA template to launch DNA replication.

primer extension A technique to determine the 5′ end of an RNA transcript.

prion An infectious agent that causes propagation of misfolded host proteins; usually consists of a defective version of the host protein.

probabilistic indicator A means of quickly identifying microbes in the clinical setting, based on a battery of biochemical tests performed simultaneously on an isolated strain.

probiotic A food or nutritional supplement that contains live microorganisms and aims to improve health by promoting beneficial bacteria.

prokaryote *pl.* **prokaryotes** Organism whose cell or cells lack a nucleus; includes both bacteria and archaea.

promoter A non-coding DNA regulatory region immediately upstream of a structural gene that is needed for transcription initiation.

promoter trap plasmid A laboratory technique to discover promoters that only drive gene expression under particular circumstances.

proofreading An enzymatic activity of some nucleic acid polymerases that attempts to correct mispaired bases.

prophage A phage genome integrated into a host genome.

propionic acid fermentation The fermentation of lactic acid to propionic acid by *Propionibacterium* species; used in the production of Swiss cheese.

prosthetic group A non-protein component of an enzyme required for catalytic ability.

protease inhibitor A molecule that inhibits a protease enzyme; some are used as anti-HIV drugs to block the virally encoded protease needed to complete HIV assembly.

protective antigen (PA) The core subunit of anthrax toxin, so called because immunity to this protein protects against disease.

protein A A *Staphylococcus aureus* cell-wall protein that binds to the Fc region of antibodies, hiding the *S. aureus* cells from phagocytes.

Proteobacteria A large, metabolically and morphologically diverse, phylum of gram-negative bacteria.

proteome All the proteins expressed in a cell at a given time. The "complete proteome" includes all the proteins the cell can express under any condition. The "expressed proteome" represents the set of proteins made under a given condition.

proteomics The biological field of proteome analysis.

proteorhodopsin A bacterial membrane protein that contains retinal and acts as a light-driven proton pump; homologous to the archaeal protein bacteriorhodopsin.

protist A motile single-celled eukaryote.

proton motive force See **proton potential**.

proton potential The potential energy of the concentration gradient of protons (hydrogen ions, H^+) plus the charge difference across a membrane.

provirus A viral genome that is integrated into the host cell genome.

pseudogene A gene that is no longer functional.

pseudomurein See **pseudopeptidoglycan**.

pseudopeptidoglycan A peptidoglycan-like molecule composed of sugars and peptides that is found in some archaeal cell walls.

pseudopod A locomotory extension of cytoplasm bounded by the cell membrane.

psychrophile An organism with optimal growth at temperatures below 20°C.

pure culture A culture containing only a single strain or species of microorganism. A large number of microorganisms all descended from a single individual cell.

purine A nitrogenous base with fused rings found in nucleotides, such as adenine and guanine.

putrefaction Food spoilage due to the decomposition of proteins and amino acids.

pyrimidine A single-ring nitrogenous base found in nucleotides such as cytosine, thymine, or uracil.

pyrogen Any substance that induces fever.

pyruvate dehydrogenase complex (PDC) The multi-subunit enzyme that couples the oxidative decarboxylation of pyruvate to acetyl-CoA and NADH production.

quarantine The separation of infectious individuals from the general population to limit the spread of infection.

quaternary structure The highest level of protein structure, in which more than one polypeptide chain interact and function together.

quinol A reduced electron carrier that can diffuse laterally within membranes.

quinolones A group of antibiotic drugs that inhibit DNA synthesis by targeting bacterial topoisomerases such as DNA gyrase.

quinone An oxidized electron carrier that can diffuse laterally within membranes.

quinone pool The oxidized quinones and reduced quinols that diffuse freely within the phospholipid membrane and are able to transfer electrons between many different redox enzymes.

quorum sensing The ability of bacteria to sense the presence of other bacteria via secreted chemical signals called autoinducers.

radial immunodiffusion A laboratory technique to determine the concentration of an antigen in solution.

Radiolaria A taxonomic group of amebas with a silicate shell penetrated by filamentous pseudopods.

rancidity Food spoilage due to the oxidation of fats; may or may not involve microbial activity.

rank A level of taxonomic hierarchy, such as phylum, class, order or family.

reaction center The chlorophyll molecule that donates its excited electron to an electron transport system.

reading frame The position in a nucleic acid sequence from which triplet codons encode amino acids.

real-time PCR A technique using fluorescence to detect the products of PCR amplification as the reaction progresses, in order to quantify the amount of DNA in a sample.

receptor-binding domain A region of a protein responsible for binding to a receptor.

recombinant DNA DNA that has been combined with other DNA to create novel DNA sequences.

recombination The replacement of host DNA with donor DNA.

recombination signal sequence (RSS) A DNA region downstream of antibody heavy and light chain genes that allows recombination between widely separated gene segments.

recombinational repair A DNA repair mechanism that relies on recombination between an undamaged chromosome and a gap that occurred during replication of damaged DNA.

red alga See **Rhodophyta**.

redox couple The oxidized and reduced states of a compound. For example, NAD^+ and NADH form a redox couple.

reduced, reduction A reduced compound is one that has gained electrons. Reduction is the gain of electrons.

reduction potential See **voltage potential**.

reductive acetyl-CoA pathway A carbon assimilation pathway in which two CO_2 molecules are condensed and reduced by 2 H_2 to form an acetyl group.

reductive evolution The loss or mutation of DNA encoding unselected traits.

reductive pentose phosphate cycle See **Calvin cycle**.

reductive (reverse) TCA cycle A CO_2 fixation pathway that generates acetyl-CoA through reversal of TCA cycle reactions. It requires ATP and NADPH.

reflection Deflection of an incident light ray by an object, at an angle equal to the incident angle.

refraction The bending and slowing of light as it passes through a substance.

refractive index The degree to which a substance causes the refraction of light, a ratio of the speed of light in a vacuum to its speed in another medium.

regolith Loose rock fragments covering bedrock; commonly refers to the surface layer of Mars or of the moon.

regulatory protein (regulator) A protein that can bind DNA and modulate transcription in response to a metabolite.

regulon A group of genes and operons that is co-ordinately regulated and shares a common biochemical function.

release factor A molecule that enters a ribosome A site containing an mRNA stop codon and initiates protein cleavage from the tRNA.

replication fork During DNA synthesis the region of the chromosome that is being unwound.

replisome A complex of DNA polymerase and other accessory molecules that performs DNA replication.

reporter gene A gene, such as *lacZ* (β-galactosidase) or *gfp* (green fluorescent protein), whose protein product can be easily quantified; commonly used in a gene fusion.

repression The down-regulation of gene transcription.

repressor A regulatory protein that can bind to a specific DNA sequence and inhibit transcription of genes.

reservoir 1. An organism that maintains a virus in an area by serving as a high titer host. 2. A part of the biosphere containing significant amounts of an element needed for life.

resolution The smallest distance that two objects can be separated and still be distinguished as separate objects.

respiration The oxidation of reduced electron donors through a series of membrane-embedded electron carriers to a final electron acceptor. The energy derived from the redox reactions is stored as an electrochemical gradient across the membrane, which may be harnessed to produce ATP.

response regulator A cytoplasmic protein that is phosphorylated by a sensor kinase and modulates gene transcription depending on its phosphorylation state.

restriction endonuclease A bacterial enzyme that cleaves double-stranded DNA within a specific short sequence, usually a palindrome. Often called a restriction enzyme.

restriction enzyme See **restriction endonuclease**.

restriction site A DNA sequence recognized and cleaved by a restriction enzyme.

restrictive temperature A temperature at which a temperature-sensitive mutation in a gene leads to the mutant phenotype, which generally includes failure to grow.

reticulate body The metabolically and reproductively active form of Chlamydia.

reticuloendothelial system A collection of cells that can phagocytize and sequester extracellular material.

retinal A vitamin A related cofactor in opsin proteins; it undergoes a conformational change in response to photon absorption.

retroelements Non-virion-producing, ancient retroviral genomes found in host genomes.

retrotransposon Retroelements that contain only partial retroviral sequences but may contain reverse transcriptase to allow further movement into the host genome.

retrovirus A virus containing a positive single-stranded RNA genome; uses reverse transcriptase to generate a double-stranded DNA.

reverse transcriptase An enzyme that produces a double-stranded DNA molecule from a single-stranded RNA template.

reversion test A way to screen the mutagenic potential of compounds by their ability to fix a gene that is necessary for the biosynthesis of a needed metabolite.

rhinovirus A picornavirus that causes the common cold.

rhizobia Bacterial species of the order Rhizobiales that form highly specific mutualistic associations with plants in which the bacteria fix nitrogen for the plant.

rhizoplane The surface of plant roots.

rhizosphere The soil environment surrounding plant roots.

Rho-dependent A bacterial transcription termination mechanism that requires Rho protein.

Rhodophyta (rhodophyte) A taxonomic group of unicellular primary algae containing red pigment; also known as"red algae."

Rho-independent A bacterial transcription termination mechanism that requires a GC-rich region near the transcript terminus.

ribosomal RNA (rRNA) RNA molecules that include the scaffolding and catalytic components of ribosomes.

ribosome-binding site See **Shine-Dalgarno sequence**. A stretch of nucleotides upstream of the start codon in an mRNA that binds to a specific location of the ribosome.

riboswitch A regulatory RNA sequence (upstream of an operon) that forms a stem-loop structure stabilized by the operon's product and modulates transcription and translation.

ribozyme A catalytic RNA molecule.

ripening The aging of cheese.

rise period During viral culture, the time when cells lyse and viral progeny enter the media.

RNA reverse-transcribing virus See **retrovirus**.

RNA world A model of early life in which RNA performed all the informational and catalytic roles of today's DNA and proteins.

RNA-dependent RNA polymerase An enzyme that produces an RNA complementary to a template RNA strand.

rod 1. A bacteria with a linear shape (also referred to as a bacillus). 2. A photoreceptor cell.

rooted tree A phylogenetic tree showing the relative distances between different species, including the earliest time of divergence from a common ancestor.

Rous sarcoma virus (RSV) A retrovirus that was the first virus shown to cause cancer.

rubisco, ribulose 1,5-bisphosphate carbon dioxide reductase/oxidase The enzyme that catalyzes the carbon fixation step in the Calvin cycle.

rumen The first chamber of the digestive tract of ruminant animals such as cattle; the main site for microbial digestion of feed.

sacculus The single covalent molecule that comprises the bacterial cell wall.

saprophytes Fungal decomposers.

sarcina *pl.* **sarcinae** A cubical octad cluster of cells formed by septation at right angles to the previous cell division.

sargassum weed Unrooted kelp forests that float in marine water.

scanning electron microscopy (SEM) Electron microscopy in which the electron beams scan across the specimen's surface to reveal the three-dimensional topology of the specimen.

scattering Interaction of light with an object resulting in propagation of spherical light waves at relatively low intensity.

schizogony Mitotic reproduction of parasitic cells to achieve a large population within a host tissue.

secondary antibody response A memory B cell-mediated rapid increase in the production of antibodies in response to a repeat exposure to a particular antigen.

secondary endosymbiont An organism evolved through engulfment of a primary endosymbiont.

secondary metabolite See **secondary product**.

secondary product Biosynthetic products that are not essential nutrients but enhance nutrient uptake or inhibit competing species (e.g. antibiotics).

secondary structure The second level of organization of polymers, consisting of regular patterns that repeat, such as the double helix in DNA or the beta-sheet in proteins.

secondary syphilis A rash that may appear at some point after the primary latent stage of syphilis.

sedimentation rate The rate at which particles of a given size and shape travel to the bottom of a tube under centrifugal force. The rate depends on the particle's mass and cross-sectional area.

segmented genome A viral genome that consists of more than one nucleic acid molecule.

selective medium A medium that allows the growth of certain species or strains of organisms but not others.

selective toxicity The ability of a drug, at a given dose, to harm the pathogen and not the host.

semiconservative The mode of DNA replication whereby each new double helix contains one old, parental strand and one newly synthesized daughter strand.

semipermeable membrane (selectively permeable membrane) A membrane that is permeable to some substances but impermeable to other substances.

sensor kinase A transmembrane protein that phosphorylates itself in response to an extracellular signal, and transfers the phosphoryl group to a receiver protein.

septation The formation of a septum, a new section of cell wall and envelope to separate two prokaryotic daughter cells.

septicemia An infection of the bloodstream.

septicemic plague Infection of the bloodstream by *Yersinia pestis*.

septum A plate of cell wall and envelope that forms to separate two daughter cells.

sequelae A serious, harmful immunological consequence of bacterial and host antigen cross-reactivity that occur after the infection itself is over. An example is rheumatic fever.

serovar A strain of a microbial species that expresses envelope proteins with an antigenicity distinct from other strains.

serum The non-cell, liquid component of the blood.

sex pilus A pilus specialized for DNA transfer between bacteria.

Shine-Dalgarno sequence See **ribosome-binding site**. In bacteria, a stretch of nucleotides upstream of the start codon in an mRNA that hybridizes to the 16S rRNA of the ribosome, correctly positioning the mRNA for translation.

shuttle vector A plasmid with origins of replication for recognized by both bacteria and eukaryotes.

side effects Drug effects that harm the patient.

siderophore A high-affinity iron binding protein used to scavenge iron from the environment and deliver it to the siderophore-producing organism.

sigma factor A protein needed to bind RNA polymerase for the initiation of transcription in bacteria.

signal recognition particle (SRP) A receptor that recognizes the signal sequence of peptides undergoing translation. The complex attaches to the cell membrane of prokaryotes (or the rough endoplasmic reticulum of eukaryotes), where it docks the protein-ribosome complex to the membrane for protein membrane insertion or secretion.

signal sequence A specific amino acid sequence on the amino-terminus of proteins that directs them to the endoplasmic reticulum (of a eukaryote) or the cell membrane (of a prokaryote).

signature-tagged mutagenesis A technique to discover pathogenicity genes by creating randomly mutated genes, each tagged with a different oligonucleotide. Mutant strains unable to infect an organism contain mutations in pathogenicity genes, which can be isolated.

silencer A eukaryotic DNA element that can lead to decreased transcription when bound by an appropriate transcription factor.

silent mutation A mutation that does not change the amino acid sequence encoded by an open reading frame. The changed codon encodes the same amino acid as the original codon.

simple stain A stain that makes an object more opaque, increasing its contrast with the external medium or surrounding tissue.

single-celled protein Edible microbes of high food value such as Spirulina or some yeasts.

siphonous alga A form of alga consiting of a single cell that forms extended siphon-like tubes and fronds without cell partitions.

site-specific recombination Recombination between DNA molecules that do not share long regions of homology but do contain short regions of homology specifically recognized by the recombination enzyme.

skin-associated lymphoid tissue (SALT) Immune cells, such as dendritic cells, located under the skin that help eliminate bacteria that have breached the skin surface.

S-layer A crystalline protein surface layer replacing or external to the cell wall in many species of archaea and bacteria.

sliding clamp A protein that keeps DNA polymerase affixed to DNA during replication.

slime mold An organism in which unicellular amebas can aggregate into a fruiting body.

sludge The solid products of wastewater treatment.

"small RNA" (smRNA) Non-protein coding regulatory RNAs that modulate translation.

small subunit rRNA (in bacteria, **16S rRNA**) A ribosomal RNA found in the small subunit of the ribosome. Its gene is often sequenced for phylogenetic comparisons.

soil A complex mixture of decaying organic and mineral matter that covers the terrestrial portions of the planet.

solute Any dissolved molecule.

sorbitol MacConkey agar A media that can detect whether a bacterial strain can ferment sorbitol. Used clinically to test for *E. coli* O157:H7.

SOS response A coordinated cellular response to extensive DNA damage. It includes error-prone repair.

sourdough An undefined yeast population, derived from a previous batch of dough, that is used in bread production.

Southern blot A technique to detect specific DNA sequences. Sample DNA segments are separated by gel electrophoresis, transferred to a blot, and probed with a labeled DNA that will hybridize to complementary DNA sequences.

specialized transduction (restricted transduction) Transduction in which the phage can transfer only a specific, limited number of donor genes to the recipient cell.

species A single, specific type of organism, designated by a genus and species name.

spike protein A viral glycoprotein that connects the membrane to the capsid or the matrix and may be involved in viral binding to host cell receptors.

spirochete A bacterium with a tight, flexible spiral shape; a species of the phylum Spirochetes (Spirochaetes).

Spirochetes (Spirochaetes) A phylum of bacteria with a unique morphology, a flexible, extended spiral that twists via intracellular flagella.

spongiform encephalopathies Brain-wasting diseases caused by prions.

spontaneous generation The theory, much debated in the nineteenth century, that under current Earth conditions life can arise spontaneously from non-living matter.

sporangiospore A haploid spore that can germinate to form a haploid mycelium.

sporangium A fungal organ that disburses non-motile spores via ballistic expulsion.

spore stain A type of differential stain that is specific for the endospore coat of various bacteria, typically a firmicute species.

sporogony The development of a parasite's zygote into a spore-like form transmissible to the next host.

spread plate A method to grow separate bacterial colonies by plating serial dilutions of a liquid culture.

staining The process of treating microscopic specimens with a stain to enhance their detection or to visualize specific cell components.

stalk An extension of the cytoplasm and envelope that attaches a microbe to a substrate.

stalked ciliate A ciliate that adheres to a substrate and uses its cilia to obtain prey.

standard Gibbs free energy change ($\Delta G°$) The free energy change under standard conditions of 1 atmosphere pressure, 298°K and 1 M concentrations of all products and reactants.

standard reduction potential ($E°$) A standard value of E, at standard temperature and pressure and assuming initial 1 M concentrations of all reactants and products.

staphylococcus *pl.* **staphylococci** A hexagonal arrangement of cells formed by septation in random orientations.

start codon A codon (usually AUG) that signals the first amino acid of a protein.

starter culture A mixture of fermenting microbes added to a food substrate to generate a fermented product.

stationary phase A period of no net increase in replication that follows the exponential growth phase.

sterilization The destruction of all cells, spores and viruses on an object.

stop codon One of three codons (UAA, UAG, UGA) that do not encode an amino acid and trigger the end of translation.

strand invasion During generalized recombination, the enzyme-catalyzed pairing of single stranded DNA with its complementary strand in the DNA duplex.

strict aerobe An organism that performs aerobic respiration and can only grow in the presence of oxygen.

strict anaerobe An organism that cannot grow in the presence of oxygen.

stringent response A cellular response to idle ribosomes (often indicating low carbon and energy stores) that includes a decrease in rRNA and tRNA production.

stroma The compartment contained by the inner chloroplast membrane where the light-independent reactions of photosynthesis occur (CO_2 fixation).

stromatolite A mass of sedimentary layers of limestone produced by a marine microbial community over many years.

structural formula A representation of molecular structure in which covalent bonds are shown as a line between atoms.

structural gene A string of nucleotides that encodes a functional RNA molecule.

structural isomer A molecule with the same molecular formula as a different molecule but a different arrangement of atoms.

subcellular fractionation A procedure to separate cell components; often includes ultracentrifugation.

substrate level phosphorylation Formation of ATP by the enzymatic transfer of phosphate from a substrate molecule onto ADP.

substrate mycelium A long multinucleate filament (hypha) emanating from the germinating spore of some species that grows along a food source.

substrate-binding protein An extra-cytoplasmic protein that binds specific substrates and delivers them to their cognate uptake ABC transporters.

sugar acid Sugars containing a carboxylic acid group; carboxylate sugars

sulfa drugs Antibiotics that that inhibit nucleotide synthesis.

sulfur granule Elemental sulfur generated by metabolism and stored inside the cell. May refer to extracellular sulfur deposits, also called sulfur globules.

superantigen Molecules that directly stimulate T cells without undergoing antigen presenting cell processing and surface presentation.

supercoil An extra twist or turn found in DNA, either positive (increases DNA winding) or negative (decreases DNA winding).

superoxide radical A highly reactive oxygen species, O_2^-, that is toxic to cell components.

Svedberg coefficient A measure of particle size based on the particle's sedimentation rate in a tube subjected to a high g force.

swarming A behavior in which some microbial cells differentiate into large swarmer cells and swim together as a unit.

switch region A repeating DNA sequence in antibody constant segment genes that serves as a recombination site during isotype switching.

symbiogenesis An evolutionary process by which two or more species become intimately associated.

symbiont An organism that lives in a close association with another organism.

symbiosis The intimate association of two unrelated species.

symbiosome Bacteroids sequestered within a sac of plant-derived membrane.

symport A transport protein where the molecules being transported move in the same direction across the membrane.

synergism Cooperation between species in which both species benefit but can grow independently. The cooperation is less intimate than symbiosis.

synthetic medium A bacterial growth solution that contains defined, known components.

syntrophy Metabolic cooperation between two different species.

tailed phage A phage such as T4 that contains a genome delivery device called the tail.

tandem repeat A stretch of directly repeating DNA sequence (direct repeats) without any intervening DNA.

taxon *pl.* **taxa** A category of organisms grouped together based on genetic relatedness.

taxonomy The description of distinct life forms and their organization into different categories.

tegument The contents of a virion between the capsid and the envelope.

teichoic acid Chains of phosphodiester-linked glycerol or ribitol that thread through and reinforce the cell wall in gram-positive bacteria.

telomerase A eukaryotic enzyme with reverse transcriptase activity that is required to replicate the ends of linear chromosomes to avoid chromosome shortening.

telomere The end of a linear chromosome, composed of a repeated DNA sequence.

tempeh A mold-fermented soy product, popular as a food in parts of Asia.

temperate phage Phage capable of lysogeny.

template (–) strand A DNA strand (or an RNA strand in some viruses) that is used as a template for the synthesis of mRNA.

terminal electron acceptor The final electron acceptor at the end of an electron transport system.

termination (*Ter*) site A sequence of DNA that halts replication of DNA by DNA polymerase.

terpenoid A branched lipid derived from isoprene that is found in hydrocarbon chains of archaeal membranes.

terraforming The idea of transforming the environment of a planet to make it suitable for life from Earth.

tertiary structure The third level of polymer structure, the unique three-dimensional shape of a polymer.

tertiary syphilis A final stage of syphilis, manifested by cardiovascular and nervous system symptoms.

tetanospasmin The tetanus-causing potent exotoxin produced by *Clostridium tetani*.

tetracyclines A class of antibiotics with four fused cyclic rings, that inhibits translation.

tetraether A molecule containing four ether links. An example is found in archaeal membranes, when two lipid side chains form ether linkages with a pair of side chains from the other side of the bilayer.

tetrapyrrole An essential primary product that contains four pyrroles (five-membered rings containing nitrogen), each with one or two double bonds. A precursor for many important cell cofactors such as chlorophylls and vitamin B_{12}.

thermocline A region of the ocean where temperature decreases steeply with depth, and water density increases.

thermophile An organism adapted for optimal growth at high temperatures, usually 55°C or higher.

Thermoproteales An order of crenarchaeote containing hyperthermophilic organisms.

threshold dose The concentration of antigen needed to elicit adequate antibody production.

thylakoid A chlorophyll-containing membrane folded within a phototrophic bacterium or a chloroplast.

Ti plasmid A plasmid found in tumorigenic strains of *A. tumefasciens* that can be used as a vector to introduce DNA into plant cells.

tmRNA A molecule resembling both tRNA and mRNA that rescues ribosomes stalled on damaged mRNAs lacking a stop codon.

tobacco mosaic virus An RNA virus that is the causative agent of tobacco mosaic disease.

Toll-like receptor (TLR) A member of a eukaryotic transmembrane glycoprotein family that recognizes a particular pathogen-associated molecular pattern (PAMP) present on pathogenic microorganisms.

tomography The acquisition of projected images of a transparent specimen from different angles that are digitally combined to visualize the entire specimen.

topoisomerase A enzyme that can change the supercoiling of DNA.

total magnification The magnification of the ocular lens multiplied by the magnification of the objective lens.

transamination The transfer of an ammonium ion between two metabolites.

transcript An RNA copy of a DNA template.

transcription The synthesis of RNA complementary to a DNA template.

transcriptional attenuation A transcriptional regulatory mechanism in which translation of a leader peptide affects transcription of downstream structural genes.

transcriptome The set of transcribed genes in a cell at given time. The "complete trancriptome" includes all the possible RNA transcription products from a given genome. The "expressed transcriptome" represent the set of RNAs present during a given condition.

transcytosis The movement of a cell or substance from one side of a polarized cell to the other side, using an intracellular route.

transduction The transfer of host genes between bacterial cells via a phage head coat.

transfer RNA (tRNA) An RNA that carries an amino acid to the ribosome. The anticodon on the tRNA matches the codon on the mRNA.

transform The conversion of cultured cells into cancer cells.

transformation The internalization of free DNA from the environment into bacterial cells.

transformed-focus assay The detection of oncogenic viruses based on their ability transform cells, generating foci of unrestricted cell growth.

transglycosylase An enzyme that links N-acetyl glucosamine and N-acetyl muramic acid into chains during bacterial cell wall synthesis.

transition mutation A type of point mutation in which a purine is replaced by a different purine or a pyrimidine is replaced by a different pyrimidine.

translation The ribosomal synthesis of proteins based on triplet codons present in mRNA.

translational control A regulatory mechanism that modulates protein production by influencing the translation of mRNA.

translocasome A bacterial cell membrane protein complex that imports external DNA during transformation.

translocation The energy-dependent movement of the ribosome to the next triplet codon along an mRNA.

transmembrane domain A region of a protein that spans a membrane.

transmembrane protein A protein with a membrane-spanning region.

transmission electron microscopy (TEM) A type of electron microscopy in which electron beams are transmitted through a thin specimen to reveal internal structure.

transovarial transmission The passage of genes or pathogens from parent to offspring via the egg cell.

transpeptidase An enzyme that cross-links the side-chains from adjacent peptidoglycan strands during bacterial cell wall synthesis.

transport protein (transporter) A membrane protein that moves specific molecules across a membrane.

transposable element A segment of DNA that can move from one DNA region to another.

transposase A transposable element-encoded enzyme that catalyzes the transfer of the transposable element from one DNA region to another.

transposition The process of moving a transposable element from one DNA region to another.

transposon A transposable DNA element that contains genes in addition to those required for transposition.

transversion A point mutation in which a purine is replaced by a pyrimidine or vice versa.

tricarboxylic acid (TCA) cycle A metabolic cycle that catabolizes the acetyl group from acetyl-CoA to 2 CO_2 with the concomitant production of NADH, $FADH_2$, and ATP.

trophic level A level of the food web representing the consumption of biomass of organisms from a lower trophic level.

tropism The tissue types infected by a specific virus in a given host.

trypanosome A parasitic discicristate protist that has a cortical skeleton of microtubules culminating in a long flagellum.

tumor necrosis factor (TNF) A cytokine released by several cell types (e.g., macrophages) in response to cell damage.

turbidostat A continuous culture device that can measure optical density and through changing culture flow rates, maintain a specific cell density.

twitching motility A type of bacterial movement on solid surfaces where a specific pilus extends and retracts.

two-component signal transduction system A message relay system composed of a sensor kinase protein and a response regulator protein that regulates gene expression in response to a signal (usually an extracellular signal).

two-dimensional polyacrylamide gel electrophoresis (2-D PAGE, 2-D gels) A technique to separate proteins based on differences in charge and molecular weight.

type I (immediate) hypersensitivity An IgE mediated allergic reaction that causes degranulation of mast cells within minutes of exposure to the antigen.

type I pilus A pilus that adheres to mannose residues on host cell surfaces.

type I protein secretion An ATP-binding cassette transport system that moves molecules directly into or out of bacterial cells.

type II hypersensitivity An immune condition in which antibodies bind to cell surface antigens, triggering cell-mediated cytotoxicity or activation of the complement cascade.

type II secretion A bacterial protein secretion system that uses a type-IV pilus-like extraction/retraction mechanism to push proteins out of the cell.

type III hypersensitivity An immune over-reaction triggered by IgG antibody binding to soluble antigens.

type III pilus A bacterial pilus that does not bind to mannose but binds to tannic acid.

type III secretion A bacterial protein secretion system that uses a molecular syringe to inject bacterial proteins into the host cytoplasm.

type IV (delayed-type) hypersensitivity (DTH) An immune response that develops 24 to 72 hours after exposure to an antigen that the immune system recognizes as foreign. DTH is triggered by antigen-specific T cells. The response is delayed because the T cells need time to proliferate after being activated by the allergen.

type IV pilus A dynamic pilus that can repeatedly assemble and disassemble; it mediates twitching motility.

ubiquitin (Ub) A small eukaryotic protein that can be attached to other proteins to target them for degradation via the proteasome.

ultracentrifuge A machine that exposes samples to high centrifugal forces and can be used to separate subcellular components.

uncoupler A molecule that makes a membrane permeable to protons, dissipating the proton motive force and uncoupling electron transport from ATP synthesis.

unrooted tree A phylogenetic tree showing only the relative distances between different species, without indicating which of these diverged earliest from the common ancestor.

upstream processing The culturing of industrial microbes to produce large quantities of desired product.

vaccination Exposure of an individual to a weakened version of a microbe to provoke immunity and prevent development of disease upon re-exposure.

van der Waals force Weak, temporary electrostatic attraction between molecules caused by shifting electron clouds.

vancomycin A glycopeptide antibiotic that inhibits bacterial cell wall synthesis in a mechanism distinct from penicillin inhibition.

variable region The amino-terminal regions of antibody light and heavy chains that confer specificity to antigen-binding and define the antibody idiotype.

vasoactive factor A cell signaling molecule that increases capillary permeability.

vector An organism (e.g., insect) that can carry infectious agents from one animal to another. In molecular biology, a molecule of DNA into which exogenous DNA can be inserted to be cloned.

vegetative cell A metabolically active, replicating bacterial cell.

vegetative mycelium A branched filament produced by vegetative cells that expands into the substrate.

Verrucomicrobia A phylum of free-living aquatic bacteria with wart-like protruding structures containing actin.

vertical transfer See **vertical transmission**.

vertical transmission The passage of genes from parent to offspring.

vesicle A small membrane-bound sphere found within a cell.

vesicular-arbuscular mycorrhiza (VAM) A mutualistic association between plant roots and certain fungi, involving hyphal penetration of plant root cells.

viable An organism that can replicate, for instance by forming a colony on an agar plate.

viable but nonculturable (VBNC) An organism that is metabolically active but can not replicate to form a colony on a plate by current means of culture. Also called a dormant cell.

viral envelope A host-derived membrane that surrounds a virus capsid.

viremia The presence of large numbers of virions in the bloodstream.

Viridiplantae A taxonomic group of eukaryotes that includes the land plants and primary endosymbiont algae.

virion A virus particle

viroid An infectious naked nucleic acid.

virulence A measure of the severity of a disease caused by a pathogenic agent.

virulence factor A trait of a a pathogen that enhances the pathogen's disease-producing capability.

virus An acellular particle containing a genome that can replicate only inside a cell.

virus shedding The release of virions from the host organism into the environment.

voltage potential difference ($E°$) The difference in electrical potential between the oxidized and reduced forms of a molecule; the tendency of a molecule to accept electrons.

wastewater treatment A series of wastewater transformations designed to lower biological oxygen demand and eliminate human pathogens before water is returned to local rivers.

water activity A measure of the water that is not bound to solutes and is available for use by organisms.

water table The layer of soil that is permanently saturated with water.

Western blot A technique to detect specific proteins. Proteins are subjected to gel electrophoresis, transferred to a blot, and probed with enzyme-linked or fluorescently-tagged antibodies that specifically bind the protein of interest.

wet mount A technique to view living microbes with a microscope by placement of the microbes in water on a slide under a coverslip.

wetlands Regions of land that undergo seasonal fluctuations in water level and aeration.

whey The liquid portion of milk after proteins have precipitated out of solution, usually during cheese production.

Winogradsky column A tube containing a stratified environment that causes specific microbes to grow at particular levels; a type of enrichment culture for the growth of microbes from wetland environments.

X-ray crystallography A technique to determine the positions of atoms (atomic coordinates) within a molecule or molecular complex, based upon the diffraction of X-rays by the molecule.

X-ray diffraction analysis See **X-ray crystallography**.

yeast A unicellular fungus.

yeast two-hybrid system An *in vivo* technique to determine protein-protein interactions in which DNA sequences encoding proteins of interest of are fused separately to the DNA-binding and transactivation domains of a yeast transcription factor. The recombinant yeast is then tested for expression of a reporter gene.

yogurt A semi-solid food produced through acidification of milk by lactic acid-producing bacteria.

zone of hypoxia See **dead zone**.

zone of inhibition A region of no bacterial growth on an agar plate due to the diffusion of a test antibiotic. Correlates to the **minimal inhibitory concentration**.

zoonotic disease An infection that normally affects animals but can be transmitted to humans.

zooplankton Heterotrophic marine microbes.

zoospore A flagellated reproductive cell produced by chytridiomycete fungi.

zooxanthella A phototrophic dinoflagellate that is a coral endosymbiont.

Zygomycota (zygomycete) A clade of fungi forming nonmotile haploid gametes that grow toward each other, fusing to form the zygospore.

zygospore In zygomycetes, the diploid structure formed by the fusion of two gamete-bearing hyphae.

Index

Genomes of representative bacteria and archaea.

Species (strain)	Genomic chromosome(s)* (kilobase pairs, kbp)	Plasmid(s)* (kbp)	Total (kbp)
Bacteria			
Mycobacterium tuberculosis Tuberculosis	4,400 		4,400
Mycoplasma genitalium Normal flora, human skin	580 		580
Burkholderia cepacia	3,870 + 3,217 + 876 	93 	8,056
Escherichia coli K-12 (W3110) Model strain for *E. coli* proteomics	4,600 		4,600
Anabaena species (PCC 7120) Cyanobacteria: Major photosynthetic producer of carbon source for aquatic ecosystems	6,370 	110 + 190 + 410 	7,080
Borrelia burgdorferi Lyme disease	911 	21 plasmids with sizes between 9–58 	>1,250
Agrobacterium tumefaciens Tumors in plants; genetic engineering vector	2,840 + 2,070 	214 + 542 	5,666
Archaea			
Methanocaldococcus jannaschii Methanogen from thermal vent	1,660 	16 + 58 	1,734
Haloarcula marismortui Halophile from volcanic vent	3,130 + 288 	33 + 33 + 39 + 50 + 155 + 132 + 410 	4,270
	 1,000 kbp	 500 kbp	

*Colored schematics indicate relative sizes of genomic elements and whether these are circular or linear. Size bars are provided under each column.

Three domains of life.

Characteristic	Traits of living organisms		
	All cells on Earth resemble each other		
Chromosomal material	Double-stranded DNA		
RNA transcription	Common ancestral RNA polymerase		
Translation	Common ancestral rRNAs and elongation factors		
Protein	Common ancestral functional domains		
Cell structure	Aqueous cell compartment bounded by a membrane		
	Comparison of domains		
	Bacteria	**Archaea**	**Eukaryotes**
	Archaea resemble bacteria		
Cell volume	1–100 μm^3 (usually)		1–10^6 μm^3
DNA chromosome	Circular (usually)		Linear
DNA organization	Nucleoid		Nucleus with membrane
Gene organization	Multigene operons		Single genes
Metabolism	Denitrification, N_2 fixation, lithotrophy, respiration, and fermentation		Respiration and fermentation
Multicellularity	Simple		Simple or complex
		Archaea resemble eukaryotes	
Intron splicing	Introns are rare	Introns are common	
RNA polymerase	Bacterial	Eukaryotic form	
Transcription factors	Bacterial	Eukaryotic form	
Ribosome sensitivity to chloramphenicol, kanamycin, and streptomycin	Sensitive	Resistant	
Translation initiator	Formylmethionine	Methionine (except mitochondria use formylmethionine)	
Cell wall	Peptidoglycan	Pseudopeptidoglycan or other polymer; or protein S-layer	
	Bacteria resemble eukaryotes and differ from archaea		
Methanogenesis	No	Yes	No
Thermophilic growth	Up to 90°C	Up to 120°C	Up to 70°C
Photosynthesis	Many species; bacteriochlorophyll Proteorhodopsin derived from archea	Haloarchaea only; bacteriorhodopsin	Many species; chlorophyll (bacterial origin)
Chlorophyll light absorption	Red and blue	Green (central range of solar spectrum)	Red and blue (chloroplasts of bacterial origin)
Membrane lipids (major)	Ester-linked fatty acids	Ether-linked isoprenoid	Ester-linked fatty acids
Pathogens infecting animals or plants	Many pathogens	No pathogens	Many pathogens
